Noligerry Nettle (Urtica heterophylla).—This nettle appears to be remarkable beyond all others for its stinging properties. It is abundant in Mysore, flourishing in Alpine jungles. The Todawars prepare the fibre of this plant by boiling the stems in water, after which they readily separate it from the woody parts and then spin it into a coarse but very strong fibre. The Malays simply steep the stems in water for ten or twelve days, after which they are so much softened that the outer fibrous portion is easily peeled off.

Yerrum Nar.—This is the native name of the fibres of the *Calotropis (Asclepias) gigantea*, a plant which grows wild, abundantly, in various parts of the Bengal and Madras presidencies, and is used by the natives in the manufacture of cord called "Lamb-dore," or "Tondee Coir."

Alse fibre, or Nar, the produce of the *Agave vivipara*, and other allied species. This is often called the "Sida grass fibre."

Pine-apple fibre, sometimes called "*Ananas flax*." This has been prepared in Java, and at Tranacore. Many fine specimens have been brought to this country.

Plantain fibre.—In the Government establishments of Ceylon this is extensively employed. Canvases and ropes are made of it. It is obtained from the *Musa sativa*. It is calculated that 8 cwt. per acre of this excellent fibre might be obtained.

Mahant bark.—Employed at St. Vincent's in the manufacture of fishing nets, common cord, and coarse lines for fishing.

New Orleans moss (Tillandsia usneoides), a substitute for horse hair as a stuffing material for upholsterers. Sometimes the fibrous husk of the Indian corn is used for the same purpose, but it is more brittle than the moss.

Palm-tree fibre. These fibres are obtained from many varieties of the palm.

Grass fibre. Many of the grasses are now being used in the manufacture of paper, and for other purposes.

The following tables by Dr. Roxburgh and Dr. Wright, afford much information as to the relative strengths of different kinds of fibrous substitutes. The first table gives experiments made by Dr. Roxburgh in 1804; some of the fibres were, however, probably imperfectly prepared.

Common Name.	Botanical Name.	Breaking Weight.
		lbs.
1. Hemp (English) - -	<i>Cannabis sativa</i> - - -	105
2. Murga (Sansevieria) - -	<i>Alocus acerosus</i> - - -	120
3. Aloe - - -	<i>Agave Americana?</i> - - -	110
4. I'jo - - -	<i>Saguerus Rumphii</i> - - -	26
5. Doasha - - -	<i>Echinospermum canabian</i> - - -	28
6. Coir - - -	<i>Cocco nucifera</i> - - -	67
7. Hemp (Indian) - -	<i>Cannabis sativa</i> - - -	74
8. Woollet comal - -	<i>Abroma Augusta</i> - - -	74
9. ———? - - -	<i>Bauhinia</i> - - -	69
10. Sana - - -	<i>Crotalaria juncea</i> - - -	68
11. Bughit paat - -	<i>Cerebarnia distans</i> - - -	63
12. Ghu nala paat - -	— <i>cupularis</i> - - -	67
13. ———? - - -	<i>Hibiscus musabot</i> - - -	61
14. Flax (Indian) - -	<i>Linum usitatissimum</i> - - -	39

In 1808, Dr. Roxburgh made another series of experiments, of which the following table gives the result :—

Common Name.	Botanical Name.	Breaking Weight.
1. Bowstring hemp - - -	<i>Asclepias</i> Sp. - - -	245
2. Callosee hemp - - -	<i>Urtica tractatissima</i> - - -	240
3. ———? - - -	<i>Cochorus copularia</i> - - -	164
4. Sunn - - -	<i>Crotalaria juncea</i> - - -	160
5. Hemp (Indian) - - -	<i>Cannabis sativa</i> - - -	150
6. Doncha - - -	<i>Neochymone cinnabina</i> - - -	138
7. ———? - - -	<i>Hibiscus strictus</i> - - -	125
8. Musta paat - - -	" <i>cannabinus</i> - - -	115
9. Banghi paat - - -	<i>Cochorus plurima</i> - - -	113
10. Plantain - - -	<i>Musa</i> - - -	79

Experiments were made not long since by Dr. Wright on several well known vegetable fibres when made into ropes. The following were the results :—

Common Name.	Botanical Name.	Breaking Weight.
1. Yereum nar - - -	<i>Calotropis gigantea</i> - - -	484
2. Janapam - - -	<i>Crotalaria juncea</i> - - -	552
3. Cutthalay nar - - -	<i>Agave Americana</i> - - -	407
4. Cotton - - -	<i>Gossypium herbaceum</i> - - -	363
5. Marom - - -	<i>Sesuvium zeylanica</i> - - -	346
6. Porly mungu - - -	<i>Hibiscus cannabinus</i> - - -	316
7. Coir - - -	<i>Cocos nucifera</i> - - -	290
		231

The defect of all these fibres is, as it regards their use in weaving, that they break at the knot, and in all weaving processes the fibres require frequent joining.

Of vegetable substances of the nature and quality of undressed hemp we imported in 1857, from

	Cwt.	Computed ret. value.
Spain - - -	7,250	£ 8,997
Mexico - - -	12,301	14,753
British East Indies - - -	5,408	6,899
Other parts - - -	2,309	2,918
	27,358	233,567

The peculiarities of these fibres are not specified, but as they are not hemp, flax, tow, or jute, we may fairly infer that many of the fibres named above are included in these importations.

FIBRE, VEGETABLE, called also **LIGNINE** (*Ligneux*, Fr.; *Pflanzen faserstoff*, Germ.) is the most abundant and general ingredient of plants, existing in all their parts, the root, the leaves, the stem, the flowers, and the fruit; amounting in the compact wood to 27 or 28 per cent. It is obtained in a pure state by treating saw-dust successively with hot alcohol, water, dilute muriatic acid, and weak potash lye, which, dissolve, first, the resinous, second, the extractive and saline matters; third, the carbonate and phosphate of lime; and, lastly, any residuary substances. Lignous fibres, such as saw-dust, powdered barks, straw, hemp, flax, linen, and cotton cloth, are convertible by the action of strong sulphuric acid into a gummy substance analogous to *dextrine*, and a sugar resembling that of the grape.

Much attention has, of late years, been directed to the conversion of vegetable fibre into paper. See **PAPER**.

FIBRINE (Eng. and Fr.; *Thierucker Faserstoff*, Germ.) constitutes the principal part of animal muscle; it exists in the chyle, the blood, and may be regarded as the most abundant constituent of animal bodies. It may be obtained in a pure state by agitating or beating new drawn blood with a bundle of twigs, when it will attach itself to them in long reddish filaments, which may be deprived of colour by working them with the hands under a streamlet of cold water, and afterwards freed from any adhering grease by digestion in alcohol or ether.

Fibrine, thus obtained, is solid, white, flexible, slightly elastic, insipid, inodorous, denser than water, but containing 4 fifths of its weight of it, and without action on

litmus. When dried, it becomes semi-transparent, yellowish, stiff, and brittle. Water restores its softness and flexibility. 100 parts of fibrine consist of 53.36 carbon, 19.66 oxygen, 7.02 hydrogen, and 19.31 azote. As the basis of flesh, it is a very nutritious substance, and is essential to the sustenance of carnivorous animals.

FILE MANUFACTURE. See **FORGE**, &c.

FILE (*Lime*, Fr; *Feile*, Germ.) is a well known steel instrument, having teeth upon the surface for cutting and abrading metal, ivory, wood, &c.

When the teeth of these instruments are formed by a straight sharp-edged chisel, extending across the surface, they are properly called files; but when by a sharp-pointed tool, in the form of a triangular pyramid, they are termed rasps. The former are used for all the metals, as well as ivory, bone, horn, and wood; the latter for wood and horn.

Files are divided into two varieties, from the form of their teeth. When the teeth are a series of sharp edges, raised by the flat chisel, appearing like parallel furrows, either at right angles to the length of the file, or in an oblique direction, they are termed *single cut*. But when these teeth are crossed by a second series of similar teeth, they are said to be *double cut*. The first are fitted for brass and copper, and are found to answer better when the teeth run in an oblique direction. The latter are suited for the harder metals, such as cast and wrought iron and steel. Such teeth present sharp angles to the substance, which penetrate it, while single cut files would slip over the surface of these metals. The double cut file is less fit for filing brass and copper, because its teeth would be very liable to become clogged with the filings.

Files are also called by different names according to their various degrees of fineness. Those of extreme roughness are called *rough*; the next to this is the *hard cut*; the third is the *second cut*; the fourth, the *smooth*, and the finest of all, the *dead smooth*. The very heavy square files used for heavy smith-work are sometimes a little coarser than the rough; they are known by the name of *rubbers*.

Files are also distinguished from their shape, as flat, half-round, three-square, four-square, and round. The first are sometimes of uniform breadth and thickness throughout, and sometimes tapering. The cross section is a parallelogram. The half round is generally tapering, one side being flat, and the other rounded. The cross section is a segment of a circle varying a little for different purposes, but all are equal to a semicircle. The three-square generally consist of three equal sides, being equilateral prisms, mostly tapering; those which are not tapering are used for sharpening the teeth of saws. The four-square has four equal sides, the section being a square. These files are generally thickest in the middle, as is the case with the smith's rubber. In the round file the section is a circle, and the file generally conical.

The heavier and coarser kinds of files are made from the inferior marks of blistered steel. Those made from the Russian iron, known by the name of old salt, and from its mark CCND, are excellent. The steel made from the best Swedish iron, called Hoop L or Dann mora, makes the finest Lancashire files for watch and clock makers.

The steel intended for files is more highly converted than for other purposes, to give them proper hardness. It should however be recollected, that if the hardness be not accompanied with a certain degree of tenacity, the teeth of the file break, and do but little service.

Small files are mostly made of cast steel, which would be the best for all others, if it were not for its higher price. It is much harder than the blistered steel, and from having been in the fluid state, is entirely free from those scales and loose parts so common to blistered steel, which is no wonder than as it comes from the iron forge before conversion.

The smith's rubbers are generally forged in the common smith's forge, from the converted bars, which are, for convenience, made square in the iron before they come into this country. The files of larger size are made from bars or rods, drawn down from the blistered bars, and the cast lugots, and known by the name of tilted steel.

The file maker's forge consists of large bellows, with coke as fuel. The anvil-block, particularly at Sheffield, is one large mass of mill-stone grit. The anvil is of considerable size, set into and welded fast into the stone; and has a projection at one end, with a hole to contain a sharp-pointed tool for cutting the files from the rods. It also contains a deep groove for containing dies or hammers, for giving particular forms to the files.

The flat and square files are formed entirely by the hammer. One man holds the hot bar, and strikes with a small hammer. Another stands before the anvil with a two-handed hammer. The latter is generally very heavy, with a broad face for the

large files. They both strike with such truth as to make the surface smooth and flat, without what is called hand-hammering. This arises from their great experience in the same kind of work. The expedition arising from the same cause is not less remarkable.

The half-round files are made in a boss fastened into the groove above mentioned. The steel being drawn out, is laid upon the rounded recess, and hammered till it fills the die.

The three-sided files are formed similarly in a boss, the recess of which consists of two sides, with the angle downwards. The steel is first drawn out square, and then placed in a boss with an angle downwards, so that the hammer forms one side, and the boss two. The round files are formed by a swage similar to those used by common smiths, but a little conical.

The file cutter requires an anvil of a size greater or less, proportioned to the size of his files, with a face as even and flat as possible. The hammers weigh from one to five or six pounds. The chisels are a little broader than the file, sharpened to an angle of about 20 degrees. The length is just sufficient for them to be held fast between the finger and thumb, and so strong as not to bend with the strokes of the hammer, the intensity of which may be best conceived by the depth of the impression. The anvil is placed in the face of a strong wooden post, to which a wooden seat is attached, at a small distance below the level of the anvil's face. The file is first laid upon the bare anvil, one end projecting over the front, and the other over the back edge of the same. A leather strap now goes over each end of the file, and passes down upon each side of the block to the workman's feet, which, being put into the strap on each side, like a stirrup, holds the file firmly upon the anvil as it is cut. While the point of the file is cutting, the strap passes over one part of the file only, the point resting upon the anvil, and the tang upon a prop on the other side of the strap. When one side of the file is single cut, a fine file is run slightly over the teeth, to take away the roughness; when they are to be double cut, another set of teeth is cut, crossing the former nearly at right angles. The file is now finished upon one side, and it is evident that the cut side cannot be laid upon the bare anvil to cut the other. A flat piece of an alloy of lead and tin is interposed between the toothed surface and the anvil, while the other side is cut, which completely preserves the side already formed. Similar pieces of lead and tin, with angular and rounded grooves, are used for cutting triangular and half-round files.

Rasps are cut precisely in the same way, by using a triangular punch instead of a flat chisel. The great art in cutting a rasp is to place every new tooth as much as possible opposite to a vacancy.

File cutting machines have been from time to time invented. In 1778 M. de Montigny read a memoir before the Committee of Commerce, in which he mentioned the inventions for file-cutting in 1699 by Duverger, in 1723 by Fardouet, in 1740 by Thiout, in 1756 by Brachet and Gannin, and in 1776; since which, in 1800, Raoul invented a file-cutting machine; and in 1836 Ericsson introduced another. Sir John Robison, just before his death, invented a method for cutting curved files; and in 1847, Messrs. Johnson, Cammell, and Co. received the medal of the Scottish Society of Arts for perfecting Sir J. Robison's scheme. The accompanying wood cuts,

will show the general principle upon which those machines are constructed.

In order to render this invention better understood, two views of the apparatus for producing the cross-cut or teeth of the files, are given.

Fig. 749 is an elevation of the upper part of the file-cutting machine, as seen on one side; fig. 750 is a plan or horizontal view, as the machine appears on the top.

a, is the head of the tilt hammer placed in the end of the lever b, which is mounted on an axle c, turning in proper bearings in the frame work of the machine; d, is the tilt wheel mounted on another axle e, also turning in bearings on the

frame work of the machine, and having any required number of projections or tappets upon it for depressing the tail or shorter end of the hammer or tilt lever b.

749

The wheel *d*, receives its rotatory motion from the toothed wheel *f*, mounted upon the same axle, and it takes into gear with a pinion *g*, upon the main shaft *h*, which is actuated by a hand power from any first mover to the rigger on its end, or in any other convenient manner. The bed upon which the blank pieces of steel bears is marked *i*. This bed is firmly supported upon a masonry placed upon proper supports. *j*, is one of the blank pieces of steel under operation, and is shown secured in the pair of jaws or holden clamps *k*, mounted on centre pins in the slide *l*, fig. 750, which slide is held down by a spring and slide beneath, and is moved backwards and forwards in the machine upon the (v) edges *m m*, of the frame, by means of the rack *n* and its pinion; the latter being mounted upon the axle of the ratchet wheel *p*, and which ratchet wheel is made to turn at intervals by means of the pawl *q*, upon the end of the lever *r*, fig. 751. This lever is depressed, after every cut has been effected upon the blank by means of the teeth or tappets of the wheel *s*, coming in contact with the inclined plane *t*, upon the lever *r*. The tappet wheel *s*, is mounted upon the end of the axle *c*, of the tilt wheel, and consequently revolves with it, and by depressing the lever *r*, every time that a tooth passes the inclined plane *t*, the click *q*, is made to drive the ratchet wheel *p*, and thereby the advancing movement of the blank is effected after each blow of the tilt hammer.

There is a strong spring *u*, attached to the upper side of the tilt hammer, its end being confined under an adjustable inclined plane *c*, mounted in the frame *w*, which inclined plane can be raised or lowered by its adjusting screws as required, to produce more or less tension of the spring.

A similar spring is placed on the under side of the tilt hammer, to raise and sustain the cutter or tool clear of the bed after every blow, and in conjunction with safety holders or catchers, to counteract any vibration or tendency the spring *u*, may have to cause the hammer to reiterate the blow.

The end of the lower spring acts on an inclined plane, mounted in the frame *x*, which has an adjusting screw similar to *u*, to regulate the tension of the spring.

In case the under spring should raise, that is, return the hammer, with sufficient force or velocity to cause the top spring *u*, to reiterate the blow, the ends of the safety holders or catchers are made to move under and catch the tail of the lever *b*, immediately on its being raised by the under springs, which is effected by the following means:—The holders are mounted upon a plate or carriage *1*, fig. 749, which turns upon a small pin or axle mounted in the ears of a cross bar; the upper ends of the holders are kept inclined towards the tail of the tilt hammer by means of a spring fixed to the cross bar, and which acts upon one end of the plate or carriage.

In order that the holders may be removed out of the way of the tail of the hammer *b*, when the tilt wheel is about to effect a blow, the tooth of the tilt wheel which is actuated upon the hammer comes in contact with an inclined plane fixed on the plate or carriage *1*, and by depressing that end of the plate, causes the upper ends of the holders to be withdrawn from under the tail of the hammer *b*. The tilt wheel continuing to revolve, the next tooth advances, and depresses the end of the hammer, but before it leaves the tail of the hammer, the tooth last in operation will have quitted the inclined plane and allowed the spring to return the holders into their former position. After the tooth has escaped from the tail of *b*, the hammer will immediately descend and effect the blow or cut on the blank, and as the tail of the hammer rises, it will come in contact with the inclined planes at the upper ends of the holders, and force them backwards; and as soon as the tail of the hammer has passed the top of the holders, the spring will immediately force the holders forward under the tail of the hammer, and prevent the hammer rising again until the next tooth of the tilt wheel is about to depress the end of the hammer, when the same movements of the parts will be repeated, and the machine will continue in operation until a sufficient length of the blank of steel (progressively advanced under the hammer) has been operated upon, when it will be thrown out of gear by the following means:—

Upon the sliding bar *6*, there is placed an adjustable stop, against which the fore-

most end of the slide *l*, *fig.* 750, comes in contact as it is moved forward by the rack *n*, and its pinion. The sliding bar *o*, is connected at its left end to the bent lever *s*, the other end of this lever being formed into a forked arm, which embraces a clutch upon the main shaft, and as the slide *l* continues to advance, it will come in contact with a stop *t*; and when it has brought a sufficient length of the blank piece of steel under the operation of the cutting tool, the slide *l*, in its progress, will have moved that stop and the bar *o* forward, and that bar, by means of the bent lever *s*, will withdraw the clutch on the main shaft, from locking into the boss of the fly-wheel, and consequently stop the further progress of the machine; the rigger and fly-wheel turning loosely upon the main shaft.

The cut file can now be removed from out of the clamps, and reversed to cut the other side, or another blank piece put in its place; and after throwing back the pull *q* of the ratchet wheel *p*, the slide *l*, and with it the fresh blank, may be moved back into the machine by turning the winch handle, on the axle of the ratchet wheel *p*, the reverse way, which will turn the pinion backwards, and draw back the rack *n*, without affecting any other parts of the machine; and on moving back the bar *o*, by the handle *u*, placed on the stop, the clutches will be thrown into gear again, and the machine proceed to cut the next blank.

When the blanks have been thus cut on one side, and are reversed in the machine to form the teeth upon the other side, there should be a piece of lead placed between the blank and the bed to protect the fresh cut teeth.

It will be seen that the position of the stop upon the bar *o*, will determine the length or extent of the blank piece of steel which shall be cut or operated upon; and in order that the progressive movement of the blanks under the cutting tool may be made to suit different degrees of fineness or coarseness of the teeth (that is the distance between the cuts), there is an adjusting screw upon the lever *r*, the head of which screw stops against the under side of an ear projecting from the frame-work, and thereby determines the extent of the motion of the lever *r*, when depressed by the tappet of the wheel *s*, acting upon the inclined plane *t*, consequently determining the number of teeth the ratchet wheel *p* shall be moved round by the pull *q*; and hence the extent of motion communicated by the rack and pinion to the slide *l*, and the blank *j*, which regulates the distance that the teeth of the file are apart, and the lever *r* is forced upwards by a spring pressing against its under side.

It will be perceived that the velocity of the descent of the hammer, and consequently the force of the blow, may be regulated by raising or lowering the inclined plane *v* of the spring *a*; and in order to accommodate the bed upon which the blanks rest to the different inclinations they may be placed at, the part of the bed is formed of a semi-globular piece of hardened steel, which fits loosely into a similar concavity in the bed *i*, and is therefore capable of adjusting itself, so that the blanks shall be properly presented to the cutting tool, and receive the blow or cut in an equal and even manner; or the piece of steel may be of a conical shape, and fit loosely in a similar shaped concavity.

There are guides 16, placed on the top of the bed *i*, for the purpose of keeping the blanks in their proper position towards the cutting tool, and these can be regulated to suit blanks of any width, by turning the right and left handed screw 17. There is also another adjustable stop on the jaws or clamps *k* which serves as a guide when placing the blanks within the jaws; and 19 is a handle or lever for raising the clamps when required, which has a weight suspended from it for the purpose of keeping down the blanks with sufficient pressure upon the bed.

The cutting tool in the face of the hammer, can be placed at any required angle or inclination with the blank, it being secured in the head of the hammer by clamps and screws. In cutting fine files a screw is employed in preference to the rack and pinion, for advancing the slide *l*, and the blank piece of steel in the machine.

Hardening the files.—This is the last and most important part of file making. Whatever may be the quality of the steel, or however excellent the workmanship, if it is not well hardened all the labour is lost.

Three things are strictly to be observed in hardening; first, to prepare the file on the surface, so as to prevent it from being oxidated by the atmosphere when the file is red hot, which effect would not only take off the sharpness of the tooth, but render the whole surface so rough that the file would, in a little time, become clogged with the substance it had to work. Secondly, the heat ought to be very uniformly red throughout, and the water in which it is quenched, fresh and cold, for the purpose of giving it the proper degree of hardness. Lastly, the manner of immersion is of great importance, to prevent the files from warping, which in long thin files is very difficult.

The first object is accomplished by laying a substance upon the file, which when it fuses, forms as it were, a varnish upon the surface, defending the metal from the

action of the oxygen of the air. Formerly the process consisted in first coating the surface of the file with ale grounds, and then covering it over with pulverised common salt (muriate of soda). After this coating became dry, the files were heated red hot, and hardened; after this, the surface was highly brained over with the dust of coals, when it appeared white and metallic, as if it had not been heated. This process has lately been improved, at least so far as relates to the economy of the salt, which from the quantity used, and the increased thickness, had become a serious object. Those who used the improved method are now consuming about one fourth the quantity of salt used in the old method. The process consists in dissolving the salt in water to saturation, which is about three pounds to the gallon, and stiffening it with ale grounds, or with the cheapest kind of flour, such as that of beans, to about the consistence of thick cream. The files required to be dipped only into this substance, and immediately heated and hardened. The grounds or the flour are of no other use, than to give the mass consistence, and by that means to allow a larger quantity of salt to be laid upon the surface. In this method, the salt forms immediately a firm coating. As soon as the water is evaporated, the whole of it becomes fused upon the file. In the old method the dry salt was so loosely attached to the file, that the greatest part of it was rubbed off into the fire, and was sublimed up the chimney, without producing any effect.

The carbonaceous matter of the ale grounds is supposed to have some effect in giving hardness to the file, by combining with the steel, and rendering it more highly carbonated. It will be found, however, upon experiment, that vegetable carbon does not combine with iron, with sufficient facility to produce any effect, in the short space of time a file is heating for the purpose of hardening. Some file makers are in the habit of using the coal of burnt leather, which doubtless produces some effect, but the carbon is generally so ill prepared for the purpose, and the time of its operation so short, as to render the result inconsiderable. Animal carbon, when properly prepared and mixed with the above hardening composition, is capable of giving hardness to the surface even of an iron file.

This carbonaceous matter may be readily obtained from any of the soft parts of animals, or from blood. For this purpose, however, the refuse of shoemakers and curriers is the most convenient. After the volatile parts have been distilled over, from an iron still, a bright shining coal is left behind, which, when reduced to powder, is fit to mix with the salt. Let about equal parts, by bulk, of this powder, and muriate of soda be ground together, and brought to the consistence of cream, by the addition of water. Or mix the powdered carbon with a saturated solution of the salt, till it become of the above consistence. Files which are intended to be very hard, should be covered with this composition, previous to hardening. All files intended to file iron or steel, particularly saw files, should be hardened with the aid of this mixture, in preference to that with the flour or grounds. Indeed, it is probable, that the carbonaceous powder might be used by itself, in point of economy, since the ammoniac or hartshorn, obtained by distillation, would be of such value as to render the coal of no expense. By means of this method the files made of iron, which in itself, is unsuceptible of hardening, acquired a superficial hardness sufficient for any file whatever. Such files may, at the same time, be bent into any form; and, in consequence, are particularly useful for sculptors and die sinkers.

The next point to be considered is the best method of heating the file for hardening. For this purpose a fire, similar to the common smith's fire, is generally employed. The file is held in a pair of tongs by the tang, and introduced into the fire, consisting of very small coals, pushing it more or less into the fire for the purpose of heating it regularly. It must frequently be withdrawn with a view of observing that it is not too hot in any part. When it is uniformly heated, from the tang to the point of a cherry red colour, it is fit to quench in the water. At present an oven, formed of fire-bricks, is used for the larger files, into which the blast of the bellows is directed, being open at one end, for the purpose of introducing the files and the fuel. Near to the top of the oven are placed two cross bars, on which a few files are placed, to be partially heating. In the hardening of heavy files, this contrivance affords a considerable saving, in point of time, while it permits them also to be more uniformly and thoroughly heated.

After the file is properly heated for the purpose of hardening, in order to produce the greatest possible hardness, it should be cooled as soon as possible. The most common method of effecting this is by quenching it in the coldest water. Some file makers have been in the habit of putting different substances in their water, with a view to increase its hardening property. The addition of sulphuric acid to the water was long held a great secret in the hardening of saw files. After all, however, it will be found, that clear spring water, free from animal and vegetable matter, and as cold as possible, is the best calculated for hardening files of every description.

In quenching the files in water, some caution must be observed. All files, except the half-round, should be immersed perpendicularly, as quickly as possible, so that the upper part shall not cool. This management prevents the file from warping. The half-round file must be quenched in the same steady manner; but, at the same time that it is kept perpendicular to the surface of the water, it must be moved a little horizontally, in the direction of the round side, otherwise it will become crooked backwards.

After the files are hardened, they are brushed over with water, and powdered coals, when the surface becomes perfectly clean and metallic. They ought also to be washed well in two or three clean waters for the purpose of carrying off all the salt, which, if allowed to remain, will be liable to rust the file. They should moreover be dipped into lime-water, and rapidly dried before the fire, after being oiled with olive oil, containing a little oil of turpentine, while still warm. They are then finished.

FILIGREE (*Filigrane*, Fr.; *Filigran*, or *Feine Druckgesticht*, Germ.) is, as the last term justly expresses it, interwisted filigree wire, used for ornamenting gold and silver trinkets. The wire is seldom drawn round, but generally flat or angular; and soldered by gold or silver solder with borax and the blowpipe. The Italian word, *filigrana*, is compounded of *filam* and *granum*, or granular out-work; because the Italians, who first introduced this style of work, placed small beads upon it.

FILTRATION (Eng. and Fr.; *Filtrieren*, Germ.) is a process purely mechanical, for separating a liquid from the undissolved particles floating in it, which liquid may be either the useful part, as in vegetable infusions, or of no use, as the washings of mineral precipitates. The filtering substance may consist of any porous matter in a solid, foliated, or pulverulent form; as porous earthenware, unglazed paper, cloth of many kinds, or sand. The white blotting paper sold by the stationers answers extremely well for filters in chemical experiments, provided it be previously washed with dilute muriatic acid, to remove some lime and iron that are generally present in it. Filter papers are first cut square, and then folded twice diagonally into the shape of a corner, having the angular parts rounded off. Or the piece of paper being cut into a circle, may be folded fan-like from the centre, with the folds joined exteriorly, and turned out sharp by the pressure of the finger and thumb, to keep intervals between the paper and the funnel into which it is fitted, to favour the percolation. The diameter of the funnel should be about three-fourths of its height, measured from the neck to the edge. If it be more divergent, the slope will be too small for the ready efflux of the fluid. A filter covered with the sediment is most conveniently washed by spouting water upon it with a little syringe. A small camel's hair paint brush is much employed for collecting and turning over the content in their soft state. Agitation or vibration is of singular efficacy in quickening percolation, as it dislodges the particles of the moistened powders, and opens up the pores which had become closed. Instead of a funnel, a cylindrical vessel may be employed, having its perforated bottom covered with a disc of filtering paper folded up at the edges, and made tight there by a wire ring. Linen or calico is used for weak alkaline liquors; and flannels, twilled woollen cloth, or felt-stuff for weak acid ones. These filter bags are often made conical like a fool's cap, and have their mouths supported by a wooden or metallic hoop. Cotton wool put loose into the neck of a funnel answers well for filtering oils upon the small scale. In the large way, oil is filtered in conical wooden bags or in a cask with many conical tubes in its bottom, filled with tow or cotton wool. Stronger acid and alkaline liquors must be filtered through a layer of pounded glass, quartz, charcoal, or bruised charcoal. The *skarrhazas* are a porous basalt of stone ware made in Spain, which are convenient for filtering water, as also the porous filtering stone of Tuscany, largely imported into England at one time, but now superseded in a great measure by the artificial filters patented under many forms, consisting essentially of strata of gravel, sand, and charcoal powder.

Fig. 731, represents a glass bottle A, partly filled with the fluid to be filtered, supported in the ring of a chemical stand, and having its mouth inverted into the same liquor in the filter funnel. It is obvious, that whenever this liquor by filtration falls below the lip of the bottle, air

will enter into it, let down a fresh supply to feed the filter, and keep the funnel regularly charged. If larger quantities are to be operated upon, the following apparatus may be employed. *Fig. 752*, *A B*, is a metallic vessel which may be made air-tight; *c* is the under pipe provided with a stopcock *u*, for letting down the liquor into the filter *b*. The upper pipe *t*, through which the fluid is poured by means of the funnel *e*, has also a stopcock which opens or shuts, at the same time, the small side tube *s*, through which, during the entrance of the fluid, the air is let off from the receiver. A glass tube *g*, shows the level of the liquor in the body of the apparatus. In using it, the cock *a* must be first closed, and the cock *u* must be opened to fill the receiver. Then the filter is set a going, by re-opening the cock *u*, so as to keep the fluid in the filter upon a level with the opening of the tube *c*. Both these pieces of apparatus are essentially the same.

In many manufactures, self-acting filters are fed by the plumber's common contrivance of a ball cock in which the sinking and rising of the ball, within certain limits, serves to open or shut off the supply of liquor as it may be required or not. *Dumont* has adopted this expedient for his system of filtering syrup through a stratum of granular ground animal charcoal or bone-black. *Fig. 753*, is a front view of this apparatus with 4 filters *c*; and *fig. 754* is a cross section. The framework *n* supports the cistern *a*, in which the syrup is contained. From it the liquor flows through the stop-cock *b*, and the connection-tube *a*, into the common pipe *e*, which communicates, by the short branch tubes *e*, with each of the four filters. The end of the branch tube, which is inside of the filter tub, is provided with a stop-

753

cock *d*, whose opening, and thereby the efflux of the liquor from the cistern through the tube *u*, is regulated by means of the floating-ball *g*. Upon the brickwork *n* the filter tub stands, furnished at *h*

754

with a false bottom of zinc or copper pierced with fine holes; besides which, higher up at *i* there is another such plate of metal furnished with a strong handle *k*, by which it may be removed, when the bone-black needs to be changed. In the intervening space *l*, the granular coal is placed. *o* is the cover of the filter tub, with a handle also for lifting it. One partition of it may be raised by a handle, when it is desired to inspect the progress of the filtration within.

m m is a slender vertical tube, forming a communication between the bottom part *A*, and the upper portion of the filter, to admit of the easy escape of the air from that space, and from among the bone-black as the syrup descends; others in the filtration

could not go on. p is the stopcock through which the fluid collected in the space under h is let off from time to time into the common pipe q , *fig. 753*. r is a trickling channel or groove lying parallel to the tube q , and in which, by means of a tube s , inserted at pleasure, the syrup is drawn off in case of its flowing in a turbid state, when it must be returned over the surface of the charcoal.

The celerity with which any fluid passes through the filter depends, — 1, upon the porosity of the filtering substance; 2, upon the pressure exercised upon it; and 3, upon the extent of the filtering surface. Fine powders in a liquor somewhat glutinous, or closely compacted, admit of much slower filtration than those which are coarse and free; and the former ought, therefore, to be spread in a thinner stratum and over a more extensive surface than the latter, for equal effect; a principle well exemplified in the working of Dumont's apparatus, just described.

In many cases filtration may be accelerated by the increase of hydrostatic or pneumatic pressure. This happens when we close the top of a filtering cylinder, and connect it by a pipe with a cistern of fluid placed upon a higher level. The pressure of the air may be rendered operative also either by withdrawing it partially from a glass vessel, into which the bottom of the filter enters, or by increasing its density over the top of the liquor to be filtered. Either the air pump or steam may be employed to create a partial void in the receiver beneath the filter. In like manner, a forcing pump or steam may be employed to exert pressure upon the surface of the filtering liquor. A common syphon may, on the same principle, be made a good pressure filter, by making its upper leg trumpet-shaped, covering the orifice with filter paper or cloth, and filling the whole with liquor, the lower leg being of such length so as to create considerable pressure by the difference of hydrostatic level. This apparatus is very convenient either on the small or great scale, for filtering off a clear fluid from a light muddy sediment. The pressure of the atmosphere may be elegantly applied to common filters, by the apparatus represented in *fig. 755*, which is merely a funnel enclosed within a

gasometer. The case a bears an annular hollow vessel b , filled with water, in which receiver the cylindrical gasometer, d, e, f, t , is immersed. The filter funnel c is secured at its upper edge to the inner surface of the annular vessel b . In consequence of the pressure of the gasometer regulated by the weight y , upon the air enclosed within it, the liquid is equally pressed, and the water in the annular space rises to a corresponding height on the outer surface of the gasometer, as shown in the figure. Were the apparatus made of sheet iron, the annular space might be charged with mercury.

In general, relatively to the application of pressure to filters, it may be remarked, that it cannot be pushed very far, without the chance of deranging the apparatus, or rendering the filtered liquor muddy. The enlargement of the surface is, generally speaking, the safest and most efficacious plan of increasing the rapidity of filtration, especially for liquids of a glutinous nature. This expedient is well illustrated in the creased bag filter now in use in most of the sugar refineries of London. See *SECHAN*.

In many cases it is convenient so to construct the filtering apparatus, as that the liquid shall not descend, but mount by hydrostatic pressure. This method has two advantages. 1. that without much expensive apparatus, any desired degree of hydrostatic pressure may be given, as also that the liquid may be forced up through several filtering surfaces placed side by side of each other; 2. that the object of filtering, which is to separate the particles floating in the fluid without disturbing the sediment, may be perfectly attained, and thus very foul liquids be cleared without greatly soiling the filtering surface.

Such a construction is peculiarly applicable to the purification of water, either alone, or combined with the downwards plan of filtration. Of the former variety an example is shown in *fig. 756*. The wooden or zinc conical vessel is provided with two perforated bottoms or sieves c, c , between which the filtering substance is packed. Over this, for the formation of the space h, h , there is a third shelf, with a hole in its middle, through which the tube d, d is passed, so as to be water tight. This places the upper part of the apparatus in communication with the lowest space a . From the compartment h, h a small air tube l runs upwards. The filtering substance consists at bottom of pebbles in the middle of gravel, and at the top of fine sand, which may be mixed with coarsely ground bone-black, or covered with a layer of the same. The water to be filtered being poured into the cistern at top, fills through the tube d, d the inferior compartment a , from which the hydrostatic pressure forces the water upward through the perforated shelf, and the filtering materials. The pure water collects in the space h, h , while the air escapes by the small tube l , as the liquid rises. The stopcock serves

to draw off the filtered water. As the motion of the fluid in the filter is slow, the particles suspended in it have time to subside by their own gravity; hence there collects over the upper shelf at *d*, as well as over the under one at *a*, a precipitate or deposit which may be washed out of the latter cavity by means of the stop-cock *m*.

As an example of an upwards and downwards filter, *fig. 737* may be exhibited. *A B C D* is a wooden or metallic cistern, furnished with the perforated shelf *e d* near its under part, upon which a vertical partition is fixed through the axis of the vessel. A semicircular perforated shelf is placed at *a*, and a second similar one at *b*. These horizontal shelves rest upon brackets in the sides of the cistern, so that they may be readily lifted out. The space *g* is filled with coarse sand, *s* with moderately fine, and *u* with very fine. The foul water is poured into the chamber *x*, and passes through *u s g* and into the space *r*, whence it may be drawn by the stopcock *f*.

Fig. 758 represents in section a filtering apparatus consisting of two concentric chambers; the interior being destined for downwards filtration, and the exterior for upwards. Within the larger cistern *a*, a smaller one *b* is placed concentrically, with its under part, and is left open from distance to distance, to make a communication between the interior cavity and the exterior annular space. These cavities are filled to the marked height with sand and gravel. The inner cylindrical space has fine sand below, then sharper sand with granular charcoal, next coarse sand, and lastly gravel. The annular space has in like manner fine sand below. The foul water is introduced by the pipe *n*, the orifice at whose end is acted upon by a ball-cock with

to lever *a*; whereby the water is kept always at the same level in the inner vessel. The water sinks through the sand strata of the middle vessel, passes outwards at its bottom into the annular space, thence up through the sand in it, and collecting above it, is let off by the stopcock on the pipe *b*. When a muddy deposit forms after some time, it may be easily cleared out. The cord *e*, running over the pulleys *ff*, being drawn tight, the ball lever will shut up the valve. The stopcock *d* made fast to the conducting tube *a* must then be opened, so that the water now overflows into the annular space at *A*; the tube *c*, in communication with the inner space *n*, being opened by taking out the stopper *h*. The water thereby percolates through the sand strata in the reverse direction of its usual course, so as to clear away the impurities in the space *n*, and to discharge them by the pipe *e* & *h*. An apparatus of this kind of moderate size is capable of filtering a great body of water. It could be constructed for that purpose of masonry; but upon a small scale it may be made of stoneware.

A convenient apparatus for filtering oil upwards is represented in *fig. 779*. *y* is an oil

cask, in which the impure parts of the oil have accumulated over the bottom. Immediately above this, a pipe *a* is let in, which communicates with an elevated water cistern *n*. *f* is the filter (placed on the lid of the cask), furnished with two perforated shelves, one at *c* and another at *d*; which divide the interior of the filter into three compartments. Into the lower space immediately over the shelf *c*, the tube *h*, furnished with a stopcock *k*, enters, to establish a communication with the cask; the middle cavity *e* is filled with coarsely ground charcoal or other filtering materials; and the upper one has an eduction pipe *l*. When the stopcocks of the tubes *a* and *h* are opened, the water passes from the cistern into the oil cask, occupies from its density always the lowest place, and presses the oil upwards, without mixing the two liquids; whereby first the upper and purer portion of the oil is forced through the tube *h* into the filter, and thence out through the pipe *l*. When the fouler oil follows, it deposits its impurities in the space under the partition *c*, which may from time to time be drawn off through the stopcock *k*, while the purer oil is pressed upwards through the filter. In this way the different strata of oil in the cask may be filtered off in succession, and kept separate. If found necessary for sale or use, without running any risk of mixing up the muddy matter with what is clear. According to the height of the water cistern *n*, will be the pressure, and of course the filtering force. When the filter gets choked with dirt, it may be easily re-charged with fresh materials.

It has been for many years the custom of the water companies to send the water taken from the river through filter beds, prepared usually of sand and gravel. It was long thought that the effect of these filter beds was merely to separate the solid insoluble matters suspended in the water. It has, however, been shown by the investigations of the late Mr. Henry M. Witt (a chemist of peculiar promise, lost too soon to science, and ere yet the world could recognise his powers), that these filter beds had the power of separating many of the dissolved substances from the water; that, in fact, the soluble salts of lime, and the like, were removed by some peculiar physico-mechanical force, resident, as it appears, as a surface force, in all porous masses. There are many very remarkable examples in nature of the operation of this power in producing beds charged with metalliferous matter, some of which will be described under the head of *Mining*.

Mr. H. M. Witt communicated to the *Philosophical Magazine* for December, 1854, an account of some experiments on filtration, which are of much value. Many of his experiments were made at the Chelsea Water Works, and they appear of such interest that we quote the author's remarks in some extent.

"The system of purification adopted by the Chelsea Waterworks, at their works at Chelsea, consisted hitherto (for the supply has by this time commenced from Kingston) in pumping the water up out of the river into subsiding reservoirs, where it remained for six hours; it was then allowed to run on to the filter-beds. These are large square beds of sand and gravel, each exposing a filtering surface of about 270 square feet, and the water passes through them at the rate of about 6½ gallons per square foot of filtering surface per hour, making a total quantity of 1697½ gallons per hour through each filter.

"The filters are composed of the following strata, in a descending order:—

	n	in.
1. Fine sand - - - - -	2	6
2. Coarser sand - - - - -	1	0
3. Shells - - - - -	0	6
4. Fine gravel - - - - -	0	3
5. Coarse gravel - - - - -	3	3

These several layers of filtering materials are not placed perfectly flat, but are disposed in waves, and below the convex curve of each undulation is placed a porous earthenware pipe, which conducts the filtered water into the mains for distribution. The depth of water over the sand was 4 feet 6 inches. The upper layer of sand is renewed about every six months, but the body of the filter has been in use for about twenty years.

"Samples of water were taken and submitted to examination:—

"1st, from the reservoir into which the water was at the time being pumped from the middle of the river.

"2nd, from the cistern, after subsidence and filtration."

Experiments were made at different seasons of the year; but one of Mr. Witt's tables will sufficiently show the results.

1. Shows the quantities of the several substances originally present, represented in grains, in the imperial gallon (70,000 grains) of water.

2. The amount present after filtration.

3. The actual quantities separated in grains in the gallon of water.

4. The per centage ratio which the amounts separated bear to the quantities originally present.

	1. Or originally present.	2. After filtration.	3. Amount separated.	4. Per centage ratio of separated Matter.
Total solid residue, including suspended matter -	55.60	22.85	32.75	58.90

Total dissolved salts -	22.62	19.216	3.404	15.04
Lime -	8.719	8.426	0.293	3.36

"It has been assumed as a principle that sand filtration can only remove bodies mechanically suspended in water, but I am not aware that this statement has been established by experiment; in fact, I am not acquainted with any published analytical examination of the effects of sand filtration.

"These experiments supply the deficiency, and show, moreover, that these porous media are not only capable of removing suspended matter (80 to 92 per cent.), but even of separating a certain appreciable quantity of the salts from solution in water, viz. from 5 to 15 per cent. of the amount originally present, 9 to 19 per cent. of the common salt, 3 per cent. of the lime, and 5 of the sulphuric acid.

"Taking the purer water from Kingston, two experiments were made simultaneously with the same water, one filtration being through charcoal alone, and the other through sand alone, the sand filter having an area of 4 square feet, and consisting of the following materials:—

	ft.	in.
Fine sand -	1	9
Shells -	1	1
Gravel -	1	1
Coarse gravel -	9

"Apart from its special interest, as compared with the following experiment, made simultaneously through charcoal, the following points are in themselves remarkable in the results obtained by this filtration through sand:—

"1st. That the filter continued increasing in efficiency even till the conclusion of the experiment, i. e., for 276 hours, not having lost any of its power when the experiment was terminated.

"2nd. That no weighable quantity of dissolved organic matter was removed by the sand in this experiment; but it must be remembered that the quantity originally present was but small.

FIRE ANNIHILATORS.

"3rd. Its power of removing soluble salts was considerable: as a maximum, 91 per cent. of the common salt being separated."

On comparing this experiment with the preceding, the following point comes out as showing the difference between the effects of sand and charcoal as filtering media.

By the charcoal, speaking generally, a considerably larger quantity of the total residue contained in the water was removed than by the sand, their maximum results being respectively as follows:—

Amount originally present.	Amount separated in Grains in the Gallon.		Amount separated in per centage of the Quantity present.	
	By Sand.	By Charcoal.	By Sand.	By Charcoal.
24 578 grs. in the gallon }	2 074	3 727	8 426	15 28

Mr. Way has also shown that agricultural soil possesses the power of separating the soluble salts and organic matter from water in a remarkable manner. There are without doubt many natural phenomena which are immediately dependent upon this power, possessed by porous bodies of all kinds, in a greater or a less degree.

FIRE ANNIHILATORS. This name is given to a portable machine invented by Mr. Phillips, which is adjusted to produce the immediate production of steam, carbonic acid and other gases, which could be at once directed on the burning mass. The machine is cylindrical in form, and slightly conical. For use it is charged with the following composition: charcoal 20 parts, nitrate of potash 60 parts, and gypsum 5 parts. These materials are boiled together in water, and afterwards dried in a stove at the temperature of 100°. The whole is moulded into the form of a brick, down the axis of which penetrates a hollow cavity for the reception of a bottle, which contains a mixture of chlorate of potash and sugar, surmounted by a globule of sulphuric acid. The charge so prepared is placed in a cylindrical vessel, perforated in many places, which is itself within another cylindrical vessel, perforated for the passage of the gases; both these are contained in a double cylindrical receiver, the lower part of which contains a quantity of water. The apparatus is closed by two covers, in the outer of which is an opening for the escape of the vapour. In the centre of the cover is placed a spike, for the purpose of breaking the glass bottle deposited in the cavity of the charge. The spike being forced down breaks the bottle, and the sulphuric acid causes the instantaneous combustion of the chlorate of potash and sugar, which fires the charge. The gases now escape through the perforations, and heating the air in the water chamber, and causing it to expand, forces the water up a tubular passage into the space between and around the cylindrical vessels placed each within each, and being thus converted into vapour, mixes with the gases, and escapes by the discharge tube, forming a dense cloud, which rapidly extinguishes flame.

FIRE ARMS, MANUFACTURE OF. This art is divided into two branches, that of the metal, and that of the wooden work. The first includes the barrel, the lock, and the mounting, with the bayonet and ramrod, for military arms. The second comprises the stock, and in fowling-pieces likewise the ramrod.

The Barrel.—Its interior is called the bore; its diameter, the calibre; the back end, the breech; the front end the muzzle; and the closing of the back end, the breech pin or plug. The barrel is generally made of iron. Most military muskets and low-priced guns were formerly fashioned out of a long slip of sheet iron folded together edge-wise round a skewer into a cylinder; they were then lapped over at the seams, and welded at a white heat. The most ductile and tenacious soft iron, free from all blemishes, must be selected for this slip. It is frequently welded at the common forge, but a proper air-furnace answers better, not being so apt to burn the iron, which should be covered with ashes or cinders. The shape of the bore is given by hammering the cylinder upon a steel mandril, in a groove of the anvil. Six inches of the barrel at either end are left open for forming the breech and the muzzle by a subsequent welding operation; the extremity put into the fire being stopped with clay, to prevent the introduction of cinders. For every length of two inches, there are from two to three welding operations, divided into alternating high and low heats; the latter being intended to correct the defects of the former. The breech and muzzle are not welded upon the mandril, but upon the horn of the anvil; the breech being thicker in the metal, is more highly heated, and is made somewhat wider to save labour to the borer. The barrel is finally hammered in the groove of the anvil without the mandril, during which process it receives a heat every two minutes. In welding, the barrel extends about one-third in length; and for musquets, is eventually left from 3 to 3½ feet long; but for cavalry pistols, only 9 inches.

The best iron plates for gun-barrels are those made of *stubb* iron, that is of old horse shoe nails welded together, and forged into thin bars, or rather narrow ribbons. At one time *damascus* barrels were much in vogue; they were fashioned either as above described, from plates made of bars of iron and steel laid parallel, and welded together, or from ribbons of the same *damascus* stuff coiled into a cylinder at a red heat, and then welded together at the seams. The best modern barrels for fowling-pieces and the modern rifles are constructed of stub-nail iron in this manner. The slip or fillet is only half an inch broad, or sometimes less, and is left thicker at the end which is to form the breech, and thinner at the end which is to form the muzzle, than in the intermediate portion. This fillet being moderately heated to increase its pliancy, is then lapped round the mandril in a spiral direction till a proper length of cylinder is formed; the edges being made to overlap a little in order to give them a better hold in the welding process. The coil being taken off the mandril and again heated, is struck down vertically with its muzzle end upon the anvil, whereby the spiral junctions are made closer and more uniform. It is now welded at several successive heats, hammered by horizontal strokes, called *jumping*, and brought into proper shape on the mandril. The finer barrels are made of still narrower stub-iron slips, whence they get the name of wire twist. On the continent, some barrels are made of steel wire, welded to their lengthwise, then coiled spirally into a cylinder. Barrels that are to be rifled, require to be made of thicker iron, and that of the very best quality, for they would be spoiled by the least portion of scale upon their inside. Soldiers' musquets are thickened a little at the muzzle, to give a stout bulking to the bayonet.

The barrels thus made are annealed with a gentle heat in a proper furnace, and slowly cooled. They are now ready for the borer, which is an oblong square bit of steel, pressed in its rotation against the barrel by a lip of wood applied to one of its flat sides and held in its place by a ring of metal. The boring bench works horizontally, and has a very shaky appearance in respect at least of the bit. In some cases, however, it has been attempted to work the barrels and bits at an inclination to the horizon of 30°, in order to facilitate the discharge of the barina. The barrel is held in a slot by only one point, to allow it to humour the movements of the borer, which would otherwise be infallibly broken. The bit, as represented in *fig* 760, has merely its square head inserted into a clamp-chuck of the lathe, and plays freely through the rest of its length.

Fig 761 represents in plan the boring bench for musquet barrels; *ff* is the slider or carriage frame in which the barrel is supported; *a* is the revolving chuck of the lathe, into which the square end of the bit, *fig* 760, is inserted; *b* is the barrel,

clamped at its middle to the carriage, and capable of being pressed onwards against the tapering butt of the borer, by the bent lever *c*, worked by the left hand of the operative against fulcrum knobs at *d*, which stand about two inches asunder. Whenever the barrel has been thereby advanced a certain space to the right, the bent end of the lever is shifted against another knob or pin. The borer appears to a stranger to be a very awkward and unsteady mechanism, but its perpetual vibrations do not affect the accuracy of the bore. The opening breach may be of a square or pentagonal form; and either gradually tapered from its thickest part, or of uniform diameter till within two inches of the end, whence it is suddenly tapered to a point.

A series of bits may be used for boring a barrel, beginning with the smallest and ending with the largest. But this multiplication of tools becomes unnecessary, by laying against the cutting part of the bit, slips of wood, called spales, of gradually increasing thickness, so that the edge is pressed by them progressively further from the axis. The bore is next polished. This is done by a bit with a very smooth edge, which is mounted as above, with a wedge of wood beameared with a mixture of oil and emery. The inside is finished by working a cylindrical steel file quickly backwards and forwards within it, while it is revolving slowly.

In boring, the bit must be well oiled or greased, and the barrel must be kept cool by letting water trickle on it; for the bit, revolving at the rate of 120 or 140 times a minute, generates a great deal of heat. If a flaw be detected in the barrel during the boring, that part is hammered in, and then the bit is employed to turn it out.

Many sportsmen are of opinion that a barrel with a bore somewhat narrowed towards the muzzle serves to keep shot better together; and that roughening its inside with pounded glass has a good effect, with the same view. For this purpose, also, fine spiral lines have been made in their interior surface. The justness of the calibre of a fowling piece or musket is tried by means of a truly turned cylinder of steel, 3 or 4 inches long, which ought to move without friction, but with uniform contact from end to end of the barrel. Whatever irregularities appear must be immediately removed.

The outer surface of the barrel is commonly polished upon a dry grindstone, but it is better finished at a turning lathe with a slide rest.

Rifle barrels have parallel grooves of a square or angular form cut within them, each groove being drawn in succession. These grooves run spirally, and form each an aliquot part of a revolution from the chamber to the muzzle. Rifles should not be too deeply indented; only so much as to prevent the ball turning round within the barrel, and the spirals should be truly parallel, that the ball may glide along with a regular pace.

The Parisian gun-makers, who are reckoned very expert, draw out the iron for the barrels at hand forges, in fillets only one-ninth of an inch thick, one inch and a half broad, and four feet long. Twenty-five of these ribbands are laid upon each other, between two similar ones of double thickness, and the bundle, weighing 60 lbs., bound with wire at two places, serves to make two barrels. The thicker plates are intended to protect the thinner from the violence of the fire in the numerous successive heats necessary to complete the welding, and to form the bundle into a bar two-thirds of an inch broad, by half an inch thick; the direction of the individual plates relatively to the breadth being preserved. This bar folded flat upon itself, is again wrought at the forge, till it is only half an inch broad, and a quarter of an inch thick, while the plates of the primitive ribbands are now set perpendicular to the breadth of the narrow fillet; the length of which must be 15 or 16 feet French (16 or 17 English), to form a fowling piece from 25 to 30 inches long. This fillet, heated to a cherry red in successive portions, is coiled into as close a spiral as possible, upon a mandril about two-fifths of an inch in diameter. The mandril has at one end a stout head for drawing it out, by means of the hammer and the grooves of the anvil, previous to every heating. The welding is performed upon a mandril introduced after each heat; the middle of the barrel being first worked, while the fillets are forced back against each other, along the surface of the mandril, to secure their perfect union. The original plates having in the formation of the ultimate long ribband become very thin, appear upon the surface of the barrel like threads of a fine screw, with blackish tints to mark the junctions. In making a double-barrelled gun, the two are formed from the same bundle of slips, the coils of the one finished fillet being turned to the right hand, and those of the other to the left.

The barrels forged, as above described, from a bundle of steel and iron plates laid alternately together, are twisted at the forge several times, then coiled and welded as usual. Fifteen workmen concur in one operation: six at the forge; two at the boring mill; seven at filing, turning, and adjusting; yet altogether make only six pairs of barrels per week. In the first instance, it will be understood, that, for the

construction of the superior barrel, a bundle of horse-shoe nails is welded into a flat bar, similar bars of scrap steel are made, and these are made up into a bundle,—a bar of iron, and a bar of steel—of eight or twelve bars. This is again welded into one bar, and the result is, when the surface is polished, that the difference in the texture of the two metals is distinctly visible. Now, if two bars of iron and one of steel, or two bars of steel and one of iron, or any other combination of the two, be adopted, there will be a variety in the pattern of the finished bar.

In constructing the barrel this bar may be twisted up singly, as described, or two bars differing in pattern may be welded together, and then twisted. It is usual to place two bars together, to twist one into a screw and leave the other plain, or to give one a right hand twist and the other a left handed one, or sometimes three bars are employed, and by twisting or otherwise previously to welding the bars together and turning or twisting the compound bar into a cylinder, a great variety of patterns are produced on the finished barrel.

The breeching is of three kinds: the common; the chamber, plug, or mortar, fig. 762; and the patent, fig. 763. The common was formerly used for soldiers' muskets and inferior pieces. The second is a trifling improvement upon it. In the patent breeching, the screws do not interfere with the touch-hole, and the ignition is quicker in the main chamber.

The only locks which it is worth while to describe are those upon the percussion principle, as flint locks have ceased to be employed. Forsyth's lock (fig. 764) was an ingenious contrivance. It has a magazine *a*, for containing the detonating powder, which revolves round a roller *b*, whose end is screwed into the breech of the barrel. The priming powder passes through a small hole in the roller, which lends to a channel in communication with the chamber of the gun.

The pan for holding the priming is placed immediately over the little hole in the roller. There is a steel punch *c*, in the magazine, whose under end stands above the pan, ready to ignite the priming when struck upon the top by the cock *d*, whenever the trigger is drawn. The punch, immediately after being driven down

into the pan, is raised by the action of a spiral spring. For each explosion, the magazine must be turned so far round as to let fall a portion of the percussion powder into the pan; after which it is turned back, and the steel punch recovers its proper position for striking another blow into the pan.

The invention of the copper percussion cap was another great improvement upon the detonating plan. Fig. 765 represents the ordinary percussion lock, which is happily directed of three awkward projections upon the flint lock, namely, the hammer, hammer spring, and the pan. Nothing now appears upon the plate of the lock, but the cock or striking hammer, which inflicts the striking blow upon the percussion cap. It is concave, with a small metallic ring or border, called a slight or fence, for the purpose of enclosing the cap, as it were, and preventing its splinters doing injury to the sportsman, as also protecting against the line of flame which may issue from the touch-hole in the cap-nipple. This is screwed into the patent breech, and is perforated with a small hole.

The safety lock of Dr. Somerville is, in its essential features, a slide stop or catch,

765

placed under the trigger. A, *fig. 766*. It is pulled forward into a notch in the trigger, by means of a spring *n*, upon the front of the guard, which is worked by a key *c*,

766

pressing upon the spring when the piece is discharged. In another safety plan there is a small movable curved piece of iron, *a*, which rises through an opening *n*, in the lock-plate *c*, and prevents the cock from reaching the nipple, as represented in the figure, until it is drawn back within the plate of the lock when the piece is fired.

To fire this gun, two different points must be pressed at the same time. If by accident the key which works the safety be touched, nothing happens, because the trigger is not drawn; and the trigger touched alone can produce no effect, because it is locked. The pressure must be applied to the trigger and the key at the same instant, otherwise the lock will not work.

The old French musket is longer than the British, in the proportion of 44·72 inches to 42; but the French bayonet is 15 inches, whereas the British is 17.

Within these few years a great many contrivances for fire arms have been brought forward, and several have been patented. The first is that of Charles Handoyn, Baron de Bertréger. *Fig. 767* shows the lock and breech of a fowling piece, with a sliding protector on one of the improved plans; *a* is the hammer, *b* the nipple of the touch-hole, *c* a bent lever, turning upon a pin, fixed into the lock-plate at *d*. The upper end of this bent lever stands partly under the nose of the hammer, and while in

that situation stops it from striking the nipple. A slider *g f h*, connected with the under part of the gun-stock, is attached to the tail of the bent lever at *i*; and when the

767

piece is brought to the shoulder for firing, the hand of the sportsman pressing against the bent part of the slider at *g*, forces this back, and thereby moves the end of the lever *c* forwards from under the nose of the cock or hammer, as shown by the dotted lines. The trigger being now drawn, the piece will be discharged; and on removing the hand from the end *g*, of the slider *f*, the spring at *h* acting against the guard, will force the slider forward, and the lever into the position first described.

Mr. Redford, gun-maker, of Birmingham, introduced a modification of the lock for small fire-arms, in which the application of pressure to the sear spring for discharging the piece is made by means of a plug, depressed by the thumb, instead of the force of the finger exerted against the trigger. Fig. 768 represents a fowling piece partly in

768

action. The sear spring is shown at *a*. It is not here connected with the trigger as in other locks; but is attached by a double-jointed piece to a lever *b*, which turns upon a fulcrum pin in its centre. At the reverse end of this lever an arm extends forwards, like that of an ordinary sear spring, upon which arm the lower end of the plug *c* is intended to bear; and when this plug is depressed by the thumb bearing upon it, that end of the lever *b* will be forced downwards, and the reverse end will be raised, so as to draw up the end of the sear spring, and set off the piece. For the sake of protection, the head of the plug *c* is covered by a movable cap *d*, forming part of a slider *e*, which moves to and fro in a groove in the stock, behind the breech end of the barrel; this slider *e* is acted upon by the trigger through levers, which might be attached to the other side of the lock-plate; but are not shown in this figure to avoid confusion. When the piece is brought to the shoulder for firing, the fore-finger must be applied as usual to the trigger, but merely for the purpose of drawing back the slider *e*, and uncovering the head of the plug; when this is done, the thumb is to be pressed upon the head of the plug, and will thus discharge the piece. A spring bearing against the lever of the slider *e*, will, when the finger is withdrawn from the trigger, send the slider forward again, and cover the head of the plug, as shown.

The Rev. John Somerville, of Currie, in April, 1833, obtained a patent for a further invention to prevent the accidental discharge of fire-arms. It consists in hindering the hammer from reaching the nipple of a percussion lock, or the flint reaching the steel of an ordinary one, by the interposition of movable safety studs or pins, which protrude from under the false breech before the hammers of the locks, and prevent them from descending to strike. These safety studs or pins are moved out of the way by the pressure of the right hand of the person using the gun only when in the act of firing, that is, when the force of the right hand and arm is exerted to press the butt end of the stock of the gun against the shoulder while the aim is taken and the trigger pulled. In carrying the gun at rest, the proper parts of the thumb or hand do not come over Mr. Somerville's movable buttons or studs.

Fig. 769 is a side view of part of a double percussion gun; and Fig. 770 is a top or plan view, which will serve to explain these improvements, and show one, out of many, methods of carrying them into effect. *a* is the stock of the gun; *b* the barrels; *c* the breech; *d* the nipples; *e* the false breech, on the under side of which the levers which

work the safety studs or pins are placed; *v* is the shield of the false breech; *a* triggers; *u* the lock-plate; and *z* the hammers. all of which are constructed as usual: *u* and *a* are

the safety studs or pins, which protrude before the shield *v*, and work through guide pieces on the under side of the false breech. The button piece is placed in the

position for the thumb of the right hand to act upon it; but when the pressure of the ball of the right thumb is to produce the movement of the safety studs, it must be placed in or near the position *x*; and when the heel of the right hand is to effect the movements of the safety studs, the button piece must be placed at *z*, or nearly so.

In these last two positions, the lever (which is acted upon by the button piece to work the safety studs through a slide) would require to be of a different shape and differently mounted. When the hammers are down upon the nipples after discharging the gun, the ends of the safety pins press against the inner sides of the hammers. When this invention is adapted to single-barrelled guns, only one pin, *a*, one lever and button piece will be required.

Mr. Richards, gun-maker, Birmingham, patented a modification of the copper cap for holding the percussion powder as represented fig. 771; in which the powder is removed from the top of the cap, and brought nearer the mouth; *a* being the top, *b* the sides, and *c* the position of the priming. The dotted lines show the direction of the explosion, whereby it is seen that the metal case is opened or distended only in a small degree, and not likely to burst to pieces, as in the common caps, the space between *a* and *c* being occupied by a piece of any kind of hard metal *d*, soldered or otherwise fastened in the cap.

George Lovell, Esq., Director of the Royal Manufactory of Arms at Enfield, introduced an improvement upon the priming chamber. He forms it into a vertical double cone, joined in the middle by the common apex; the base of the upper cone being in contact with the percussion cap, presents the most extensive surface to the fulminate upon the one hand, while the base of the under one being in a line with the interior surface of the barrel, presents the largest surface to the gunpowder charge, upon the other. In the old nipple the apex of the cone being at its top, afforded very injudiciously the minimum surface to the exploding force.

Guns, Rifling of the Barrels.—The outside of rifle barrels is, in general, octagonal. After the barrel is bored, and rendered truly cylindrical, it is fixed upon the rifling machine. This instrument is formed upon a square plank of wood 7 feet long, to which is fitted a tube about an inch in diameter, with spiral grooves deeply cut internally through its whole length; and to this a circular plate is attached about 5 inches diameter, accurately divided in concentric circles, into from 5 to 16 equal parts, and supported by two rings made fast to the plank, in which rings it revolves. An arm connected with the dividing graduated plate, and pierced with holes, through which a pin is passed, regulates the change of the tube in giving the desired number of grooves to the barrel. An iron rod, with a movable handle at the one end, and a steel cutter in the other, passes through the above rifling tube. The rod is covered with a core of lead one foot long. The barrel is firmly fixed by two rings on the plank, standing in a straight line on the tube. The rod is now drawn repeatedly through the barrel, from end to end, until the cutter has formed one groove of the proper depth. The pin is

then shifted to another hole in the dividing plate, and the operation of grooving is repeated till the whole number of ridings is completed. The barrel is next taken out of the machine, and finished. This is done by casting upon the end of a small iron rod a core of lead, which, when besmeared with a mixture of fine emery and oil, is drawn, for a considerable time, by the workmen, from the one end of the barrel to the other, till the inner surface has become finely polished. The best degree of spirality is found to be from a quarter to half a revolution in a length of three feet.

Military Rifles.—An essential improvement in this destructive arm has been introduced into the British service.

The intention in all rifles is to impart to the ball a rotatory or spinning motion round its axis, as it passes out through the barrel. This object was attained, to a certain degree, in the rifles of the old pattern, by cutting seven spiral grooves into the inside of the barrel, in the manner shown by fig. 772, the spherical ball, fig. 773, being a little larger than the bore, was driven down with a mallet, by which the projecting ribs were forced into the surface of the ball, so as to keep it in contact with their curvatures, during its expulsion. Instead of this laborious and insecure process, the barrel being now cut with only two opposite grooves, fig. 774, and the ball being formed with a projecting belt, or zone, round its equator, of the same form as the two grooves, fig. 775. It enters so readily into these hollows, that little or no force is required to press it down upon the powder. So much more hold of the barrel is at the same time obtained, that instead of one quarter of a turn, which was the utmost that could be

safely given in the old way, without danger of stripping the ball, a whole turn round the barrel in its length, can be given to the two grooved rifles; whereby a far more certain and complete rotatory motion is imparted to the ball. The grand practical result is, that better practice has been performed by several companies of the Rifle Corps, at 300 yards, than could be produced with the best old military rifles at 150 yards; the soldier being meanwhile enabled to load with much greater ease and despatch. The belt is bevelled to its middle line, and not so flat as shown in the figure.

This mode of rifling is not, however, new in England. In fact, it is one of the oldest upon record; and appears to have fallen into disuse from faults in the execution. The idea was revived within the last few years in Brunswick, and it was tried in Hanover also, but with a lens-shaped (*linsenförmig*) ball. The judicious modifications and improvements it has finally received, have brought out all its advantages, and rendered it, when skilfully used, a weapon of unerring aim, even at the distance of 500 yards.

The locks, also, for the military service generally, are receiving important im-

provements. In Lovell's lock the action of the main spring is reversed, as shown by fig. 776, thus rendering the whole mechanism more solid, compact, and convenient;

while the ignition of the charge is effected by percussion powder in a copper cap. Mr. Lovell, inspector of small arms for her Majesty's service, and director of the

777

781

Royal manufactory, at Enfield Chase, directed his mind to the construction of a sure, simple, and strong musket, with which, under his superintendence, the whole of her Majesty's soldiers were long provided. He has also furnished them with a short, but clear set of instructions for the cleaning and management of these excellent arms, illustrated by a series of wood engravings. From this little work the following notice is copied.

Fig. 777. The barrel, reduced to one-seventh size. *a*, the breech; *b*, the nipple-seat or lump; *c*, the back sight; *d*, the back-loop; *e*, the middle loop; *f*, the swivel-loop; *g*, the front loop, with the bayonet-spring attached; *h*, the front sight; *i*, the muzzle.

Fig. 782. The lock, outside, half size. *a*, the plate; *b*, the cock; *c*, the tumbler-pin; *d*, the hollow for the nipple seat.

Fig. 783. The lock, inside, half size, showing all the parts in their places with the cock down at bearer. *a*, the main-spring; *b*, the sear-spring; *c*, the sear; *d*, the tumbler; *e*, the bridle; *f*, the main-spring-pin; *g*, the sear-pin; *h*, the sear-spring-pin; *i*, the bridle-pin.

Barrel-welding by Machinery. — The barrels of muskets, birding-guns, &c., or what are called *plain*, to distinguish them from those denominated *stub* or *twisted* barrels, have of late years been formed by means of rolls, a process in which the welding is first effected on a short slab of thick iron, and then the barrel is brought down to its destined length and form, by repeatedly passing it between a pair of rolls, that have been previously grooved to the exact shape of the barrel intended to be made.

The iron being thoroughly refined, and reduced into flat bars by the process described, is cut by the shears into slabs or lengths of 10 to 12 inches, and 10 to 10½ lbs. weight, or less, according to the description of gun-barrel that is intended to be made. These slabs are then heated, and bent in their whole length, by means of conveniently grooved bending rolls, until they assume the form of rough tubes, of the 2nd of section shown by *A*, *fig. 784*. They are then placed on the hearth of the reverberatory furnace, and brought to a full welding heat, and as soon as the edges of a tube come to a semi-fluid state, it is taken out and passed between rolls having grooves somewhat smaller in diameter than the exterior of the

tube, by which means the tube is perfectly welded from end to end; and if care be taken in the management of the heat, and the juncture be kept clear of dirt and cinders, the iron will be found perfectly homogeneous in every part, and there will be no

appearance whatever of the seam where the the edges came together. These tubes are repeatedly heated, and passed between the barrel rolls, which are of sufficient

784

diameter to admit of gradually decreasing grooves, the whole length of the intended barrel being indented on their surfaces.

To preserve the tubular form, and insure regularity in the size of the bore during the welding process, they are taken out of the furnace, by thrusting into them a tool called a mandril, *a*, fig. 783, which consists of a long rod of iron, having a short steel treblett on its end, of the diameter that the bore of the barrel is meant to be. This rod is so adjusted by means of a strong iron plate *c*, near its handle, which is of wood, and long, that when passed with the heated tube on it between two transverse holding bars, the short steel treblett *b* shall be found exactly between the point of impact of the barrel rolls, *k*, *l*.

785

The adhesion of the hot iron to the surface of the rolls is strong enough to draw the tube off the mandril, which thus keeps the bore open from end to end, and by repeating the process through the whole series of grooves in the rolls, the barrel is

gradually elongated, and brought down to the exact form required; any superfluous length at the muzzle is then cut off. The breech end is then adjusted by the hammer — a triple-seat welded on by hand if it be intended for a percussion lock; and then the barrel is ready to go forward to the mill to be bored, turned, and finished.

Gun barrels formed by this mechanical method are found to stand proof better than those worked by hand, because the heat is more equalised; and any imperfections in the original mass of iron are more dispersed over the whole extent of the tube.

(Of late years large strides have been made towards increasing the efficacy of military fire-arms.

The first attempt to improve the rifle in use in the French army, was that proposed by M. Delvigne, an officer of the royal ex-guard (*fig. 786*), in which the upper

786

orifice of the chamber that contained the powder took the form of a cup, wherein the ball (somewhat wider in diameter) was received, and by two or three smart blows of a heavy-headed rammer (also capped out for the purpose) became expanded laterally, and thus the rotary motion was imparted to it by the spiral grooves of the barrel in passing out. Colonel Poncharra suggested the addition of a wood bottom or wad under the ball and a greased woollen patch; and Colonel Thouvenin proposed (*fig. 787*) a steel stem or pillar about 2 inches long inserted into the face of the breech-

787

pin; round this pin the charge of powder was received, and the diameter of the ball, when resting on the top of the pin, was enlarged by the blows of the heavy-headed rammer, as suggested by Delvigne.

This system took the name of "Caroline à Tige," and has been very generally introduced for the service of fusilier battalions in continental armies; very grave objections, however, have been found against it in use, from the impossibility of keeping the chamber (or part round the pin) clear; and from the severe labour to the soldier in ramming down and enlarging the diameter of the ball sufficiently to insure the rotary motion desired.

But if the ultimate results thus attained with spherical balls turned out not entirely satisfactory, it was made clearly manifest, in the course of the experiments carried on, that no insuperable difficulty stands in the way of rendering the fire of infantry very much more accurate and powerful, by the use of rifled barrels throughout the army, and thus leading to a verification of the prediction made by Robins above one hundred years ago, that "whatever state shall thoroughly comprehend the nature and advantages of rifled barrel pieces, and having facilitated and completed their construction, shall introduce into their armies their general use, with dexterity in the management of them, will by this means acquire a superiority which will almost equal any thing that has been done at any time."

Not besides smoothing the way to such an essential improvement, it has been elicited of late years, that when the accuracy of flight is secured by the rotary motion derived from the rifling, the bullet, instead of being limited to the form of a sphere as heretofore, may, up to certain limits, be elongated with considerable increase of destructive effect; and with an augmentation of range very much beyond any thing that has hitherto been considered to lie within the reach of small arms — placing them, in fact, with reference to artillery and cavalry, in the first place instead of the last.

An immensely extended field has thus been opened to experimenters. 1st. Mons. Dillion proposed a true oval (*fig. 788*) as the best form of bullet, so that, when shortened by the blows of the heavy rammer and widened in its diameter, it might be brought nearer to the spherical shape before leaving the barrel.

2nd. Mons. Delvigne took a patent for a bullet (*fig. 789*) under the designation of "Cylindre Ogivale;" it had a conical opening behind, in which he imagined that the force of the powder would exert itself with sufficient energy to expand the lead permanently, and so make the ball take the rotary movement derived from the rifling, without any fatigue to the soldier in loading: with this projectile, indeed, the operation is but slightly more difficult than with the ordinary cartridge and smooth barrels.

The bullet (*fig. 790*) of the "Carabine à Tige" was called "Cylindro Conique," and was said to possess this advantage over the preceding, that, being brought more to a point in front, it bored its way through the air with greater ease, and thus retained

greater velocity, and of course, more extended range; and with this bullet it was that Mons. Tamisier introduced three sharp-edged channels round it, which he stated were necessary to keep its flight steady, by offering a resistance to the action of the air.

Finally Mons. Minie, an officer of the French line, suggested (*fig. 791*) the addition of a *disjoncteur* or culot to the hollow ball of Delvigue. This, in the form of a little cup made of sheet iron, is placed in the orifice of the conical hollow of the ball behind, and by the energy of the powder is driven into the ball, enlarging its diameter permanently, and thus giving all the accuracy of the rifle, with nearly the same facility of loading as with the plain barrel.

The principle of the invention, as thus developed, has, we learn, been adopted by our government for the general use of the army, seeing that it offers so great advantages over the system of plain barrels, but the bullet (*fig. 792*), as modified by the Inspector of Small Arms, has on its exterior no channels, they being found not only useless as to steadying the flight of the projectile, but absolutely injurious in lowering its velocity. The bullet in its improved form too, being more truly balanced in its proportions, and made by mechanical means instead of by casting, has no tendency to the gyrations which appear to have so puzzled French artillerymen, and for which they have invented the word "*dérivation*," and wasted much learned disquisition.

But even if it were ever to happen, which is not likely, that these various projectors could be brought to agree as to the best form of projectile, they will then flout out, that although by the general introduction of rifled and elongated bullets an immense advantage has been realised over plain barrels, their plans, based as they all are upon a system of loading at the muzzle, are at best but one step in advance; and that a good sound military fire-arm loading at the breach will, after all, remain the great desideratum — an arm that, without any less accuracy or power to reach masses of artillery or cavalry at a thousand yards' distance, will enable the soldier to triple the quantity of his fire at any moment that he may be called upon to repel a charge of cavalry or attack or defend a breach at close quarters; of such simple construction, and so easily handled in every position of the body, that the soldier can pour every shot of his most murderous fire upon the enemy with unerring precision, whilst he himself may lie coolly behind a stone or in a ditch in entire security.

These are no longer wild imaginings, although so many hundreds of attempts towards the same object, from the earliest period to the present day, have been one after another seen invariably to fail. The Germans have been long and steadily pursuing the great object, and at length Herr Dreyer, of Sommerda in Thuringia, has succeeded, after more than twenty years of continued labour, in establishing a musket, under the name of "*Zündnadelgewehr*," which if not quite perfect, is so well adapted for the uses to which it is applied that the Prussians have armed the whole of their line and the *Landwehr* with this weapon.

The needle musket (*fig. 793*) consists of a strong socket *a*, open on the upper side

and screwed on to the barrel *b*, which is rifled in the usual manner; within this socket is a slider *c*, which in fact constitutes the lock, as it contains the spiral spring and

mechanism that produce ignition by percussion; it has a stout heel, or handle, by which it is moved backwards and forwards freely. The cartridge (*fig. 794*) consists of the ball *a*, the sabot *b*, or bottom of hard paper, and holding the priming matter, and lastly the charge of powder *c*, the whole being made up in paper pasted together. In use the slider being drawn back, the soldier puts the cartridge with the point of the ball in front into the open breach of the barrel, pushes the slider forward, and secures its close junction by a turn to the right against an inclined edge of the open socket. The spiral spring is then brought into action by pressing the spring case forward with the thumb.

794

To Captain Drayson, R. A., we are indebted for the following. The Enfield rifle, which has lately been approved of for the use of the army, is constructed principally by machinery.

The factory at Enfield, at which this arm is manufactured, is considered one of the most complete establishments in the world.

The barrel, lock, wood-work, furniture, and bayonet are all constructed at Enfield, and as each portion is made exactly of the same size and shape, a part of one rifle will fit into the same part of another.

The total length of this weapon, including bayonet, is 6 ft. 6½ in. long, and weighs 9 lb. 3 oz.; the barrel is 3 ft. 3 in. in length, and weighs 4 lb. 2 oz.; the diameter of bore is .577 inch. The bullet is elongated, and rotates on leaving the piece like a spherical bullet. The general figure of the bullet is cylindrical, but its front end is rounded, and its rear end has a conical-shaped cavity. In the Minié rifle, some of which were introduced into the service, a small iron cap was placed to the hollow at the rear end of the ball for the purpose of causing the bullet to expand, but in the Enfield rifle this opening is filled by a wooden plug instead. This diminishes the fouling of the bore, and answers all the purposes of expansion.

The bullet is .568 inch, length 1.062 inch, weight 530 grains. The barrel is proved at Enfield, and when flaws are supposed to exist as much as 15 drams of powder have been fired, without bursting the barrel. The service charge is 2½ drams. The weight of 60 rounds of ammunition including 75 caps is 5 lb. 8 oz.

The bore has three grooves, each groove forms a spiral of ½ a turn in 3 feet 3 inches. The rifle is sighted up to 900 yards, but an effective range may be obtained beyond that distance.

The number of rifles lately turned out at Enfield is from 1000 to 1200 per week; but there is shortly to be an increase in this quantity, when it is expected that upwards of 1500 per week will be turned out.

For neatness and completeness of workmanship, as well as for efficiency, the Enfield rifle is undoubtedly superior to any other fire-arm yet in use.

FIRE BRICKS. See **BRICKS** and **CLAY**.

FIRE-DAMP; the carburetted hydrogen of coal-mines, produced, in some cases, by the slow decomposition of the coal itself; in others, it is probably the result of the changes in the constitution of the vegetable matter of which the coal itself is formed, which has been confined under great pressure in the interstitial spaces of the coal beds or rocks immediately in connection with them. The accumulation of this gas in the "goaf," or waste spaces of a coal mine, is probably due to the changes which the coal itself undergoes. The sudden outbursts of this gas, known as "blowers," are no doubt the result of the liberation of the gas by suddenly removing the pressure under which it has been confined. This gas is the constant product of the decomposition of carbonaceous bodies under water; it has hence been also called marsh gas. It is a proto-carburetted hydrogen, its formula being C_2H_4 .

This carburetted hydrogen gas does not explode when mixed with air in a proportion much above or below the quantity necessary for complete combustion. With three or four times its volume of air it does not explode at all, with five and a half or six volumes of air it detonates feebly, and with seven or eight most powerfully. When mixed with fourteen volumes of air the mixture is still explosive, but with larger proportions of air the gas only burns about the flame of the taper. See **SAFETY LAMP** and **MIXING**.

FIRESTONE, signifies a stone which will bear the heat of a furnace without injury. In geology the term is generally applied to the sandstone which occurs at the top of the upper green sand in the south of England, which, from its power of withstanding the effects of heat, is frequently used for lining kilns and furnaces. It is a greenish calcareous sandstone, soft, and easily worked in any direction when first taken from the quarry; but on exposure it becomes extremely hard and durable, and well suited for building purposes. Many of the older churches in Dorsetshire are built of this stone.—H. W. H.

FIRE WORKS. See **PYROTECHNY**.

FIR-WOOD. (*Alder.*) 1. THE SILVER FIR, *Pinus abies*. (*Sapen Commun*, Fr.; Weiss Oder Edel Tanne, Germ.) 2. SCOTS FIR, *Pinus sylvestris* (*Pin D'Ecuise*, Fr.; Kiefer Oder Fisher, Germ.) These are valuable as timber-trees, and for the resinous juices which exude from them.

FISH SKIN. The skin of the dog-fish, shark, and other ganoids, used occasionally in polishing and in cleaning roundel and irregular works in pattern making.

FLAGSTONE: a stone which splits freely in a particular direction along the original lines of deposition of the rock. These are generally sandstones, and the splitting surfaces are frequently produced by thin laminae of mica; but thin bedded limestones also furnish flagstones, of which some beds of Purbeck limestone and the Stonefield slates are examples. Flagstones are also obtained from lias limestones, which are, in fact, thin beds of laminated clay.—H. W. B.

FLAKE WHITE. This name is applied indiscriminately to pure white lead, and to the triminite of bismuth.

FLAME (*Flamme*, Fr. and Germ.), in the ordinary acceptation, is the combination of a mixture of an inflammable gas or vapour with air. That it is not, as many suppose, combustion merely at the exterior surface where the gas and the air come in contact with each other, is proved by passing a fragment of phosphorus or sulphur into the centre of a large flame. Either of these bodies ignited in passing through the film of flame will continue to burn there with its peculiar light; thus proving that oxygen is mixed with the vapour in the interior. If we mix good coal gas with as much atmospheric air as can convert all its carbon into carbonic acid, the mixture will explode with a feeble blue light, but if we mix the same gas with a small quantity of air, it will burn with a rich white flame; a knowledge of this fact has led to the practice, in many of our large gas works, of pumping air into the gasometers with the coal gas, a dishonest and a dangerous system. In the latter case, the carbonaceous particles are precipitated, as Sir H. Davy first showed, in the interior of the flame, become incandescent, and constitute *white light*. far from the ignition of solid matter alone can the prismatic rays be emitted in that concentrated union. Towards the interior of the flame of a candle, a lamp, or a gas jet, where the air is scanty, there is a deposition of solid charcoal, which, by its ignition, increases in a high degree the intensity of the light. If we hold a piece of fine wire gauze over a jet of coal gas close to the orifice, and if we then kindle the gas, it will burn above the wire with its natural brilliancy; but if we elevate the gauze progressively higher, so as to mix more and more air with it before it reaches the burning point, its flame will become fainter and less white. At a certain distance it becomes blue, like that of the above explosive mixture. If a few platinum wires be held in that dim flame they will grow instantly white hot, and illuminate the apartment. On reversing the order of this experiment, by lowering progressively a flat piece of wire gauze from the summit towards the base of a gas flame, we shall find no charcoal deposited at its top, because plenty of air has been introduced there to convert all the carbon of the gas into carbonic acid; but as we descend, more and more charcoal will appear upon the meshes. At the very bottom, indeed, where the atmospheric air impinges upon the gauze, the flame is blue, and no charcoal can therefore be deposited.

The fact of the increase of the brilliancy and whiteness of flame by the development and ignition of solid matter in its bosom, illustrates many curious phenomena. We can thus explain why olefant gas affords the most vivid illumination of all the gases; because, being uncharged with charcoal, its hydrogen lets it go in the middle of the flame, as it does in an ignited porcelain tube, whereby its solid particles first get ignited to whiteness, and then burn away. When phosphorus is inflamed, it always yields a pure white light, from the ignition of the solid particles of volatilised phosphorus rapidly converted to phosphoric acid.

In the blowpipe flame from an oil-lamp or a candle, the lower blue flame has the greatest heat, because there the combustion of the whole fatty vapour is complete. The feeble light of burning hydrogen, carbonic oxide, and sulphur, may, upon the principles now expounded, be increased by simply placing in them a few particles of oxide of zinc, slender filaments of amianthus, or fine platinum wire. Upwards of twenty years ago Dr. Ure demonstrated, in his public lectures in Glasgow, that by narrowing the top of a long glass chimney over an argand flame either from oil or coal gas, the light could be doubled, at the same cost of material. The very tall chimneys used by the lamp-makers are very wasteful, as they generate a strong current of air, and the combustion of the solid matter is carried on with great rapidity. With a narrow chimney of half the length we can have nearly as good a light, and save 30 per cent. of the oil. See BLOWPIPE.

FLANDERS BRICKS, commonly called Bath bricks. These are made in large quantities at Bridgewater, from the soft clay deposited in the estuary, which contains

n large quantity of fine sand. These bricks are much used for domestic purposes, also in making foundlers' cores, and for polishing some steel articles.

FLANNEL. A plain woollen stuff of a rather open and slight fabric. See **WOOLLEN MANUFACTURES.**

Wales is the country in which flannel was originally made, and the Welsh flannel is still held in much estimation. Hand labour is still employed in the production of Welsh flannel, and though it is not so cheap as some others, the quality and finish of this fabric generally causes it to be preferred for vests worn next the skin and similar purposes. Flannels are now made more extensively at Rochdale than in any other part of the world. In that neighbourhood the manufacturers produce the greatest variety of widths, finish, and substance, viz.: the thin, the medium, the thick, double raised, and swanskin. Saddleworth produces the so-called Saxony flannels, which are much admired, and some varieties are produced at Leeds, and finished the natural colour of the wool. In the west of England flannels are made, but not extensively, and in Ireland a few varieties of low flannels and coatings, called Galways, are manufactured from Irish grown wool.

FLAT RODS. In mining, a series of rods for communicating motion from the engine, horizontally, to the pumps or other machinery in a distant shaft.

FLAX (Latin, *linum*; French, *lin*; Italian and Spanish, *lino*; Portuguese, *linha*; German *flachs*; Dutch *vlas*), the *Linum usitatissimum*, a plant of the class Pentandria, order Pentagynia, in the system of Linnaeus, and the type of the order Linaceæ, in the natural system of Botany, largely cultivated for its fibre and seed, and, next to cotton, the most extensively used raw material for textile manufacture in the vegetable kingdom. This plant was primarily a native of Asia, and was introduced as an early period, into Europe. Frequent mention is made of it in scripture history, as grown both in Palestine and in Egypt, as well as of the fabrics manufactured from its fibre. It was probably introduced into Europe by the Phœnician traders, or the Greek colonists of Egypt and Syria. Homer alludes to the linen manufacture of Greece.

At the present day, the flax plant is grown for fibre alone, for seed alone, or for both products together, in many countries of the eastern, and in some of the western hemisphere. For seed alone, in Hindostan, Turkey, and the United States of America; for fibre and seed in Russia, Belgium, Holland, France, Germany, Scandinavia, Italy, Switzerland, the Iberian Peninsula, Great Britain, and Egypt; in Ireland, chiefly for the fibre, without utilizing the seed.

The average annual production of fibre, in the chief countries where flax is grown, is as follows:—

	Tons.
Russia -	130,000
France	48,000
Belgium	18,000
Holland	9,000
Austria	60,000
Prussia	32,000
Ireland	35,000
Egypt	10,000

and adding all other countries, we may estimate the entire annual weight of fibre produced throughout the world, at 400,000 tons.

The quantity of seed may be taken at nearly 2,000,000 of quarters. At the average value of fibre and seed, the annual production in all countries, of the former, may be given in value at 20,000,000*l.*, and of the latter at 8,000,000*l.*, making in all, 28,000,000*l.*, as the worth of the raw produce, before its conversion into woven fabrics and sewing stuffs.

The flax plant has a single slender stem, varying from 2 to 4 feet in height, according to the nature of the soil and the season, with the difference of climate, and mode of culture. It has lanceolate, sessile leaves, of a rich green colour, and branches out, at the top, into two or more small stems, each of 2 or 3 inches in length, and bearing light blue flowers, succeeded by globular capsules, pointed at the apex, and bearing 6 to 10 seeds of a reddish brown, when ripe. The stem of the plant consists of an inner part, or core, sometimes hollow, but more frequently solid, composed of ligneous matter, surrounded with a bark of fibres, which are united to each other by a gum, the whole being sheathed in a fine epidermis. The plant arrives at maturity in 14 or 15 weeks after the seed is sown. It has then changed to a pale yellow or straw colour, and the seeds have become brown. The usual period of sowing, in European countries, is from March to May, although in some parts of the Continent the seed is put in the ground in autumn, but in this case nothing is gained, as the plant becomes mature very little earlier than when the sowing is done in

spring. It is grown on a wide range of soils, sandy, calcareous, clay, loam, peaty, &c., but that best adapted to it is, either a deep, friable, clay loam, or the alluvial deposit of rivers, whether along their banks, their deltas, or where reclaimed from the sea, as in the case of the polders of Holland. Deep tillage, good drainage, and repeated pulverisation of the soil, are very requisite. The preparations for the crop are begun in winter, by ploughing the surface, and turning it up to the action of frost: they are completed in spring, by plowing and harrowing. The seed is sown at the rate of 2½ bushels per statute acre, the best season being April. In the British Isles, Belgium, and Holland, the favourite seed is obtained from Russia, Riga being the port of shipment. Dutch seed is also extensively in use in Ireland, in the heavier class of soils. American is also occasionally used in Ireland, and a good deal of home grown seed—the first year's growth from Riga seed (one year from the barrel), which is considered quite equal to the parent. No manure is used in Ireland, but in Belgium and France, rape cake dissolved in urine is considered very useful. The seed is sown broadcast, and the soil is afterwards rolled. When the plant is a few inches high, weeds are carefully removed, and no further attention is necessary until the season of pulling. Flax is not cut with the scythe or sickle, but is pulled up by the roots. About the middle of August it is generally ready for pulling, in the British Islands, but in Belgium and France, it is in a fit state 2 to 3 weeks earlier.

The after treatment varies in different countries. In Russia, part of Belgium and Holland, and in France, the plant after being pulled, is dried in the sun, being set up on the root end in two thin rows, the top interlacing in the form of the letter V inverted. The sun and air soon thoroughly dry the stems and they are then made into sheaves, and the seed afterwards beaten off. The stems are steeped subsequently. Another mode, in general use in Ireland and in part of Flanders, is to steep the green stems immediately after they are pulled. In Flanders, the seed is invariably separated from the stems before the latter are immersed in water. In Ireland, although this is practised to some extent, yet the great bulk of the flax crop is put in the water at once, with the seed capsules attached, and consequently there is a very considerable annual loss to the country, by this waste of a most valuable product of the plant. In the Walloon country of Belgium, in its eastern provinces, and in the greater part of Germany, *dew-retting* is practised. That is, in place of immersing the stems in water, they are spread thinly on short grass, and the action of the dews and rains ultimately effect what immersion in a running stream or pool accomplishes in a much shorter time, namely, the decomposition of the gum which binds the fibres to the stem and to each other. Fibre obtained by this method is, however, of very inferior quality and colour.

If the fibre of flax be separated from the stem, without the decomposition of this matter, it is found to be loaded with impurities, which are got rid of afterwards in the wet-spinning, the boiling of the yarn, the subjection of the woven fabric to the action of an alkaline lye, and the action of the atmosphere.—of rains and of alternate dippings in water, acidulated with sulphuric acid, and of a solution of chloride of lime, which are all required to perfect the bleaching. The great object, therefore, is to obtain the fibre as nearly free from all foreign substances as possible, and, consequently, the mechanical separation of it from the woody pith of the stem is not to be recommended.

At various periods attempts have been made to prepare flax fibre without steeping. Weak acids, solutions of caustic potash, and of soda, soap, lye, and lime, have all been tried, but have all been found objectionable. In 1815 Mr. Lee brought before "the trustees of the linen and hempen manufactures of Ireland" his system of separating the fibre without steeping. He alleged that a large yield was thus obtained, that the colouring matter could afterwards be discharged by the most simple means, and that the fibre possessed greater strength. But it was found that the system was practically worthless. In 1816, Mr. Pollard, of Manchester, brought forward a plan of the same nature, and proposed to make an article from flax, which could be spun on cotton machinery. This also fell to the ground. In France and Belgium, at different periods, similar projects were found equally unpracticable. In 1820, and again in 1837, Mr. Doulan revived the same, but the same fatal objections prevented the success of the system. The fibre was loaded with impurities, and the apparently larger yield over steeped fibre, consisted solely of these very impurities, which had to be got rid of in the after processes of manufacture. At the same time it must be recognised that the "dry separated" fibre can be rendered useful for one class of manufactures, viz., those where no bleaching is necessary, and its great strength is here an object. For ropes, rick-covers, tarpaulins, railway-wagon covers, &c., where pitch or tar are used, and prevent the decomposing action of moisture and of atmospheric changes, this mode of obtaining flax fibre is highly useful.

The immersion of the flax stems in water, either as pulled full of sap, or after

drying, appears, as yet, to be the best mode of effecting the decomposition of the gum, and obtaining the fibre pure, or nearly so. The water most suitable for this purpose is that obtained from surface drainage, springs generally holding more or less of mineral matters in solution. Spring-water from a calcareous soil is peculiarly unsuitable, the carbonate of lime which it contains being adverse to the putrefactive fermentation of the vegetable extractive. In Russia, much of the flax grown is steeped in lakes. In Holland, it is always steeped in pools filled with the surface drainage. In France and Belgium, it is either steeped in pools or rivers. In England and Ireland, generally in pools, though occasionally in rivers. The most celebrated steep-water in the world is the river Iys, which rises in the north of France, and flows through the west of Belgium, joining the Escaut at Ghent. Although the water of this stream has been analysed, chemists have not been able to discover why it should be so peculiarly favourable to the steeping of flax. All along its course flax is steeped. The trade is in the hands of factors, who purchase the dried stems from the growers, and undertake all the after processes, selling the fibre to merchants when it has been prepared for sale. The apparatus in use consists of wooden crates, 12 feet long, 8 wide, and 3 deep. The sheaves of flax-straw are placed erect in the crates, and the root ends of one are tied to the top ends of another, to secure uniformity of packing. The crate, when filled, is carried into the river, and anchored there, the upper part being sunk by the weight of stones, 6 inches underneath the surface. The period of steeping begins in May, and ends about September. The previous year's crop is thus steeped, having lain over in the state of dried straw during the winter. All the flax thus treated produces fibre of a yellowish white colour, very soft and lustrous, with very finely divided filaments, and strong. From it almost exclusively is made cambric, the finest shirtings, and damask table-linen. It is a strange fact that flax straw is brought to the Iys, from a great distance, and even from Holland, as no other water has yet been found to give such good fibre.

In 1847 a new system of steeping was introduced in Ireland, by Mr. Schenck, of New York. It had been successfully tried in America on hemp, and the inventor crossed the Atlantic to try its efficacy on flax. His plan consisted in hastening the putrefactive fermentation of the vegetable extractive by artificially raising the temperature of the water to 90° Fahrenheit. By this means instead of an uncertain period of seven to twenty-one days being required for the steep, according to the state of the weather and the temperature of the atmosphere, the flax was retted uniformly in sixty hours. The flax straw, after the separation of the seed, is placed in wooden or brick vats, and the heat is communicated by forcing steam into a coil of iron or leaden pipes, placed under a false bottom perforated with holes.

The annexed plan (*fig. 795*) of a retting on Schenck's system, capable of consuming annually the produce of 400 acres of flax, and employing, in all the operations of seeding, steeping, drying, and scutching, 30 men and 55 girls and boys, or an aggregate of 85 persons, will give an idea of the arrangements. The seedling-house requires to be of large size, as flax straw is a bulky article. It is on the ground floor, for the convenience of carting in the flax. The loft above it is used for cleaning and storing the seed. The vat and spreading-rooms are in a building of one story only, built with a vaulted roof resting on pillars. That part of the roof which is over the vats has lower windows to aid the escape of the vapours from the vats. The drying sheds at the top of the plan are on an open space, well exposed to the wind, and fifty or sixty feet apart. The hot air rooms or desiccating house are fire-proof, each room capable of containing the flax turned out in one day's work. The scutch mill, with engine and boiler-house, complete the plan.

The advantages of this system were so manifest that it was speedily adopted in many parts of the United Kingdom and of the Continent. It was found, however, to have some defects. The small quantity of water soon became thoroughly saturated with the products of decomposition, and the fibre of the flax, when dried, was, consequently, found loaded with a yellow powder, offensive to the smell, causing inconvenience in the preparing and spinning, and worse still, acting prejudicially on the quality of the fibre itself, rendering it harsh and dry.

To obviate these defects, Mr. Pownall, of London, conceived the idea of pressing the flax straw, immediately when taken out of the steep, between a pair of smooth cast-iron cylinders, while, at the same time, a stream of water played upon the rollers. By these means the foul water of the vat is pressed out of the flax stems, which are flattened and bruised, thus tending to aid the separation of the bundles of fibres into minute filaments, while the stream of water effectually washed away all remaining impurities.

It has recently been found that better fibre can be obtained by reducing the temperature and extending the time of steeping. The most perfect adaptation of Schenck's system is at the rettery of M. Auguste Scrive, near Lille, and *fig. 796* is a repre-

sentation of it. Tanks of wood or stone are used, each to contain two and a half tons of flax straw. The straw is classified according to quality and length before being packed

795

CONVEY

in the tank. It is put in erect, the root ends resting on the perforated false bottom, and slightly pruned together, but not so much as to prevent a free circulation of water,

796

Ground Plan.

Top of Tank.

Side of Tank.

and a free exit for the gases generated by the fermentation. The tank being filled with water, the whole is secured at the tops of the sheaves by narrow strips of wood

four inches thick *a*, catching the tops on the whole length of each row of bundles. These strips of wood are kept firm by cross iron holders *b*, secured by iron bars *c*, fastened in pieces of wood *d*, worked into the side walls of the tank, leaving a surface of four inches deep of water over the top of the flax. When the tank has been filled with cold water through the wooden shoot *e*, the whole is rapidly heated to 78° Fahrenheit, by means of steam pipes coiled under the false bottom. A second open shoot *f*, carries heated water at 90° to discharge on the surface, besides two closed pipes *g g*, one of which brings hot water of the same temperature, and the other cold water. When fermentation sets in, which is ordinarily in eight hours, the pipe as well as the shoot of water at 90°, is set at play. The first to create a continual current of fresh water through the mass of flax, clearing off the products of decomposition, and bringing them to the surface; the second to drive this foul water to the openings *h h*, where it is discharged by the overflow. The two pipes with heated and cold water going to the bottom of the tank, as well as the two shoots containing cold and hot water, to go to the surface, are also made use of to equalise the temperature during the whole operation, which is ascertained by the use of a thermometer in the square wooden box *i i*. The steeping of coarse straw requires 36 to 48 hours, medium qualities 50 to 60 hours, and the finer descriptions 60 to 72 hours. The "wet rolling" between cylinders after the steep is accompanied by a shower of water at 78°, not on the flax but on the top of the cylinders. This removes the remaining impurities, and prepares the straw for being easily dried. The heated water may be obtained from the waste water of a spinning-mill, or from a condensing steam-engine.

Flax steeped by Schenck's system is dried in various ways. Some retters have drying houses with heated air, others set up the flax loosely on the root end, in the field, or spread it thinly on the grass, while others, again, clasp it between two slender pieces of wood about a yard in length, and hang these up in a building open at the sides, so that a current of atmospheric air is constantly passing through.

In 1853 another mode of retting flax was introduced by Mr. Watt, of Glasgow. Instead of immersing the stems in water, he subjected them to the action of steam. Square iron chambers were employed, in which the flax straw was packed. The door by which it was introduced was then fastened by bolts or nuts, and steam was then driven in. The steam penetrated the stems of the flax, and being partially condensed on the top and sides of the iron chamber, a constant drip of water, lukewarm, fell upon the flax. In twelve to fourteen hours the stems were removed, and, after being dried,

797

the fibre readily separated from the woody core, the water remaining in the iron chamber being of a dark brown colour, without offensive odour. The fibre obtained by

this method was of a greyish colour, and was at first well thought of by manufacturers ; but, in the end, on more extended trials it was found to possess several defects, and Watt's system is not now carried out.

Another system of treating flax was introduced by M. Clauseen, a Belgian, and for some time it attracted much attention. He separated the fibre from the stem without steeping, and then, by the employment of acids and alkalies, he got rid of the vegetable extractive and other impurities, and produced a fibrous mass strongly resembling cotton. He professed to make an article capable of being spun with cotton or wool. The higher value of flax fibre, however, was a great obstacle, and at present the only use made of his process is to convert scotching tow — the refuse flax fibre — into an article to be spun with wool, and even this is practised to but a very small extent.

Messrs. Barton and Pyle's patent (*fig. 797*) is a modification of the hot water steep. By this process the flax straw, after the seed is removed, is passed through a machine composed of plain and crimping rollers, by the combined action of which the woolly part is rendered easily separable from the fibre. The latter is then placed in a vat, holding about a ton, which is subsequently filled with cold water. This vat has a perforated false bottom, under which steam, with a pressure of 50 lbs. to an inch, is in-

798

troduced and disseminated by perforated tubes. Another tube conveys into the vat a cold mixture of fuller's earth in water. The introduction of the mixture and the steam

is continued until the liquid in the vat reaches 80° Fahrenheit. The flax remains in it at this temperature for thirty hours, when the surface of the liquid is covered with a saponaceous froth. Then an apparatus of cross bars of wood, closely fitting into the interior of the vat, and pressed by two powerful screws, expresses the impurities from the fibre. The supply of the fuller's earth is stopped, and cold water is alone supplied with the steam, so regulated that the temperature is by degrees raised to 150° , the pressure being continued until the water appears free from impurities. The water is then withdrawn from the vat through a valve in the bottom, and a pressure equal to 200 tons is applied to the mass of the flax. It remains under this pressure for four hours, when it is half dry. It is then taken out and dried in sheds open at the sides to the air. The fibre produced by Mr. Pye's method appears of good quality and strong, but the system has not as yet been carried out on a sufficiently large scale to admit of a decided opinion on its merits.

The same may be said of the plan of M. Terwagne, of Lille, who employs hot water at a temperature of 15° to 17° centigrade, 60° Fahr., in which chalk and charcoal have been placed. His process requires seventy two hours on the average, and he employs brick tanks. The water is, as in all the preceding cases, heated by steam.

Before leaving the subject of steeping, reference may be made to a process patented by Mr. F. M. Jennings, of Cork, by means of which coarse flax fibre is rendered capable of being subdivided into minute filaments, or, in other words, made fine. While the fibre of cotton is incapable of subdivision, that of flax, as viewed through the microscope, is seen to consist of a bundle of extremely delicate filaments adhering together, so that fine and coarse flax are really relative terms. Mr. Jennings throws down upon the flax fibre, as it appears in commerce, a small quantity of oil, say half an ounce to the pound of fibre. He effects this by holding the fibre in an alkaline soap lye, washing with water, and then boiling in water slightly acidulated with pyroligneous acid, which decomposes the soap and leaves its fatty constituent on the fibre. It is afterwards washed once more, and is then found to be soft and silky, and the coarse fibres capable of being readily separated on the hackle, while the strength is not apparently reduced. There is also a greater facility in the bleaching of the linen made from flax fibre so treated, and less loss in weight in the bleaching process.

While some of the inventions referred to for hastening and equalising the time of steeping are being carried out to a considerable extent, and promise well, when brought to a greater degree of perfection by experience in practical working, to be yet more largely employed, the great mass of the flax grown throughout the globe is steeped in pools, rivers, or lakes. It will, therefore, be most advisable to follow the processes, as practised by the growers or factors.

When the flax has been sufficiently retted, i. e. when on taking a few stalks out of the water the fibre can be readily separated by the fingers along its entire length from the woody interior, it is removed from the water, and placed to drain on the banks of the pool or river. It is then taken to a closely shorn grass-field or old pasture land, and spread thinly and evenly on the ground. In Flanders, however, the system of drying is somewhat different. Instead of being spread flat on the ground, the sheaves are divided into four portions, and these are set upright in *capelles*, i. e. the butt ends are spread widely out in a circle on the ground, and the tops are kept close together. By this means the sun and air soon dry the flax. When thoroughly dried it is tied up in sheaves, and after remaining a few days in the usual form of a grain stack, it is cickled. In this state it may remain for years without the fibre being deteriorated.

The next process is termed *scutching* (French, *trilage*), and is intended to separate the fibre from the woody matter of the stem, and thus to make it fit for the spinner. The first part of this process is to bruise the stems thoroughly, so that while the fibre, from its tenacity, is intact, the brittle woody part is flattened and broken in such a manner as to admit of its easily being beaten off by the action of the scutch-blade or scutch-mill. In most countries the bruising is done by hand. In Flanders and France the flax straw is first laid flat on the ground, the sheaf being untied and spread thinly, and the workman, placing his foot upon it, beats it with an instrument called a *mail*, having a curved handle and a heavy square indented mallet, *fig. 799*.

The next part of the process is to give the flax repeated blows in a machine termed a *brood or broyeur*, *fig. 800*. This is generally made of wood, but sometimes of iron, and consists of two rows of grooves *T T*, the upper one moving on a pivot at the socket *S*. A stout pole *P* runs from end to end of the upper row of teeth. The latter are wedge-shaped, $\frac{1}{2}$ inch deep, $1\frac{1}{2}$ inches thick at top, and $3\frac{1}{2}$ inches long from the head *H* to the socket *S*. The head weighs about 8 lbs. and is 10 inches long, and $5\frac{1}{2}$ inches thick. The lower row of teeth consists of four, while the upper is three, fitting into the interstices. The best wood for the machine is that of the apple-tree.

Next comes the scutching proper, still following the Belgian, French, and Dutch method of hand-work. After the flax has been bruised by the *mail*, and crushed by

the *brayre*, it is ready for the scutching process. In Belgium and France the method pursued is by the employment of a wooden stand (fig. 601). A broad plank of

799

600

pine or beech, about 4 feet high, and rather more than a foot broad, about $\frac{7}{8}$ inch thick, is fixed in a wooden sole n. 3 feet from this sole is a cut in the wood of the upright plank, about $1\frac{1}{2}$ to 2 inches wide. This cut serves for the introduction of a handful of the flax straw, bruised as before described, and the workman holding it three-

fourths exposed through the slit, beats it with a tool called the scutch-blade, fig. 602. It is made of walnut wood, and is very tough and flexible. In Ireland the system of scutching by hand is very rude, and prevails chiefly in the western counties. A brake similar to that of Belgium is employed, but instead of the Belgian scutch tool, a rude instrument is employed, generally of ash-wood, in the form of a sword blade.

It must be stated that the system of handscutching is only to be recommended where the quality of the flax fibre is so superior as to render economy in waste of primary importance, or else where the wages of labour are so low, as to render the power of machinery of little consequence, as regards economy. But, where wages are high, and flax of medium or low quality, there is no question that machine-scutching is the most advisable, and the most economical. This has been especially recognised in Ireland, where in 1857, 1037 scutch mills were in operation, when the growers sent their crops to be prepared for market, at a reasonable rate, much less than hand-scutching would have cost. Scutch mills have been introduced with advantage into Russia, Prussia, Austria, Denmark, Holland, Belgium, France, Italy, and Egypt. In Ireland, although in several districts flax is scutched by hand, machine or mill scutching has been for more than half a century in operation. As in the hand-scutching, the operation consists of two processes: first, the bruising of the stems, and secondly, the beating away of the woody parts from the fibre. The original

system of bruising is still very general. It consists of a set of three smooth wooden rollers, one underneath and the two others above it, parallel to each other, and one of them horizontal to the lower roller. The labourer sits opposite the lower roller, and inserts a handful of flax straw between the latter and the upper one, which is horizontal to it. The flax being drawn in and bruised between these, passes up between the two upper rollers, and reappears at the outside. It is again put through, once or twice, according to its thickness, or to its being more or less steeped, and the fibre, consequently, more or less easily freed from the ligneous part. The scutching apparatus consists of a wooden shaft, to which are attached, at intervals, like radii of a circle, short arms, to which are nailed the *stocks*, which are parallelogram shaped blades of hard wood, with the edges partially sharpened. The labourer stands beside an upright wooden plank, very similar to that figured in the description of the Belgian hand-scutching apparatus, and through just such a slit exposes one half of the handful of bruised flax-straw to the action of the stocks, which revolve with rapidity along with the shaft, and strike the flax straw, beating off the ligneous matter, and leaving the fibre clear. When the end exposed to the stocks is cleared, the workman turns the handful and exposes the other end. It is usual to have a set of either two or three men, at as many different stands, and instead of each thoroughly clearing out the handful of flax, he only partially does so; the second then takes it up and finishes it; or, if there be three in the set, he does not quite clean it, but hands it over to the third to do so. In the latter case, the first workman is called the *buffer*, the second the *midler*, and the third the *finisher*. The motive power in these scutch-mills is generally water; in some cases they are wind-mills, and in a few instances they are driven by horses. Latterly, the use of steam-engines has considerably increased, as being more to be depended upon than water, which frequently fails in a dry season.

808

It has been found that the woody waste produced in the scutching, is quite sufficient fuel for the boiler, without its being necessary to purchase coal or peat, and this waste had hitherto been applied to no useful purpose, being with the greatest difficulty decomposable for manure.

The first improvement on this old scutch-mill apparatus was the introduction, by Messrs. MacAdam Brothers, of Belfast, of a machine for bruising the flax straw, prior to steeping, and it has since been extensively employed, with very satisfactory results. It consists of a series of slated rollers, running vertically on each other, the slatings varying in width, the widest set being the first through which the flax straw

passes, and the others diminishing in width, until the finest is the last. While acting strongly on the ligneous matter, at the same time bruising and crimping it, and reducing it almost to powder, it does not injure or disarrange the fibres. One breaking machine of this construction is capable of supplying 12 scutching stands of the ordinary mill. It is attended by two boys, one to feed the flax-straw into the machine, by means of a feeding table, and the other to remove it at the opposite extremity. Three passing through the machine is quite sufficient to prepare the flax straw thoroughly for being scutched. The force required to drive it is one horse-power. *Fig. 803* will best show its construction and mode of action.

It having been found that many disadvantages were inherent in the old scutch-mill, several persons have set themselves to work to supply a machine which would reduce the cost of labour, obviate the necessity of obtaining skilled workmen, and diminish the great waste of fibre, which was but too frequent in the ordinary mill. Among the most successful of these scutching-machines, is an invention of Mr. Mac-Bride, of Armagh, Ireland, *figs. 804, 805*. It consists of a cast-iron frame, at

804

805

each end of which is a compartment, enclosing a double set of beaters, of peculiar construction, which revolve rapidly in a contrary direction, striking alternately on each side of the flax, as it is submitted to their action, and thoroughly removing the woody part, which falls down in dust into a pit or hollow under the machine. In order to carry the flax gradually through the machine, and present it in a proper manner to the beaters, in succession, an endless double rope is introduced, carried in the hollow of a large grooved wheel, in which it is kept tight, by means of tension weights. The flax-straw, made into handfuls, is introduced at *a*, under the double rope, at one end of the machine, and is at once grasped by it firmly, rather above its middle, and carried along slowly, by the movement of the grooved wheel, until it enters, hanging downwards, the compartment *a*, containing the first set of beaters. By the time the flax-straw has been carried through them, all its lower half, which has been exposed to the action of the beaters, is cleaned out, and the rope, passing on a short way farther, arrives at a point where a second grooved wheel is revolving, furnished with ropes in like manner, but arranged at a rather lower level. By a simple arrangement, the flax is here transferred from one set of ropes to the other, the second set grasping it near its lowest end, thus leaving all the uncleared part, or upper half, ready to be scutched. The second wheel moves on, and carries the flax to-

wards the compartment containing the second set of beaters, cleaning all the upper portion of the flax. It then issues out at *n*, cleaned throughout, and is received by a person placed there for that purpose, who makes it up into the usual package for sale, 16 lbs. A constant succession of similar handfuls of flax-straw are thus kept passing through the machine without interruption. *x x* are the beaters, *v v* are two cones, carrying a leather band, which gives the motion to the ropes, or carrying apparatus. By shifting the position of this band towards one end or the other of the cones, the speed of the carrying-ropes may be varied at pleasure, so as to keep the flax a longer or shorter time under the beaters. Some kinds of flax require more scutching than others. *a a* are the driving pulleys, for giving motion to the machine, by means of a band from motive power, which may be steam, water, wind, or horses. Each pair of pulleys drives one set of beaters separately from the other set, and hence, if requisite to drive one set faster than the other, which is sometimes the case when the top end of the flax is hard to clean, this is easily done by using a similar pulley on the machine, or a larger drum on the driving shaft. *h h* are the tension weights and levers for keeping tight the carrying-ropes. *j j* are bearers of wood for carrying the frame of the machine. *k k* are pits underneath the compartments containing the beaters, and are for receiving the woody dust as it falls from the flax-straw. The machine occupies a space of $11\frac{1}{2}$ feet, by 10 feet, but some space is required round it for handling the flax. The height of the machine is $6\frac{1}{2}$ feet. The power required is three-horse.

M. Merrens, of Ghent, Belgium, has invented a scutching-machine, which merits notice. It is portable and cheap, and requires the attendance of only boys or girls, to put the flax-straw in and take the scutched-fibre out. The action is something similar to that of the Irish scotch-mill, but the bruised flax-straw is placed in iron clamps, one end being first cleaned out, and then the clamps opened, the flax-straw reversed, and a second insertion in the machine clears out the other end.

Messrs. Rowan, of Belfast, have very recently introduced a scutching machine, whose action differs from all hitherto in use. The flax-straw is not previously bruised, but is at once fastened in iron clamps, which are placed in a slide, the action of the machine carrying them on along one side, while two parallel bars of iron, toothed, comb the straw and separate the woody part from the fibre. The first portion of these bars have coarse teeth, and the teeth become closer by degrees up to the end of the slide. There a workman or boy takes out the clamps, unscrews the nuts fastening them, and reverses the position of the straw, so that the portion not previously subjected to the action of the machine is now presented to it, while that already cleaned out is untouched. The machine is double, i. e. has two sides of combs, each capable of containing twelve of the clamps, and each cleaning out one end of the flax-straw. Hence, after the workman or boy has unclamped the half-cleaned straw, turned it upside down, and presented the uncleaned end to the other side of the machine, the same action of combing, already described, clears out that end thoroughly, and by the time the progressive movement of the mechanism brings the slide to the extreme end, the flax fibre appears free from woody refuse, and in a fit state for market. It is then unclamped and made up into bundles.

There have been a great number of other scutching machines invented, but it is not necessary to particularise them.

In the operation of scutching, however carefully it may be done by hand or by machine, there occurs more or less waste, i. e. the beating of the flax-straw, in order to separate the marketable fibre from the useless wood, causes a portion of the former to be torn off in short filaments mingled with the wood, and this torn fibre is very much less valuable than the long filaments when finally cleared out. In general, it will not average more than an eighth or a tenth of the value of the long fibre. It is termed *scutching-tow* or *cudda*, and when properly cleaned is dry-spun for yarns employed in making coarse sackings, tarpaulins, &c. Being very much mixed with the woody-matter of the flax-stems, it is necessary to get rid of the latter before the scutching-tow can be spun into yarn. To accomplish this, shaking by hand is the first process, and subsequently the stuff is put into a woody machine termed a "devil," in which, by a mechanism something resembling the shakers in a threshing machine, the woody particles and dust are got rid of. The tow is sorted into different quantities, and, in some cases, it is *hackled* before being sold. In France and Belgium, it is chiefly retained at home, spun by hand, and woven into such fabrics as coats, trousers and shirts, for the labouring classes, aprons, table-covers, &c. &c. What is produced in Russia, is partly used for similar purposes among the serfs, but the great mass is exported, Great Britain and Ireland being the chief mart, and Dundee especially.

The great aim in all the different methods of scutching, has been to obtain the largest possible yield of long fibre from the flax-straw, and to waste as little as pos-

sible in scutching-tow. The French and Flemish system of hand-scutching is most successful in this respect, but as the quality of fibre there produced is very much finer, and consequently more valuable than all others, the additional expense of hand-labour is compensated by the larger yield of long fibre; whereas, in Ireland, the fibre being generally coarser and less valuable, occupying an intermediate place between the Flemish and Russian, the cheapness of mill-scutching turns the scale, and, except in remote districts, it is now universal. In Egypt, until some fifteen years ago, the method of scutching was of the most primitive form. The fellahs, after steeping their flax in the Nile, and drying it on the banks, proceeded to clean out the fibre, by first beating the straw between two flat stones, and then striking it against a wooden post. Mehemet Ali and his successors, however, introduced Irish scutch mills, driven by steam-power, and since then a marked improvement has taken place in the state in which Egyptian flax has been brought to market. It may be interesting to note here, that in the early period of Egyptian civilisation, the dwellers by the Nile were able to manufacture cambrics of a finer texture than the most finished modern mechanism can produce,—as is evidenced by the cerueloths wrapping the mummies, and that from a fibre so coarse in comparison to European flax, that while the latter may be spun by machinery to 300 or 400 leas, and by hand to 1200 leas, the former cannot be put higher than 40 to 50 leas, and rarely even to that.

In the scutching operation, three several matters are obtained from the flax stems. The first is the fibre, which is the primary object, and which is the really valuable portion, that known as “flax” in commerce. The second is the woody refuse of the stems, hitherto applied to no other use than as fuel, or occasionally in Ireland as a covering for cuttings of potatoes, when planted, to protect them from frost. Mr. Pye, of Ipswich, however, proposes to make it available as an auxiliary food for cattle, having the authority of Professor Way that a sample analysed by him yielded 7.02 per cent. of oil and fatty matter; 7.93 of albuminous matter (containing 1.25 nitrogen), and 26.29 starch, gum, sugar, &c. He (Mr. Pye) recommended its use for feeding live stock, in conjunction with ground oats or other farinaceous food. Professor Hodge, nevertheless, in analysing another sample of this ground ligneous matter, gave quite a different result, his estimate of the nutritive constituents being as follows:—nitrogenised flesh-forming matters, 2.23 per cent; oil and fatty matters, 2.91; gum and soluble matters, 14.66; and he compared this with the average results of seven analyses of oil cake, giving nitrogenised matters, 23.47; fatty matters, 12.90; gum and other soluble matters, 39.01.

The third portion separated by the scutching process is termed “scutching-tow,” in Ireland; in Russia and Prussia, “*codilla*,” in France and Belgium, “*étoupe de teillage*,” described above. These branches of the trade consume annually many thousand tons, imported chiefly into Scotland, from Russia and Prussia. In France, Belgium, and Holland, the codilla or scutching tow is chiefly retained by the growers or factors at home, for a domestic manufacture of similar goods, and of coarse blouses and trousers. It has also been employed for conversion, by Claussen’s process, into a finely divided mass of fibres, capable of being mixed with wool and spun along with it into yarn, the fabric made from this yarn being chiefly hose.

Before proceeding to treat of the processes to which flax fibre is subjected subsequent to scutching, it may be well to glance at the uses to which the seed is applied. This valuable product of the plant furnishes two articles of much utility, and of very extensive use,—the oil and the cake. When the seed has been separated, dried and threshed out, it is either sold again for sowing or for conversion into cake and oil. Of course the former purpose only consumes a small proportion of the seed produced throughout the world, and in many countries it is not of a quality suitable to the chief flax-growing localities. Thus, while northern Russia, Germany, the Low Countries, and France either export seed for sowing, or consume their own produce to a considerable extent for this purpose; the southern provinces of Russia, the states along the Mediterranean, Egypt, Turkey, Greece, and the East Indies, while large exporters of seed for crushing, cannot sell any for sowing. The supply of the seed crushers of the United Kingdom is more largely obtained from Russia and Hindoostan than from any other countries. The entire annual import of seed into the British Islands averages 600,000 to 800,000 quarters, value between a million and a half and two millions sterling. The conversion of flax seed into oil and cake is carried out by different methods. In France, Belgium, Holland, and the north of Europe generally, where a large quantity is crushed, the apparatus employed is very simple and yet very effective. Lille, in France, Courtrai and Ghent, in Belgium, Neuss, in Prussia, and the province of Holstein are the great seats of this manufacture. See LIMESEED.

The seed is pounded in a kind of wooden mortars, cut out of solid timber, and at the bottom lined with thick copper. By means of a revolving shaft, furnished with projecting notches of wood, beams of oak 20 feet long, the ends shod with

channelled iron, are alternately raised up and let fall into the mortars, where, in a short time, they convert the seed into a pulpy mass. When sufficiently pounded, this is then removed and put into woollen bags, which are then wrapped up in a leathern case lined with a hard twisted web of horse-hair, covering both sides and ends, but open at the edges. These are then ready to be pressed, and for this purpose are packed perpendicularly in an iron receptacle, narrow at the bottom, and widening towards the top. Packings of metal are then put in, and in the centre of the bags is inserted a beech wedge. A beam similar to that employed in pounding the seed is then set in motion, and at each descending stroke it drives the wedge in tighter, thus squeezing the bags of seed against the iron sides of the press. When the wedge has been driven home, another is introduced and battered by the beam, until it will drive no farther. At the bottom of the press are holes through which the oil thus pressed out of the seed runs into a receptacle beneath. In order to loosen the wedges and admit of the bags being removed from the press, a wedge of a different form, wide at bottom and narrow at top, and already a suture in the press, but raised up and fastened by a rope during the driving of the other wedges, is released from the rope, and another beam drives it home, thus partially starting the differently constructed wedges and loosening the mass. The bags with the pressed seed are then taken out, and the latter, having lost the greater part of its oil while subjected to so considerable a pressure is found in a thin hardish cake, taking the form of the leathern case, and off it the woollen bag is readily stripped by the workman's hands. The oil obtained by this process is the purest and most limpid; but another process has to be performed before the seed yields all that the pressure is capable of extracting from it. The cakes, therefore, when taken out of the bags, are broken up and put into the mortar, where the same pounding operation takes place. When again brought into a comminuted state, the powder is put into a circular iron pan or kettle, under which is a fire, and slowly roasted in it, being kept from burning by means of an iron arm which is moved round inside by the machinery, constantly turning the ground seed. When sufficiently warmed by this operation, during which it is made to part more freely with the oil, the mass is again filled in bags and pressed as before, after which they are finally, the bags being stripped off, pared at the edges, put in a rack to dry, and stored for sale. The oil thus obtained is darker in colour than that by the cold process, and contains more mucilaginous matter. Many foreign oil-millers, however, only employ the hot plan, believing that they have thus a larger yield than when the cold pressure is first used. See LINSEED OIL.

In England, the cold pressure is little, if at all, practised, the seed being almost invariably warmed before pressure. The system of crushing, formerly universal here, had some resemblance to the Flemish method above detailed, the chief difference being in the mode of preparing the seed, prior to its being put in the press. The first process is to pass slowly from a hopper, the whole seeds into a pair of smooth or fluted metal rollers, which, in turning on each other, crack the seeds. Heavy edged stones then grind them into a meal, a little water being added during the operation, which facilitates the comminution of the seed. The meal is then put in the *Arrels* before described, and while heated and stirred in it, the water mixed with it is evaporated. It is then bagged and put in the press, where the *stampers*, falling on the wedges, effect the desired results. The most recent improvement in the mode of pressure, and one now largely adopted, is the hydraulic press, and it is generally considered that a larger yield of oil can be obtained by its use than by the wedge and stamper-down method. Blundell's (of Hull) patent is that most generally employed, and Messrs. Simmellon of that place are distinguished as makers of it, having introduced themselves some modifications and improvements. The oil obtained from flax-seeds or linseed, as it is generally termed, is of very extensive use in the arts, and is the chief vehicle for paints. To suit it for this purpose, and to make it dry quickly, it is mostly boiled in an iron pan, and during the operation a quantity of litharge is dissolved in it. The cake is a very favourite article with stock-feeders, being combined, as containing much nutriment in small bulk, with roots or other vegetable food, having large bulk with small nutriment. So extensively is it consumed in Great Britain, that besides the very large quantity made from imported seed, fully 80,000 tons of foreign cake are annually imported. On the continent inferior qualities of cake are ground to a coarse powder, and either applied to the soil as a top-dressing, or steeped in a liquid manure, and the mass spread out on the land in that state.

Scutched flax fibre appears in the market made up in different ways. Russian is in large bales or bundles; Dutch and Flemish in bales weighing 2 cwt., the fibre being tied in "heads," each of which is about as much as the hand will grasp. Irish is made up in bundles termed "stones," the weight of which is either 16½ lbs. or 24½ lbs. In this state it is piled in the stores of the spinner, care being taken that it be placed

on a ground-floor, flagged or tiled, and not in a boarded loft, as the humid atmosphere of the former is conducive to the preservation of the suppleness and "spinning quality" of the fibre, whereas it deteriorates considerably when exposed to a drier air.

The first operation which it undergoes in the spinning factory is *hackling*.

This process is required to comb and straighten the fibres, to get rid of any knots, and to lessen and equalise the size of the filaments. The action of the hackles necessarily divides the scutched flax into two portions, the long, straight ones, which remain after the flax has passed through the operation, being termed "line," and the woolly or cottony looking mass which remains, being designated "tow." Both of these are spun, but the line produces the finer and better qualities of yarn, and is consequently much more valuable than the tow. The great object, therefore, is to obtain the largest possible quantity of the former from a given weight of scutched flax, and the yield of line varies considerably according to the nature of the season. Spinners, therefore, are anxious as each new crop of flax is brought to a marketable state, to test the yield of line, so as to guide them in their purchases. They are thus enabled to ascertain more clearly the suitability of the samples for "warp" or "weft" yarns, and for thread-twisting. Warp-yarns being those which constitute the long threads of a linen fabric, require to be harder and stronger than weft-yarns, which form the cross or short threads.

The yield of line, as well as the general economy of the operation, is, of course, greatly dependent on the nature of the hackling-machine employed, and great scope for care and ingenuity is thus given to the machine makers. A great number of hackling-machines have, from time to time, been brought out, employed in the factories, and subsequently abandoned, when others, having greater merit, have been invented.

In the early period of the linen manufacture, when spinning was done exclusively by hand, no hackling-machines were employed. The process was exclusively effected by hand-hackles. Even after the introduction of machine-spinning, they were, for a long period, the sole means of hackling. Of late years, the machine has been more and more brought into use, and although hand-hackling still exists to a considerable extent, the other method is by far the more extensively employed.

For hand-hackling, the tools used consist of a surface studded more or less thickly with metal points, called *hackle-teeth*, through which teeth the flax is drawn by the operator.

The hackles ordinarily used for hand-hackling in this country are in the form of rectangular parallelograms, presenting a line of 7 inches towards the worker, and 4 to 5 inches deep. The first tool employed is called the "ruffer," the pins of which are about $\frac{1}{2}$ inch square at their base, and 7 inches long, and brought to a fine point; the second is the "common 8," which is always used after the "ruffer"; then the "fine 8," the "10," the "12," the "18." The pins of all these tools are similarly placed as those of the ruffer, but are somewhat shorter in length, and are more slender as the tools increase in fineness. In all these tools the pins are held in wooden blocks of about $\frac{1}{2}$ inch in thickness and covered with sheet tin. This sheet tin, through which the pins are driven, helps to support them and prevent the wood from splitting. These tin covered stocks are only of a size necessary for the extent of pins employed, and are themselves screwed to other larger pieces of board, a little broader and some inches longer than themselves, and by which they are ultimately fixed to the hackler's bench, inclining somewhat backward with their points from the worker, and a sloping board behind to prevent the flax entering too much in the pins, thus:

Fig. 806, end view of a hackle; fig. 807, front view of hackle; fig. 808, hackle, &c., fixed up for working. a pins; b tin covered stock; c foundation board; d beam of table or bench; e back board; f table to receive the tow, &c.; g hand of workman. Such is

the form of hackle used in England, and also the manner they are, of whatever description, fixed for work.

The operation of manual hackling is simple in principle, although it requires much experience to acquire dexterity.

The workman having first divided the flax into handfuls or stricks, of which there are 300 to 400 to the cwt., proceeds to grasp one as flatly spread as possible between his forefinger and thumb, by about its middle, and wind the top end round his hand in order the better to prevent the slipping of the fibres; he then begins by a circular awing of his arm to lash the root end into the hackle, taking care to commence as near the extremity as possible, now and then collecting the fibres by holding his left hand in front of the tool, turning the stick from time to time. He thus gradually works up as near as possible to his right hand, when he seizes the ruffled part of the stick and holds it in the same manner as at first, and proceeds by a similar treatment to "ruff" the top end; when this is finished the "ruffed" work is taken to the tool called a "common 8," the pins of which are much closer placed than those of the ruffer, and are only four or five inches long. This "8" is always used after the ruffer, but from it the work can be taken to any of the finer tools, viz. 8, 10, 12, and sometimes 18. It is usual and better to dress both ends over each tool before taking the work to the next. The pins of all these tools are 4 inches long, in order, as was supposed, to have sufficient spring. The flax is not lashed into them as into the ruffers, neither are the ends required to be wound round the hand. But the root end of the flax is always the one to be first worked, and the hackling begun at nearly the extremity of the stick, which on being drawn through the hackle is received by the left hand of the workman, and by it carried back and laid upon the back board and over the point of the pins, for the angle of inclination of the hackles and a slight lowering of the right hand causes it to enter sufficiently on being drawn forward. As it is impossible to ruff or dress entirely up to the hand, when the hold is changed in either operation, there must of necessity be left a certain space to be re-passed through the tools; this is called the "shift," but the less length that is required for this purpose the better for the yield of line. The numerous long fibres that slip from the strick in ruffing must be collected and drawn from the mass of tow attached to them, when they can be relaid in the strick, or kept to be dressed separately under the name of "shorts," and from time to time the short fibres or tow sticking to the teeth of the finer tools are removed. Whenever one-half of the length of the strake of flax is hackled, it is turned round to hackle the other half. This process repeated upon each hackle. From 100 pounds of well-cleaned flax, about 45 or 50 pounds of hackled line may be obtained by the hand labour of 12 hours; the rest being tow, with a small waste in woody particles of dust. The process is continued, till by careful handling little more tow is formed.

To aid the hackle in splitting the filaments, three methods have been had recourse to; beating, brushing, and boiling with soap-water, or an alkaline lye.

Beating flax either after it is completely hackled, or between the first and second hackling, is practised in Bohemia and Sillesia. Each hackled tress of flax is folded in the middle, twisted once round, its ends being wound about with flaxen threads, and this head, as it is called, is then beaten by a wooden mallet upon a block and repeatedly turned round till it has become hot. It is next loosened out, and rubbed well between the hands. The brushing is no less a very proper operation for parting the flax into fine filaments, softening and strengthening it without risk of tearing the fibres. This process requires in tools, merely a stiff brush made of swine's bristles, and a smooth board, 3 feet long and 1 foot broad, in which a wooden pin is made fast. The end of the flax is twisted two or three times round this pin to hold it, and then brushed through its whole length. Well hackled flax suffers no loss in this operation; unhackled, only a little tow; which is of no consequence, as the waste is thereby diminished in the following process. A cylindrical brush turned by machinery might be employed here to advantage. These have been tried in establishments for machine spinning, but not found advantageous.

The object of all hackling being to produce a good yield of line with tow of good quality, that is to say, free from broken, unsplit fibres, lumps, and knots; the care and attention necessary to do this, with the expense and uncertain result of the individual skill of workmen, urged manufacturers to attempt the establishment of machines for effecting the process. Therefore many contrivances were invented with this view, but it was long doubted whether any of them made such good work, with so little loss, as hand labour. In hackling by the hand it was supposed that the operator would feel at once the degree of resistance, and be able to accommodate the traction to it, or throw the flax more or less deeply among the teeth, according to circumstances, and draw it with suitable force and velocity. For a considerable period these ideas, or rather prejudices, as they may now be called, seemed to be confirmed; for the earlier

attempts to supersede hand hackling, like those in many other undertakings, though partially favourable, were, on the whole, rather discouraging. In attaining one point desired another was lost, for too much still depended on the care and attention, if not on the actual skill, of the persons attending the machines.

It will be desirable, therefore, to give particulars respecting some of those which have been from time to time invented, although they are not now in use, as a lesson for preventing the repetition of things already known, as well as to illustrate the steps successively taken. The first machine invented, or, at least, published, was called the "Peter," and was intended to illustrate, as clearly as possible, the movements of the hand hackler. The flax was first divided into small convenient portions or handfuls, about 4 oz. each, called "stricks," which, before being taken to the machine, were slightly straightened and dressed over the ordinary hand "rounger." Each of these was then placed between a pair of short iron bars, called a "holder," one of which had an indentation in the middle, and the other a corresponding projection. Thus, when tightened together by screws $4\frac{1}{2}$ inches apart (such length being equal to a man's grasp), the stick of flax was firmly held while exposed to the action of the hackles. The holder was then suspended from movable levers over a truncated rectangular cylinder, upon the angles of which were fixed, at a certain angle, hackles similar to those used in the manual operation. The levers supporting the holders received from a crank a short up and down motion, so timed in their oscillations as to strike the holder nearly against the points of the pins at the time they were passing under, coming thus as nearly as possible to the effect of a man striking in and drawing through the hackles, except that the flax remained nearly stationary, and the hackle was drawn through it by the rotation of the cylinder, whereas in the hand process the hackle was stationary, and the flax drawn through it by the operator. Each machine carried two holders. The tow made and collected from the holders was seized and taken off by boys stationed for that purpose, while another, at the ringing of a bell, took out and changed the sides of the stricks to be presented to the action of the hackles, and subsequently withdrew them from the first machine to another similar but with finer hackles, and thus continued until the root end—always the first operated on—was dressed to the desired degree of fineness, when they would be taken to a table where another set of boys, previously to removing the first holder, put on a second to the already hackled part, leaving about $2\frac{1}{2}$ to 3 inches to be re-hackled. This operation is termed "shifting," and the space left, "the shift;" it is thus performed and remains so called at the present day, the only change being that in the holder now in use one screw is used for two stricks instead of two screws for one stick.

Fig. 809 will more clearly show the construction of this machine. A, square truncated cylinder carrying the hackles; B, oscillating arm or lever for supporting the holder; C C C, framing; D, crank and shaft; E, connecting rod from crank to oscillating arm; F F F F, hackles; G G G G, back board; H, holder. The first motion was given by pulleys on the shaft D, which revolved 4 times to 1 of the hackle cylinder, by the intervention of suitable wheels. The worm and wheels for the bell motion were attached in the usual manner to the shaft of the cylinder.

Machines of this construction continued in rather limited use without any change or competition till about the year 1825, when a patent was taken for a machine known as the pendulum machine. The flax in the

809

holder being suspended and swung backwards and forwards while the hackle remained fixed, the flax was thus hackled, stroke for stroke, on each of its sides. The boys, as in the last described, snatching off the tow as it was formed, and at certain times, that is at each rise of the pendulum, for it had a rising and falling motion to imitate the hand workers in commencing at the extreme end of the flax, passing the holder from one reeve to another of the pendulous table, so as to arrive at the progressively finer tools when ranged along the machine; but sometimes the different tools were fixed upon the angles of a square cylinder that presented a finer range, the whole length of the machine, by turning up a new angle at each rise of the pendulum, when the labour of the boys was simply to put in the tow and take out from it the flax. The adjoining diagram (Fig. 510), without entering

on any details of a machine that was so little used, will make the theory of its action quite clear.

A, hackle bench, sometimes revolving so as to present different degrees of hackles at its various angles, sometimes stationary with the gradations of hackles upon its length; B B, pendulum arms; C C, equal wheels working into each other; D D, crank arms; E, radial slide-bars to preserve the holder table vertical; U, holder table; F F F F, hackles; G G, back levers; T T, direction in which the holders swing; there were the same wheels, &c., at each end of the machine, and the holder table U reached from one to the other. The wheels, C C, with all attached to them, were made to rise and lower upon the hackles, and the back-levers G to rise when the hackle bench turned.

About the same time another patent was taken out for a machine, where the holders were suspended above one end of a travelling sheet of hackles. This

machine also required hand labour to turn and transfer the sticks, though the tow was caused to fall clear from the hackles by mechanical means. The following sketch (fig. 811) shows the principle upon which this machine works, and though never much employed at the time of its appearance, has subsequently served as a foundation for those that are now in the zenith of their prosperity.

A A (fig. 811), sheet of hackles; B, support for holders; C C, carrier pulleys for the sheet of hackles. Fig. 812, a larger view of the hackle bar G G, in order better to show the faller D D D, in the staples or grooves X X, and fig. 813, at the end of the hackle-bar G G: F F, pins of the hackles, between the rows of which the faller D D D acts to push the tow off the pins. There is a clearing faller D to each hackle, which is kept to the bottom of the hackles at that part of their course where they are in contact with the flax, but at the turn F D fly beyond the points, as shown by the effect of the centrifugal force.

All these machines, possessing great similarity of features in regard to the personal attention required, never came into such general operation as to supersede entirely hand-dressing, either from their own defects or prejudices against their employment. About the year 1830, in consequence of the new mode of spinning

being carried on with considerable energy, it was found advantageous to cut the flax into 2, 3, or more lengths previously to hatching, which rendered it necessary to have machines peculiarly adapted for this new short description of material. This machine, known as the eccentric or circular machine, deserves considerable attention for its own inherent merits, and the extensive utility it has proved to be of in suggesting the principal parts of those by which it has been supplanted. In its original form it was made of a breadth suitable for only one stick, and consisted of a

original form it was made of a breadth suitable for only one stick, and consisted of a

cylinder 3 ft. diameter, upon the whole circumference of which at intervals of 3 or 4 inches were fixed the hackles. As each machine could only carry one description of hackle, it was necessary to employ a series of these machines, called a "class," when the flax required to be dressed over a succession of finer tools, each succeeding machine carrying a finer tool than its predecessor. The hackles were cleared of tow by coming in contact at one part of their revolution with a brush roller, which also revolved in contact with a cylinder covered with card clothing, the points of the pins being in such a direction as to clear the brush from tow, and all of itself to be in its turn cleared by the oscillations of a comb, whence by rollers the tow was brought into a sliver. In order to preserve the continuity in the supply of tow, and maintain the regularity of the sliver produced by it, the holders with the flax were presented to the hackle cylinder in a manner peculiar to this machine, and in endless succession by means of certain circular carriers placed at each end of the hackle cylinder, but eccentric thereto, and at such a distance apart as each should bear one end of the holder as it extended across the cylinder parallel to its axis. Thus, the holders introduced at that part of the circumference of these carriers furthest from the hackles were carried forward, while the flax was in operation, till they were brought almost into contact with the points of the pins, when, by the intervention of a slide, they were withdrawn from

814

the machine, but with one side only of the flax dressed, and that but on one tool; therefore the holder required replacing in the same machine, in order that the second side of the stick should be dressed as was the first. The holders then required to be carried by hand to each succeeding machine of the class.

The preceding figure (814) shows the leading features of these machines: *A*, a hackle cylinder; *n*, *n*, eccentric wheel to carry holders in its recesses *A*, *A*, *A*, *A*; *v*, slide upon which the holders were laid so as to fall into the recesses *A* of wheel *n*; *p*, slide for taking out holders; *r*, brush cylinders with brushes; *a*, cylinder covered with card clothing; *c*, holder come out; *i*, doffing comb. The spurs of the holder carrying wheel was filled with holders, and so maintained in endless succession, and thus each served in some measure to keep the end of its preceding one down into the hackles.

About 1833, a machine was patented consisting of two parallel cylinders, over which the flax was carried, revolving in its progress so as to present the alternate sides of the stick to the hackles, the progressively finer tools being ranged along these cylinders, so that having passed the length of one cylinder one end was completely finished. When the holder was taken out, "shifted," and replaced, it was carried back along the second cylinder, and thus returned to where it commenced, finished. This machine, however, never was carried further than the experimental one for the patent.

Another machine (Wordsworth's) the same year made its appearance, and which for some time enjoyed much celebrity. It consisted of two parallel vertical sheets of hackles running together, and so geared that the hackles of one intersected the intersices of the other. The flax suspended in its holder from a species of trough passed between these two sheets, and was thus hackled simultaneously on each side in

its course through the progressively finer hackles from one end of the machine to the other.

A A (815), hackle sheets, n n, holder trough or slide; c c c, pulleys for carrying

the hackle sheets; D D, brush rollers; E E, rollers covered with card clothing to clear the brushes; F F, doffer combs; n n, holder trough or slide; c c c, pulleys for carrying

It is unnecessary to notice more at length the different machines brought out, employed for a time, and then rejected. Although the hackling and spinning of flax, in the full length as it grows, was what was first practised by hand, the first really successful machine for hackling was what was known as the "circular machine" for hackling "cut line," as it is called, or the long flax fibre broken into several lengths. It had always been known that the top and root ends of the fibre were of very inferior quality to the middle, and of course when all was spun in one length the yarn produced was inferior to what the middles could be spun to, while superior to what the tops and roots would produce. It therefore occurred that in the general qualities of flax the division of the fibre, so as to separate the different portions named, would be advantageous to the spinner. The operation of cutting was performed by a simple machine consisting of a pair of jaws, so constructed that when the flax is introduced between them the different parts, instead of being clearly cut off, are, so to speak, bitten off, leaving ragged ends. This is desirable in order that the ragged ends might interlace in the spreading prior to going through the preparing machines, which precede the spinning operation. The machine for hackling cut line was brought out about thirty years since, and underwent, before it was finally set aside, a considerable number of modifications for the purpose of economising the labour in working it. About the same time the "flat machine" was introduced, which was more particularly intended for hackling long flax. The nature of the operation of these machines was the same, the flax being acted on by different series of hackles fixed in the circumference of a cylinder in the one machine, and on an endless sheet in the other. The curvature of the cylinder was no objection in hackling cut flax, but for acting on long fibres it was necessary to put the hackles on a sheet, for the purpose of getting sufficient length of flat surface. The most successful machines, and which displaced all previous ones, have been modifications of these of different kinds, some of them being simply contrivances for saving manual labour, and giving certainty to the action, and others combining other improvements with this object. Carmichael's patent machine (figs. 816, 817) was, as brought out at first, simply the old flat machine with self-

816

817

acting motions for actuating the holders applied to it. It was afterwards much improved by the adoption of an inclined sheet in imitation of a very successful self-acting modification of the old flat machine which was brought out by Combe, of Belfast, whose machine, at this time, is considered by many to be the best one in use for long line.

The distinguishing feature in these rival machines is, that in Carmichael's the motions are all performed by the descent of ponderous weights, while in the other they are performed by the direct action of the machine.

There are other differences affecting the working of the machines, which are by practical hacklers considered of great importance, and as giving more value to Combe's machine. The most important of these is the facility of adjusting the place where the holders approach the flax, which greatly affects the yield of line.

The same principles of actuating the holders were applied to cylinder machines for hackling cut flax, but as these have been displaced by more recent inventions, it is not necessary further to refer to them. Wordsworth's machine, already figured (815), was of importance, as being the basis of several other valuable machines. Its essential feature was arranging the hackles on two sets of endless sheets placed opposite each other, and driven and connected by wheel-work so as to revolve together, the surfaces being placed so close together, that the hackle pins penetrated the flax from both

sides, and hackled at the same time. The large circle described by the points of the hackles in this machine, which prevented them cutting the flax close to the holders, and other imperfections, led to its abandonment. About sixteen years since, Combe,

of Belfast, designed for the eminent flax-spinning firm of Marshall and Co., of Leeds, a modification of this machine, which since has been known as Ardill and Parker's machine, and has come into extensive use. The principal new feature in this machine was the introduction of cranked wheels for supporting and carrying the hackles, for the purpose of making the points of the hackles describe a small circle, and thus enable them to cut close to the holders. Although successful, this invention did not fully accomplish the object aimed at. About the same time, Marsden's intersecting machine was brought forward, and possessed a great reputation for a length of time. Its success was a good deal owing to the flax hackled by it having an apparent fineness, but this was not found to be of practical value, as the spinning quality was not improved thereby. For this reason it has gone greatly out of use.

The next machine which came into extensive use was Combe's reversing cylinders, *fig. 818*. These machines are constructed in a great variety of forms for different kinds of work, and seem to give very good results. They are simple in their construction, and give little trouble, acting lightly on the flax and making very dry fibres. They are made of all sizes, from 12 to 30 inches in diameter, and with 4, 6, or 8 graduations of hackles, according to the kind of work to be done on them. The flax is hackled on each side, or each graduation of hackles, by reversing the direction of the rotation of cylinders. The tow, or short fibre, is thrown off the hackles by stripper rods, placed between the rows of pins.

The next machine to be named is by the same inventor, and is styled the patent reversing sheet hackling machine. It is far longer, on the same principle as that just described, except that it has the hackles fixed on flat sheets, as in the "old flat" machine. It is simple and complete; easily driven and attended, and a considerable number are now in use. From the hackles being on a flat sheet, it is necessary to make the holders descend, first on one side while the sheets are moving in one direction, and then on the other while they are moving the other way. This is done by supporting the channels which carry the holders on four levers fixed on two oscillating shafts, to which motion is communicated by a shaft. The holders are still through by a lever on the top, which acts on a sliding bar, by means of a ball, which forms a universal joint and actuates the holders, whatever position the channels are in. The drawing here given, *fig. 819*, will show the mechanism.

Both the machines last described are made double, or in fact, the construction of each is that of two machines in one. The table for filling and changing the flax in the holders is attached to the machine. One side hackles one end of the flax, and the other side the other end.

We now have to describe a machine for hackling cut line, patented by Mr. Lowry, of Manchester, and now extensively in use at home and on the continent. It is virtually a modification of Wordsworth's machine, already described.

Fig. 820 is a side elevation of a sheet hackling machine in which these improvements are applied; *fig. 821* is an end elevation of the same; *fig. 822* is a front view; and *fig. 823* an end view of one of Lowry's improved hackle bars. In *figs. 820* and *821*, *a a* represent the belts, sheets, or chains to which the hackle bars *b* are attached. These belts, sheets, or chains pass around the small drums *c c*, and larger drums *d d*, which are turned round by the gearing, shown in the drawing, or by any other suitable arrangement of gearing. The hackle bars *b*, are made with a recess to receive the stock of the hackles *c*.

The hackle bars *b* are connected to the belts, sheets, or chains *a, a*, by means of rivets or screws, passing through the flanges *b*, and through the belts, sheets, or chains *a*; and at each end of each hackle bar is a stud or guide pin *b'*, which, when the hackles arrive near the small drums *c, c*, take into the groove in the guide plates. The object of these guide plates is to support the hackle bars in passing over the small rollers *c*, and during the operation of striking into the stick of flax or other fibrous material to be operated upon. The holders with the strikers depending from them, are placed within the rails *i, i*, and these rails are made to rise and fall and the holders are made to pass from one end of the machine to the other, in the usual manner. When the machine is at work the drums *c* and *d* revolve in the direction of the arrows in *fig. 821*, and the hackle bars being attached to the belts, sheets or chains *a*, and supported by the guide plates, cause the hackles to enter the strikers of fibrous material at or nearly at right angles to the fibres thereof, and to retain that position at the commencement of their downward motion; whereby as the belts, sheets, or chains continue to descend, the hackles are drawn through the fibrous material for the purpose of removing the short fibres and extraneous matter. Another great advantage resulting from this improved mode of attaching the hackle bars *b* to the belts, sheets, or chains *a*, is, that the hackles can be made to enter the fibrous material at a point closer to the holder than in any of the sheet machines now in use. When the hackles are passing round the drums *d d*, they are cleaned by the

revolving brushes *jj*, which deposit the material removed from the hackles on to the card drums *k, k*. These drums are cleaned or doffed by the combs *ll*, or in any other convenient manner.

This machine is also used to a very large extent, and well liked for dressing half line and full length flax. For this purpose the sheets require to be made six inches

longer from centre to centre, and the head or trough to lift 3 inches higher, and the top rollers to approach and recede from each other simultaneously with the rising and falling of the head.

Combe, of Belfast, has recently produced another edition of Wurdsworth's machine. Its novel feature consists in dispensing with bars altogether, in carrying the backles and in fixing them directly on the leather sheets. By this means a very true action is obtained, and the working parts are so light, that the machine bears any speed with scarcely any wear and tear. In this invention there is also combined convenient modes of regulating the lift and severity of the cutters to suit different kinds of flax, and the holders are carried through the machine by a separate apparatus for that purpose, while they are at their highest elevation, instead of during the whole process of lifting, as had always been the case in other machines.

The cutting of flax already referred to, is effected by a machine consisting of a species of circular saw about 20 in. in diameter; but, instead of a single blade, it is constructed of 3 or 4 plates of steel, each about $\frac{1}{4}$ in. thick, and having angular projections from their circumference. This revolves at a considerable velocity, while the flax, firmly grasped in each hand by its ends, is still further held and slowly

carried against the saw by two pair of grooved pulleys pressed together by a considerable weight. It is thus partly sawn and partly broken through. Flax may be cut into 2, 3, and sometimes 4 divisions: and sometimes the dead harsh fibres that are frequently found at each of its ends only are cut off and used as tow; but more generally the different portions are hackled and used for the purposes they are sorted for.

Description of flax cutting machine (figs. 824, 825). A A, framing; B, the grooved

pulleys for holding and carrying the flax; C C, the driving pulley; D, saw or cutter; E, F, wheels for gearing together the pair of holding pulleys; G, H, I, K, pinions and wheels for producing the proper relative speeds between the cutter and pulleys; L, weight, which by levers M and N, causes the pressure of the holding pulleys.

Preparing.—By this term is understood those preliminary operations through which both line and tow must pass after the hackling and before the spinning process.

The mechanism and modes of proceeding for this purpose which consist of repeated drawings, are similar for “long” line or “cut;” though the dimensions and fineness of the machinery must be made suitable for their various lengths and qualities. But in the preparation of tow a peculiar additional operation is demanded, as a consequence of the different state of the fibres of which the material is composed; this operation, termed “carding,” has for object to bring the highly irregular and entangled mass into a somewhat more homogeneous and uniform state, previously to its being afterwards drawn and equalised to a manner similar to line.

In the preparation of line the first operation is called “spreading,” or first drawing; and the machine employed a “spreader,” those subsequently are the second and third “drawings” (sometimes a fourth is used), and lastly the “roving.” It is upon the spreader that the separate sticks of line are first combined and drawn into long uniform bands or ribbons, called “slivers,” of determinate lengths. This is effected by subdividing the sticks into two or three portions, and then placing them consecutively, slightly elongated, and overlapping each other about $\frac{1}{10}$ th of their length upon and in the direction of an endless creeping sheet or apron. The machines are generally made with two of these creeping sheets or aprons, and upon each sheet are thus laid two distinct lines of sticks; each of which forms a thick uniform body of line, and capable of being maintained to an indefinite length. These endless creeping sheets supply continuously another part of the machine, where the body of “line” is drawn out to between 20 and 60 times its original length, according to whether it is composed of cut or long flax. This part of the machine comprises a pair of holding or back rollers; an endless succession of bars called fallers, bearing combs of closely ranged steel pins, through which the slivers are drawn; a pair of drawing rollers; an arrangement of diagonal or doubling bars; and a pair of delivering rollers. It is generally termed the “gill frame,” or “gill head,” probably from the French word “aiguilles” (needles), as descriptive of the combs, and to distinguish this machine from

those formerly used for the same purpose, which simply consisted of a series of rollers, under and over which the line was passed.

The following figures, 826, 827, show the outline of the present most approved gill spreader or first drawing.

826

A A, general frame of the machine; B, driving pulleys; C, auxiliary frame for endless sheets; D to V, rollers for carrying the endless sheets or aprons; W, con-

827

ductors to guide and slightly condense the four bodies or slivers of line; R, can for receiving the sliver; U, lever for weight on front or drawing roller; N, lever for weight on back roller; A, delivering roller shaft, spring, and bed, which, by the intervention of gearing between it and the front roller, is caused to ring when any desired length of sliver is delivered.

a a, the iron drawing roller or boxes; b b b, the wooden or pressing roller, by the pressure of which upon a a the sliver is held during the greater velocity of these rollers over that of c; the holding or back rollers elongate in exact proportion of its sag-

mentation; the holding roller *c* is in like manner pressed against another in order to assist the "gills" in retaining the fibres; *A A*, hooked rods to connect the weighted lever *A* with the holding roller *c*, and by the pressure thus caused insure its effect;

d the sheet or surface of "gills" composed of separate bars, as seen at *fig. 830*, *831*; *e*, rubber or cleaner of pressing roller *b*; *f f*, conductors to contract laterally the sliver at the moment of drawing; *g*, plate of metal having diagonal openings at an angle of 45° (this plate is sometimes called the "doubling bars," having been first made of separate bars) to the original course of the sliver, in order to enable it to be

turned in a rectangular direction and guided to the delivering rollers *A A*; this direction of the sliver is more distinctly seen at *fig. 833*; *i*, hanger or connector of pressing roller *b* to its weight lever *c*; *l l*, the screws or worm shaft for carrying the gill bar *d d*; *m m*, the shaft with bevel wheels by which the screws at opposite sides of the frame are caused to move simultaneously; *a n*, pinions for connecting the upper and lower spirals of each pair; *o n*, the cams or excentrics for lowering and raising the gill bars; *p p*, weighted guide lever or bell cranks for guiding the faller in its descent, and moderating the shock caused by its weight when coming in contact with the lower slide or support; *q* and *r*, worm and wheel for bell motion; *s, t, u, v, w, x*, line of wheels from pulley to front roller and from front roller to back; *1, 2, 3*, line of gearing from back roller to sheet; *4, 5, 6, 7*, line of gearing from roller to delivering roller; *8*, from roller to brush; *y y*, from back shaft to back roller.

The machines for the second, third, and fourth drawings, though in principle essentially the same, yet differ in some of their minor details from the foregoing, as

they do not require the feeding sheet to supply them, the "aliver," from the spreader having sufficient coherence as to allow itself to be drawn from the cans direct by the back rollers of these machines; neither is a belt motion requisite to determine the length of alivers produced by them. The subjoined sketches show the general parts requisite (*figs. 832, 833*).

A A (*figs. 832, 833*), framing; m, driving pulley; c, support of aliver carrier; n, roller for carrying aliver; r, conductors; r, can containing the alivers from the first drawing; o, receiving can; n n, the handle carrying spirals; i, the diagonal or doubling bars; k, delivering rollers; l, the drawing rollers; m, m, m, the retaining rollers.

833

The roving frame is the same in regard to the arrangement of its back and front rollers and gills, as the drawing frames; and as the position and manner of regulating the poles are generally the same as adopted for cotton, the description of these parts therefore does not require to be repeated; but an improvement patented a few years since by Sir P. Fairbairn, of Leeds, of that part of these frames which relates to

regulating the taking up movement of the bobbin merits particular attention, as by it the inconvenience of the older method of a weighted belt and cone, and those of the more recent disc frames, are entirely overcome. The principle of this improvement consists of driving a pulley by pressure between two discs revolving at equal speeds in opposite directions, as seen at *Figs. 834, 835, 836.*

Fig. 834. To obtain the variable speed, instead of using a cone and belt as in

some frames, or the pulley and single disc as in others, *a b*, the horizontal driving discs, the lower one *a* is keyed to the shaft *d*, while the upper *b* is free to turn upon it; *i*, bevel wheel fitted to or forming one piece with the upper disc *b*; *c* bevel wheel keyed to shaft *d*; *e* intermediate bevel wheel gearing in the bevel wheels *c* and *i*, so as to turn them in opposite directions, and consequently the discs to which they are directly or indirectly attached; *g*, the variable pulley covered with leather and resting upon the lower disc *a*, and itself pressed upon by the weight of disc *b*; it is thus driven at speeds varying according to its approach to or from the shaft *d*, thus answering the purpose of the traversing leather belt of the cone movement; *h*, shaft keyed in the

pulley *g*, from which the variable motion is transferred to the bobbins.

A series of preparing machines, termed a "system," consists in general of 1 spreading of 4 shivers at the drawing rollers, united into one by the doubling bars at the delivering roller, 2 frames of second drawing, in all 24 boxes 2 frames, third drawing containing

835

836

together 36 busses; if a fourth drawing is required, 2 frames of 24 busses each, or 48 busses in all. 180 spindles of roving in 3 frames will well supply 3000 spindles of medium spinning. The mode of using this "aynd" is, as has already been said, first to spread the sticks of line upon the feeding-sheet of the "spreader," then to receive the sliver or slivers there produced into cans capable of holding 1,000 to 1,200 yards of sliver. These cans specially intended to receive the slivers from this machine, are all made to one regular weight; thus, when filled, the weight of line each contains is correctly ascertained, and by the bell motion the length is also known. Upon this basis is founded the method of producing any desired number of yarn, and by doubling the slivers, a degree of equalisation that the simple spreading would be unable to effect; for at each drawing, and at the roving, several of the slivers from the preceding drawing are put together, to be again reduced to one for this object alone. Hence, the weight of a determinate length in yards of the desired yarn being known, a calculation is made, combined of the drafts and number of doublings the material has to undergo, to determine what the weight should be of that length of slivers contained in the cans from the spreader. It is ordinary to put 10 or 15 of these "cans" together, to form what is called a "set," the slivers of which are united at the second drawing with the subsequent drawings and rovings. The combination of two or three slivers at each boss is sufficient.

Though the above is descriptive of the "gill" frames now in use, yet it should be understood they are by no means the first or only results of the attempts made to correct the defective principle of the original roller machines, which were incapable of holding or retaining the flax with a sufficient degree of regularity, owing to its unequal lengths and unadhesive nature. The consequences were that the yarns produced were "lumpy" and unlevel, making it evident that some improved means were necessary for more completely restraining and regulating the drawing of the fibres. The most obvious way to do this was to introduce some mode of partial detention by creating a friction among the fibres to imitate the action of the fingers in hand-spinning. This led to causing the slivers to pass through and among several ranks of serrated pins, which was found very nearly to attain the object, and certainly greatly improved the levelness and uniformity of the slivers. Thus the use of "gills" became general about thirty years since.

Those first brought into general use were constructed with circular discs or plates for carrying the faller or gill bar, which at the same time were guided by their ends passing in fixed slots, so as to bring the gill in a vertical position and as near the drawing roller as possible.

The figures (837, 838) are profile and front views of one of these gills:—*a*, a slotted plate or disc, of which a pair were keyed upon a shaft *b*, so as to carry each end of the faller *c*, passing through the slots *c c*; *d*, the fixed eccentric slide; *e*, the drawing rollers; *f*, the holding rollers.

This was succeeded by the "chain gill," in which the fallers were carried forward by an endless series of connected links, or jointed together "slotted plates," instead of the simple circular. The object of this was to increase the flat surface of the bars between the holding and drawing rollers, making it more suitable for the longer descriptions of material. The slides and rollers, being similar in these machines to those in the former, are not repeated, but the sketch of five slotted plates is given in

fig. 839.

From the evident importance of bringing the retaining effects of the gills as closely

as possible to the point where the movement of the drawing fibres is greatest, several attempts have been made to improve the above described gills in this respect. With this view Messrs. Taylors and Wordsworth patented a gill of considerable ingenuity (fig. 840), which therefore deserves mention, though it never came into use. Its description is as follows:

a b the faller or "gill bar" in one piece, which was carried forward by an endless chain; c, d, slides placed horizontally over the gill sheet guiding the ends of certain bell-cranks e, f, joined at their angle in the recess, g, h, of the gill bar, and at their other end to the gill or comb a. By this arrangement, as long as the bell cranks are in the parallel parts of the slides c, d, the gill teeth will be above the faller a, b, but when they arrive at the contracted part the guided ends will be brought into the position q q, and consequently the gill depressed is a 2; this is so timed as to cause them to clear the drawing roller, when, on again continuing their course, they are again caused to rise and penetrate the aliver by the reversed inclination of the slides c, d, at the back roller.

The objection to this ingenious machine was the largeness of the space suddenly left open by the de-

scend of the gill, as the double faller, bell crank, and gill necessarily occupied great width.

The screw or spiral movement of the fallers, which was soon afterwards invented, quickly superseded all others in use, as by these means the faller was caused, even in the manner they were first constructed, to approach closer than even in the most perfected construction of the others, to the side of the drawing roller, and still maintain the pins in a vertical position. Recently this object has been more perfectly attained by a patented improved construction adopted by Messrs. P. Fairbairn and Co., whereby the obstacle to the faller wholly touching the roller has been removed, and thus producing the full holding effect of the gill to the latest possible moment. This is effected by employing a method of supporting the spirals by their working in tubular recesses in the side plate of the machine; along these recesses are longitudinal openings through which the faller end passes to enter between the threads of the spiral, and which serve also as slides to support the faller. As by this means the supports or plunger blocks that intervened between the end of the spirals and the roller are suppressed, the faller is enabled to advance to the place they formerly occupied. Figs. 841 and 842 show this comparison of the older and more recent methods. A, B, spirals; C, C, the parts by which they are supported, being in fig. 841 small pivots in plummet block D D, and in fig. 842 hollow tube-like recesses in frame plate C C; E E, pinions to work the upper and lower spiral together; F, bearings; G, drawing-rollers; H, pressing rollers; I I, passage of the faller's descent.

Here it may be as well to observe that the same parties have still more lately introduced another important amelioration in these machines for remedying the noise and wear and tear which ordinarily attend them by the abrupt and violent descent of the faller. Fig. 843 shows a sectional front view of a head having this improvement applied. A A, supports for screws; B, C, top and bottom screws; D D, the new canvas

fixed on shafts parallel with the screws, and revolving at the same speed. Thus, these cams *d d* receive the faller *e e* at their largest diameter, at the moment they are free to descend, and guide them gradually down to the lower slide.

Thus constructed, the "screw gill" continues to be the most esteemed in principle, though not without some serious objections in practice. For the abrupt and angular movement of the "faller" even here not only liberates too suddenly a portion of the

fibres that should be but gradually relaxed at the moment of being drawn, but causes considerable wear and tear to itself, the slides, and the gills attached to it; to which cause of destruction must be added the great friction of the worm movement; these, however, in "line" preparing, where the fibres are long and straight, and the drafts employed large, and where, consequently, a comparatively slow movement of the

gills is required, are not so much felt as in the preparation of tow, where they become serious.

In "tow preparing" the first operation, as before stated, consists of "carding," which is generally repeated over two separate machines, which are respectively called the "breaker" and the "finisher" cards. They are essentially the same in principle, and vary but little in construction, the only difference being that the "breaker" is fed or supplied by the disjointed parcels of tow from a creeping sheet (as the spreader with "line"), and delivers its slivers into a can, whereas the finisher is fed from a bobbin upon which several of the slivers from the "breaker" are united by a machine expressly for that purpose, called a "lap frame;" this card thus receives its supply of work in a very regular form, and previously to delivering it in the form of slivers causes them to pass over a gill, to consolidate and strengthen them before delivering them into the receiving can; it is also generally clothed with a finer description of wire filleting than the breaker. Though it is the better method to card thus the tow twice, yet this second carding is sometimes dispensed with; in that case this auxiliary "gill" is similarly fixed to the first card or breaker. The cards employed for tow are machines of considerable weight and importance, the main cylinder, or, as it is sometimes called, "swift," being from 4 to 5 feet diameter and 4 to 5 feet long; those most generally employed are 6 feet long. Previously to entering upon the detailed description of a card, it may be as well first to trace in general terms the progress of its operations, as tending to elucidate the explanation of the machine itself.

The tow is first divided by weighing into small parcels of 10 to 20 drams; these are then shaken out and spread so as to cover certain definite portions of the creeping feeding sheet, by which they are conducted to the first pair of rollers, called the feeders. These rollers are covered with a leather band, in which are fixed in close array a number of wire points about $\frac{1}{2}$ an inch long, and having a tangential inclination to the circumference of the rollers, which are about 2 $\frac{1}{2}$ inches diameter. The tow passing at a slow rate of progression between these rollers, is by them gradually presented to the points with which the swift is likewise covered, also set in leather bands, but which are about 2 inches wide; these points, the same length as those of the feeders, have an inclined direction pointing to that in which the cylinder turns. The much greater velocity of the "cylinder" combs and somewhat opens and breaks the tow as it slowly arrives in contact, and the inclination of the pins at the same time carries it forward. All such lumps and fibres as are not sufficiently opened and straightened by this first contact, remaining prominent on the surface of points on the cylinder, are carried by it against another roller, whose axis is parallel, and whose wire-covered circumference is brought as near as possible, without absolute contact, in order to catch and retain these prominent lumps and fibres; the points of this roller (called a "worker") are inclined in a direction opposed to the movement of the swift, and, therefore, hold the "tow" to be again combed and straightened as at first it was by the feeders: this is repeated eight or nine times, by having that number of workers to the card; each of these workers has its attendant roller, also covered with wire points, by whose inclination in a contrary direction, and by the greater velocity of the roller, the tow is stripped from the workers, to be again laid on to the cylinder. The strippers, though running at a greater velocity than the workers, are still slower than the cylinder. The tow thus carried forward gradually improving in openness and regularity as it passes each pair of "workers and strippers," finally arrives at the roller called a doffer, of which there are two or three upon a card, the wire points of which are in such a direction as to hook or catch the tow "as it flies." The use of these several doffers is, that by placing each succeeding one progressively nearer the swift, the longer and shorter fibres are successively and separately taken off. Each doffer is cleared by an oscillating comb, and the slivers conducted, if intended for the lap machine, into a can by delivering rollers; but if finished, these delivering rollers are as it were the back rollers of the auxiliary gill, patented for this application by Messrs. Fairbairn and Co.; whereby the slivers are not only saved from all danger of derangement in their loose and porous state as direct from a card, but the hitherto double expense of carding and first drawing is reduced to that of carding alone.

A A A (Fig 844), framing. B, swift or main cylinder; C, feed rollers; D D D, strippers to feed rollers and workers driven by one belt from pulley E, and maintained

tight by the movable pulley *r*; *g g g*, workers; *i i i*, the three doffers; *h h h*, intermediate wheels to connect the movement of the doffers with one another; *k k k*, oscillating combs for their respective doffers; *l*, delivering rollers; *m*, back roller of auxiliary gill; *n*, gill surface; *o p*, drawing rollers; *q*, delivering rollers and bell motion for measuring the sliver in the cans *u*; *s s*, doubling plate; *t*, pulley for driving auxiliary gills by belt from the pulley *e*.

845

The lap frame, to which allusion has already been made as the necessary adjunct to the cards when double carding is to be performed, is employed to collect together a number of slivers from the "breaker" by winding or lapping them upon a cylindrical piece of wood, which may be described as a bobbin shank, thus producing an equalization of the slivers of tow as the making up of sets effected in line preparing; from 50 to 60 lbs. of tow is the usual complement of one of these bobbins, the length and the diameter, when full, about 22 inches; thus, a 6 feet wide finisher card will take off these bobbins at once; from 15 to 20 is the number of slivers usually wound together, and the completion of a bobbin by the ringing of a bell, connected with the measuring cylinder of the machine. The following is a descriptive drawing of the lap machine.

846

A A A (figs. 846, 847), framing; *n*, measuring and pressing cylinder; *c c c*, driving pulleys connected with different gearing to change the speed as the bobbins

fill; *n*, bobbin or shank intended to be filled; *s*, table to receive the bobbin when about to be taken from the machine; *r*, weight to increase the effect of pressure of the

measuring cylinder by the connecting rods *a a a*, which are split for part of their length in order to pass the shaft *u*, and at another, *g g*, have racks into which work pinions keyed on the shaft of the hand wheel *z*, for the convenience of raising and lowering the cylinder and weight. The shaft *u* is divided at the plates *x* and *z*, and provided with sockets to receive the end of the bobbin shank *v*, which is introduced by sliding back the piece *u n*, and returning it by lever *m*, and thus is coupled and turns together with two pieces of shaft *u*, as also the disc plates *x* and *z*, which are to serve as temporary ends to the bobbin during the time of its filling, and thus by turning with it avoid that rubbing and felting effect upon the edges of the tow so injurious in the machines formerly constructed, and by the bobbin acting as the driver to the cylinder the slivers are drawn tighter, and thereby avoid those plaits that the other machines were so liable to produce.

As before mentioned, some objections were found to the working of the screw-gill, of a nature detrimental to the machines themselves, which, though not of great importance in "line," were much aggravated in tow preparing, as the lesser drafts there employed cause a greater wear and tear of the fallers and gills. The objection to these machines, however, is not confined to this point only, but extends also to their effect upon the material itself. The fibres of the tow sliver, as coming from the card, are in a light and much confused state, which renders them liable to be easily separated; so that the faller, by its sudden descent, has a tendency to draw some down, and become lapped by them, as well as to make so marked a difference in the thickness of the sliver, by the withdrawal of the retaining comb, so as materially to injure the quality of the yarn. Thus this "gill" was not enabled to hold its place in tow spinning, when other circumstances led to greater attention being paid to this important branch of the flax business, and it became a desideratum to have a machine free from these defects, and capable of working without derangement, at much greater velocity than was safe with the "screw-gill." These desiderata the "rotary" gill, patented by Messrs. Fairbairn and Co., supply supplies. For in this gill the circular form of the gill sheet obviates the necessity of having several fallers, and the simple motion creates neither friction nor abruptness of effect, while the retention of the fibres being continuous, the slivers produced are perfectly level and uniform; consequently these gills are extensively applied, as the auxiliary gill explained in carding, as well as for the subsequent drawings and rovings of tow, and sometimes, as will be after-

wards seen, to coarse spinning. The theoretical construction of these rotary gills will be seen by the annexed sketch.

κ (fig. 848), back rollers, but when applied to a card a top and bottom holding rollers are again employed; π, the rotary gill sheet having the pins inclined backwards, so as to ensure the impalement of the sliver when the fibres begin to draw; ρ

849

and σ, the drawing and pressing rollers; the doubling bars or plates are the same to these gills as to the "screw-gills."

A machine has been lately invented, and brought out by Sir P. Fairbairn and Co. of Leeds, called Heilmann's tow combing machine (fig. 849), which, on trial, is much approved of. The tow is first carded in the ordinary way, say on a breaker card, and then on a finisher card; the latter delivers the tow in the shape of a sliver into cans, which are next placed at A, or back of the tow combing machine.

849

From the cans A the tow goes to the back conductor κ, divided into as many compartments as there are slivers; and from the conductor κ, to the feeding box c suspended on shaft π, without being keyed to it. The front lip π of the feeding box is

dated and fitted with leather, and a corresponding nipper *r* hung from the same shaft *v*, and keyed upon it, completes the jaw which has to hold fast the tow, while the cylinder *a* combs it.

The feeding box *c* derives its motion from the nipper *r*, which is moved by lever and eccentric as shown, and follows that nipper by its own weight, until stopped by indiarubber buffers *u*; when the nipper *r* in going further back leaves it, and the jaw *u* *r* opens for more tow to be fed, and the tow already combed to be drawn through the detaining comb *z*, as explained hereafter.

The top *x* of feeding box is movable up and down, by means of the connecting rod *z*, hung on a fixed centre *m*, so that the top part *x* opens or shuts as the body of the box goes backwards or forwards. The levers *m* *n* *n* are only used to keep the top and bottom of the box parallel to each other.

As shown in the drawing, the top of the feeding box is fitted with hackles passing through two grates *o* and *p*, fast on bottom of feeding box, and leaving between them a space through which the sliver has to pass.

By the above arrangement, the hackles are caused to withdraw from the tow, while the whole box is drawn backwards on slides of table *q*, by the eccentric motion *a* *n* *n*. The last backwards motion takes place while the jaw *r* is yet shut, and the top of the box up; but when the latter has got closed again, then the whole box slides down on the table *q* to its former position, bringing with it the sliver of a quantity equal to that move: this completes the feeding motion.

Now as the feeding box recedes, the lip *z* comes nearer to the combing cylinder *a*, the hackles *s* *s* cleaning the tow projecting outside the nipper *r*. As soon as they are passed through, the feeding box comes back to the most forward position, when the nipper *r* leaves it, and the jaw *u* *r* opens: at the same time the two rollers *t* *u* have reached their top position. The top one *t* is then thrown forwards (by the lever arrangement shown in *v* *v* *v*) upon the leather *w*, stretched on parts of surface of cylinder *a*; this roller *t* is thus driven, and takes hold of the points of the tow presented to it by lips or bottom jaw *z*: a fine detaining comb *z* being just before interposed between them to keep back the noils, that have not been carried off by the combing cylinder.

450

In that way the points of the tow are driven upon the sheet *x*, until the roller *t*, by being thrown back again off the leather *w*, their motion is stopped at the same moment, the two rollers *c* and *r* are allowed to drop down by eccentric *v*, drawing with them (through the detaining comb *z*, and quite out of the rest of the sliver) the other ends of the fibres of which they have got hold.

While this has been going on, the feeding box has advanced the sliver a step, the

nipper closed, and forced the said feeding box forwards so as to bring the lip *x* within the reach of hackles *s* on cylinder *a*, which then met it, cleansed the tow, and so on as before.

At that time the rollers *r* and *v* come up again, and during that upwards motion

851

the latter ends of the fibres partly combed and overturned by the cylinder hackles, as shown in drawing, are combed by them in their turn. Then the roller *r* is once more driven round by the leather *w* stretched on cylinder, the new points place themselves

852

above the back ends of the fibres combed before, and are carried forward into a continuous sliver on the leather sheet *x*, from the leather sheet to the rollers *z* *x*, then to the trumpet conductor *a*, the front delivery roller *c*, and (when more than one head to the machine) from *c* to the end delivery *e*, over the conducting plate *d*.

In *c*, *f*, *g*, and *h*, are the usual brush, doffer, comb, and tow box for the noils.

These combing machines are made of different sizes to suit all sorts and lengths of tow; the yarn produced from them is much finer than that produced by the ordinary carding system alone. The combed tow can generally be spun to as high numbers as the line from which it has been combed, and in some instances has produced good yarn, even to higher numbers. The combed tow, after the combing machine, is passed through a system of drawing, roving, and spinning, similar to that used for cut line.

Subsequently to the carding the preparation of tow is completed by making up sets of cans for the second drawing, as explained for line; these slivers are doubled and drawn once or twice more, and then roved. The drafts used in tow preparing are from 9 to 8, for, as the fibres are shorter, it necessitates the employment of less draft. In both line and tow preparing, lesser drafts are employed as the stages advance, the gills finer, and the conductors narrower: also for both materials much attention is requisite to keep the various parts of the machines in good order, free from bent or broken pins, and chipped or indented rollers, for no subsequent operation can cure the defects that may be produced by negligence in these particulars. The drawing and roving frames for tow are shown in *figs.* 850, 851, 852.

A A (*fig.* 851), drawing frame; a, driving pulleys; c, rotary gill sheet; n, drawing roller; r, pressing; v, a pair of delivering rollers; u, doubling plate; t, back conductor; k, back roller wheel with pulley to turn the sliver rail L.

A A (*figs.* 851 & 852), roving frame; n, pulley and fly wheel combined; c, drawing roller; u, rotary gill; a a, stand for gill movement. The regulation of the bobbins is effected in the same manner as already described for line roving.

Spinning.—This operation consists in drawing the “rovings” down to the last degree of tenacity desired, and twisting them into hard cylindrical cords, which are called “yarns.”

There are three modes of performing this operation: the first, and perhaps oldest, is that where the drawing and twisting are performed altogether, with the material preserved dry, and without breaking or shortening the fibre; the second is that which likewise, without changing the length of the fibres, draws them while dry, but wets them just at the moment before twisting. This method is the nearest imitation of hand spinning, and makes the yarn more solid and wiry than the first; as the fibres of flax losing their elasticity while wet, unite and incorporate better with one another. The third mode of spinning has been much more recently introduced than either of the others, and by it the fibres are wetted to saturation previously to being drawn, whereby they are not only much reduced in length, but their degree of fineness is increased by the partial solution of the gummy matter, inherent in the flaxen material: owing to these circumstances equally good yarns can be produced by this mode of spinning from line and tow of inferior quality, to what could be employed upon either of the others, and not only that, but much finer yarns can be now spun than were possible previous to its introduction. It has therefore not only nearly superseded all other methods of spinning for yarns from 20's to the finest, but has much increased the extent and importance of the flax manufacture.

The only difference in spinning frames for “line or tow,” when employed for the older methods, consists in the length of reach, which generally involves the necessity of having separate machines for each material, though sometimes they are made with a capacity to be adapted to either purpose. In the third method the same machines are used promiscuously for “line or tow.”

The yarns spun wholly dry are used for the coarse description of woven goods, as packing canvas, corn sacks, and, when partially bleached, for sheetings and towellings, as from its greater elasticity and openness it fills up better in weaving. Those spun partially wetted are employed for a somewhat superior description of linen goods, and the solid silky appearance qualifies them for drills, damasks, &c., as well as for sewing and shoe threads; a somewhat inferior material, by this manner of treatment, makes an equally good yarn as a better material spun dry. The yarn produced from this wet principle is rather inclined to have a cottony appearance, and from the comparative ease with which an inferior material can be made to present an apparently fine good yarn, the application of yarns thus produced is exceedingly various and sometimes deceptive, though when good materials are used, these yarns afford durable and handsome drills, shirtings, lawns, and cambrics, as well as fine sewing threads.

The mechanical arrangements for twisting, and then winding the yarn upon a bobbin, is called the “throstle” principle, supposed to be so called from the whistling noise they create when working at full speed, which is from 2,500 to 4,000 revolutions a minute. The following diagram will explain the principle, which is applied alike to all the modes of spinning above described.

A A (*fig.* 853), the spindle; a, the bobbin, loose and independent of the spindle in

regard to turning, and rising, and lowering, but through which the spindle passes; *cc*, the flyer screwed to the spindle top; *v*, table called bobbin lifter, as while at work it rises and lowers to lay the yarn on the whole bobbin equally; *x*, a small cord to press on the bobbin by the weight *w*; *o*, pulley by which the spindle is driven.

Many attempts have been made to improve upon this principle, in order to avoid or lessen the strain upon the thread in its passage from the drawing rollers to the flyer eye; but, till recently, without any degree of success. The only improvement at present known, and which promises to become general, is that where the necessity to have a top to the bobbin is avoided. It will be seen from the above

853

854

diagram (853), that the yarn is compelled to rub the top of the bobbin, and the friction thereby created quickly causes it to become rough; and therefore it has a tendency to catch and break the thread. The desirableness, therefore, of having a clear course for the yarn was evident, and this improvement that we are about to explain produces the effect by employing what is called a coping motion, which, like that used in mulespinning, preserves the layers of thread upon the bobbin ever in a pointed or conical state, and therefore self-supporting without the aid of the wooden end of the bobbin. See COTTON SPINNING.

The arrangement of the rollers for holding and drawing the slivers or rovings, as well as the plates and rollers for adding to retain the twist of the rovings, in order to render their elongation more equable when to be drawn dry and spun upon the older methods, will be seen in fig. 854.

A (fig. 854), roving bobbin; *b*, back or holding roller; *c*, carrying roller; *d*, flat plate with a slightly curved face; the carrying roller and plate are so placed as to cause a degree of friction to the roving when passing over them, so as to retain the twist, and thus act as the pins in the "gill frames;" *e*, tin conductor for contracting the roving at the moment of being drawn; *f*, metal roller; *g*, wooden roller pressed against the drawing roller in order to pinch the roving; *h*, lever and weight. When it is intended to wet the yarn previously to twisting, the trough *i* is used, in which is water, which is supplied to the roller *g* by the capillary attraction of a piece of cloth immersed therein, and bearing against the roller by lever *k*.

The machines for "wet" spinning are of a very different construction and appearance; as the close proximity of the holding and drawing rollers prevents the inter-

vention of holding rollers or friction bars, while the force requisite to draw the rovings at the short reaches used, varying from 2½ to 4 inches, requires each pair to be deeply

and accurately fluted into one another. The water used is heated, in order by the expulsion of the fixed air more rapidly and completely to saturate the rovings while passing through it. The following drawings and description will be sufficient to give an accurate idea of the principle of these machines, which are generally 20 to 30 feet in length, and contain 200 to nearly 300 spindles; that is, 100 to 150 on each side.

A A A (figs. 855 & 856), framing; n n, stand for roving bobbins; c, driving pulleys fixed upon the axle of cylinder d, from which pass endless cords to drive the spindles e e; F, step-rail of spindles; a, collar rail for ditto; n, bobbin lifter; T T, front roller; K K, back roller; L, back pressing roller; M, top pressing roller (these are generally made of box wood, but sometimes of gutta percha); x, x, levers in connection with the eccentric to produce the rise and fall of the bobbin lifter; o o, thread-plate; q q, saddles or transverse bars resting on the axles of the back and front pressing rollers, so that one lever and weight acts for both by the connecting rod and lever r r, which, in order to cause more pressure on the drawing than on the back roller, is placed on the saddle nearer the former than the latter. 1, 2, 3, 4, 5, 6, 7, 8, train of wheelwork, by which the movements are distributed. n a a, the trough of hot water maintained by steam-pipes at the desired temperature; b b, guide rods or pipes to cause the roving to pass under the water. In order to avoid the rollers becoming indented by the roving always passing on the same place, they are caused to traverse the breadth of the rollers by a traversing guide rail, moved by an eccentric at the worm and wheel c; d, flyers, and f, spindles.

Here it may be proper to introduce a description of the machines for twisting the yarns when spun into "threads" used for sewing, &c. The yarns spun for this purpose should always be made of a somewhat superior description of line to that employed for the same number of yarns for weaving, and have rather less twist. They are generally taken while wet on the spinning bobbins to the twisting frame, and, when combined together, the onlon is effected by a torsion in the opposite direction to the original twist of the separate yarns.

Reeling.—This operation consists in winding the yarn off the bobbins of the spinning or twisting frames, and forming it into hanks or skeins. The various denominations of the skeins into which yarn is reeled, and then the forms or combinations they are made up into, are as follows:—

The lea containing 300 yards	
10 leas making	1 hank
20 hanks	1 bundle
6 bundles	1 packet.

It is by the standard lea of 300 yards that the description of yarn is known from the number contained in 1 lb. weight; thus, No. 20 contains 20 leas or 6000 yards for 1 lb. weight. In Scotland, the subdivisions are rather different from the foregoing, which are employed in England and Ireland; the lea, however, remaining the same:—

38 leas make	1 spindle
6 "	1 ratel
12 ratels "	1 dozen.

The reeling is performed upon exceedingly simple machines, generally put in motion by the hand of the person attending them, though sometimes they are driven by the motive power of the factory. The reel is made sufficiently long to receive twenty bobbins, and the barrel upon the yarn is wound in one length; the diameter, however, varies so as to suit the different sizes yarned to be reeled. For the coarsest yarns and down to 16 and 20, the largest circumference is used of 3 yards, from that to about No. 100, 2½ yards, and for the finest yarn 1½ yards is found most convenient. These various circumferences are compensated either by putting a great number of threads into each "tye," or increasing the number of tyes, so that opposite to each one of the 20 bobbins an entire hank should be formed before taking the yarn off; thus at each "stripping," one bundle is turned off. To facilitate the stripping, one of the rails of the barrel is made to fall in, and thus slacken the hanks; care is taken to leave the lea bands very loose, in order to allow the yarn to be spread out in drying and bleaching. The determinate lengths of yarn, when wound on the reel, are notified by the ringing of a bell connected with the axle of the barrel. Fig. 857 below shows the form of an ordinary hand-reel.

A A (fig. 857), framing; n n, reel barrels; c, box or trough to receive empty bobbins, &c.; t t, bobbins in position of being reeled; F K, guide rails, movable so as to place the leas side by side on the reel; f f, bell wheels; g g, bells for each reel barrel suspended on springs.

To these hand-reels there are many objections; for it is evident that the correctness of measure depends entirely upon the attention of the reeler, and the stoppages arising from the breaking of a thread or the finishing of a bobbin interrupt the work of all the others. These objections rendered it necessary to attempt some ameliorations of the system by the introduction of a reel that should automatically prevent these causes of error. Such a reel was patented a few years since, and is now in general use in Scotland; it is so contrived as to have the capacity of stopping itself when a thread breaks, when a bobbin finishes, and less and hanks completed; and having but four or five bobbins in one compartment, the stoppages affect but few at a time; and as this machine can be

857

worked by less skilful persons without possibility of error, much saving is effected both in wages and material. The annexed figure (858) shows the principle of this improved reel.

A A (fig. 858), framing; B reels; C C, pendulums on which are hung the bobbins to

858

be wound off; D, driving shaft with ratchet wheels opposite to each pendulum, so that when a thread breaks, the pendulum to which it is attached falls into the ratchet wheel, and thus stops it.

The drying of wet spun yarns should always, when possible, be done in the open air by spreading the hanks upon horizontal poles through them, with another similar pole resting inside upon their lower extremities, in order to keep them straight. If artificial heat is employed, that from steam or hot water is preferable, and it should never exceed 90° Fahr., as otherwise the yarn is apt to become harsh.

Making up.—By this operation is first produced upon the yarns a certain softness and suppleness, and then the hanks are folded and tied up in conveniently-sized packages.

In order to give the yarns that soft and mellow feel so agreeable and characteristic of flax yarns, the hanks when brought from the drying are what is called shaken

down and pin-worked. This is done by separating a few at a time, and passing them on to a strong arm of wood fixed to a wall or pillar, when with a heavy baton put through them, the workman proceeds to stretch the hanks with a sudden check or jerk, which operation he repeats in two or three places so as to thoroughly straighten and shake them loose; he then, using the same baton as a lever, twists them lightly backwards and forwards till the desired degree of suppleness is obtained. A brush is sometimes used to aid the straightening and separating, as well as to increase the gloss on the yarn. The hank or hanks will then be found to have assumed a flat shape, as on the reel, which facilitates their folding with a dexterous twist by their middle, when they are laid in square piles upon a table with their twisted folds one upon another. They are maintained in the perpendicular by a few supports fixed in the table. Sometimes these packages, which, according to the sizes of the yarn, consist of from $\frac{1}{2}$ of a bundle to 5 or 6 bundles, are bound together by some of their own hanks, but sometimes by cords in three or four places of their length. It is, however, better to employ a bundling press than an ordinary table, as the yarn can then be made up more solidly, thus both improving its appearance, and causing it to occupy less space for packing and stowage. The bundling presses are made upon the same principle, but on a smaller scale, for making up the small packets in which sewing threads are generally presented for sale, and are upon the following construction (figs. 859, 860).

Fig. 859, front view; Fig. 860, profile. A A A, frame; B, table or flat top of frame; C, rising table; D D, iron uprights fixed to B; E E, bars hinged at one end to uprights D D, to shut across the press, and be caught and latched down by the spring catch I, fixed to the upright D along one side of the press; F F, racks for lifting the table C by the pinions on shaft G; G, crossed levers for turning the shaft G; H, ratchet wheel engaging the detent K, and thus retaining the shaft G in any required position, and thus of course maintaining the pressure of table C against the top cross-bars L.

Weaving, is the operation by which the yarns are combined into textile fabrics, such as canvas, linens, lawns, drills, damasks, &c., and a great variety of other denominations of article for use and ornament.

Hitherto the weaving of linens has been carried on by the ancient and well known hand process, so ancient and so well known as to place the operative practising it among the worst paid of any other art. Now, however, there are several extensive and thriving establishments where machinery has taken the place of much squand misery, and at much cheaper rates produce to consumers superior articles, and still afford good payment to the operative. The improvements in power weaving which have led to this result are not founded upon one or even a few successful inventions or contrivances, but are the combination of a great many that have occupied much time to mature. Many difficulties had to be overcome in the weaving of flax that did not exist in that of other materials; and for a considerable period the expense of linens rendered their consumption so limited, as to make their production by power weaving

but a very secondary object. The greatest obstacle of a practical nature to the introduction of the power loom weaving of linens was, the stubbornness or want of elasticity in the yarn, which caused frequent breakages, and much confusion. In woollen or cotton goods, if a thread or yarn should chance to be a little tighter than the others in the warp, its elasticity will allow it to come up to the general bearing of the others when the web is struck up by the reed; but in linen from the want of that elasticity, a thread so situated would break, and by crossing some others, cause those also, if not to be broken direct by that circumstance, at all events to produce an obstruction to the shuttle that would lead to further mischief. Hence it was most material in linens to have such a method of winding the yarns upon the warp beams that should insure the greatest regularity; but strange to say, that point, though now attained, was at first wholly lost sight of. That circumstance, as well as the great mistake of attempting to use the same looms as are found suitable for cotton, produced so much discouragement in the earlier attempts as to give rise to a high degree of prejudice against the possibility of success in this undertaking, which may account for the backwardness in which this branch of the flax manufacture was found till quite recently.

The roving machine, called by the ingenious inventor, Mr. W. K. Westley, of Leeds, the *SILVER ROVING FRAME*, seems to be a philosophical induction happily drawn from the nature of the material itself, and accommodated to its peculiar constitution. It is remarkable for the simplicity of its construction, and, at the same time, for its comprehensiveness: requiring no nicety of adjustment in its application, and no tedious apprenticeship to be able to work it.

It is known that the mucilaginous matter of the plant may be softened by water, and hardened again by heat; of this fact advantage is taken, in order to produce a roving wholly without twist; that is, in the form of a ribbon or aliver, in which the fibres are held together by the glutinous matter which may be natural to them; or which may, for that purpose, be artificially applied. The silver roving, as long as it remains dry, possesses all requisite tenacity, and freely unwinds from the bobbin, but on becoming again wetted in the spinning frame, it readily admits, with a slight force, of being drawn into yarn, preserving the fibres quite parallel.

The diagram, fig. 661, shows in explanation, that

A, is the drawing roller of the roving frame in front of the usual cone.
N, the pressing drawing roller.
C, a shallow trough of water.
D, a cylinder heated by steam.
E, a plain iron roller for winding.
R, a bobbin lying loose upon the winding roller, and revolving upon it, by the friction of its own weight.

The roving, or aliver, as shown by the dotted line, after leaving the drawing rollers, A, N, passes through the water, in the trough C, which softens the glutin of the fibres; and then it is carried round by the steam cylinder N, which dries it, and delivers it hard and tenacious to the bobbin R, on which it is wound by the action of the roller E.

This is the whole of the mechanism required in producing the silver roving. All the complex arrangements of the common cone roving are superseded, and the machine at once becomes incomparably more durable, and easier to manage; requiring only half the motive power, and occupying only half the room. A frame of 48 bobbins is only 6 feet long, and affords rovings sufficient to supply 1200 spinning spindles.

This machine, though here described, is but little used, being capable of but very limited application.

Combe of Belfast has lately introduced an improvement in the roving frame. It consists in the application of a peculiar expanding pulley, instead of the cones, or discs and runners which have hitherto been always used for the purpose of regulating the "take-up" of the bobbins. It is evident that a strip of 2 or 3 in. broad, working over the cones, placed with the small end of one opposite the large end of the other is an imperfect and rude mechanical contrivance, and that there must be a constant straining and stretching of the belts. There is the same imperfection attending the disc and runners. The expanding pulley is free from these objections, as its acting surface is a line; and therefore it works with the greatest accuracy, while it is also a great simplification of the machine generally. In rovings for flax and tow it is

generally driven directly from the front roller, by which means a large number of wheels and shafts are avoided.

The following sketch shows the arrangement of the machinery in the most important rooms in a modern flax mill of 7000 to 8000 spindles, capable of producing, weekly, about 1000 bundles of line yarn, No. 25's to 120's; and about 700 bundles of tow yarn, No. 10's to 40's.

863

There are three systems of long line machinery for No. 25's to 70's; two systems of cut line machinery for No. 10's to 120's; and three systems of tow machinery for No. 10's to 40's.

The building is 56 feet wide and 162 feet long; which is a very suitable and convenient size, and which admits of the most economical arrangement of the machinery. The following is a description of the machines shown in the preparing room:—

A A, two of Baxter's patent sheet hackling machines for long tow.

B, a flax-cutting machine.

C, one of P. Fairbairn & Co.'s patent double line of holder hackling machines for cut line.

n n, are two breaker cards, 4 feet diameter \times 6 feet wide.
 n, lap machine.

864

r r r, are three finisher cards 4 feet diameter \times 6 feet wide, with P. Fairbairn and Co.'s patent rotary gill drawing heads attached.

o o, are two patent rotary gill drawing frames for long tow, 12 slivers each.

n n, two ditto regulating roving frames, 48 spindles each, for long tow.

j, is a screw gill second drawing frame of 3 heads for cut line tow.

k, is a screw gill third drawing frame of 3 heads for cut line tow.

l, a screw gill regulating roving frame of 72 spindles for cut line tow.

m m m, are three long line first drawing frames or spreaders of 4 bosses each.

n n n, are three long line second drawing frames of 2 heads each.

o o o, are three long line third drawing frames of 2 heads each.

r r r, three long line regulating roving frames, 60 spindles each.

q q, are two cut line spreaders of 4 bosses each.

s s, two cut line second drawing frames, 2 heads each.

t t, two cut line third drawing frames, 2 heads each.

u u, two cut line regulating roving frames, 72 spindles each.

The spinning room contains 34 spinning frames of 184 to 244 spindles each, apportioned to the several systems as described below.

I. System of long line machinery for spinning No. 25's to 40's.

1 flaxter's patent sheet hackling machine, 6 tools.

1 spreader or first drawing frame, 4 bosses.

1 second drawing frame, 2 heads, 4 bosses each.

1 third drawing frame, 2 heads, 6 bosses each.

1 patent disc regulating roving frame, 60 spindles, 10 spindles per head, 8 inches \times 4 inches bobbin.

3 spinning frames, $2\frac{1}{2}$ inches pitch, 200 spindles each, 1000 spindles.

The production of this system is about 66 bundles, or say, 420 lbs. of No. 30's yarn per day.

II. Two systems of long line machinery for No. 40's to 60's.

1 flaxter's patent sheet hackling machine, 6 tools.

2 spreaders or first drawing frames, 4 bosses each.

2 second drawing frames, 2 heads of 6 bosses each.

2 third drawing frames, 2 heads of 6 bosses each.

2 patent disc regulating roving frames, 60 spindles each, 12 spindles per head, 6 inches \times $3\frac{1}{2}$ inches bobbin.

10 spinning frames, 220 spindles each, $2\frac{1}{2}$ inches pitch, 2200 spindles. Production about 130 bundles, or 472 lbs. of No. 55's yarn per day.

III. Two systems of three cut line machinery for No. 40's to 120's (one for 40's to 70's, and one for 70's to 120's).

1 flax cutting machine.

1 P. Fairbairn and Co.'s patent double line of holder hackling machine.

2 spreaders or first drawing frames, 4 bosses each.

2 second drawing frames, 2 heads each, 6 slivers per head.

2 third drawing frames, 2 heads each, 8 slivers per head.

2 patent disc regulating roving frames, 72 spindles each, 12 spindles per head, 6 \times 3 inches bobbin.

5 spinning frames, 220 spindles each, $2\frac{1}{2}$ inches pitch, = 1100 spindles.

3 spinning frames, 244 spindles each, $2\frac{1}{2}$ inches pitch, = 1220 spindles.

Production about 65 bundles or 236 lbs. of No. 53's yarn per day, and about 50 bundles or 103 lbs. of No. 95's yarn per day.

IV. Two systems of long tow machinery for No. 10's to 25's.

1 breaker card, 4 feet diameter, 6 feet wide, doffed by rollers.

1 lap machine.

2 finisher cards, 4 feet \times 6 feet, with P. Fairbairn & Co's patent rotary gill drawing frames attached.

2 patent rotary gill drawing frames, 12 slivers each.

2 patent rotary gill disc regulating roving frames, 45 spindles each, 3 inches \times 4 inches bobbin.

3 spinning frames, 154 spindles each, 3 inches pitch for No. 10's to 18's = 552 spindles.

3 spinning frames, 200 spindles each, 2 $\frac{1}{2}$ inches pitch for No. 16's to 25's = 600 spindles.

Production about 29 bundles, or 483 lbs. No. 16's per day, and about 39 bundles or 512 lbs., No. 25's per day.

V. One system of cut tow machinery for No. 25's to 40's.

1 Breaker card, 4 feet diameter, 6 feet wide, doffed by combs.

1 Finisher card, with P. Fairbairn & Co's patent rotary gill drawing frame attached.

1 Screw gill second drawing frame, 3 heads each, 4 busses per head.

1 Screw gill third drawing frame, 3 heads each, 6 busses per head.

1 Screw gill patent disc regulating roving frame, 72 spindles, 12 spindles per head, 6 \times 3 $\frac{1}{2}$ inches bobbin.3 spinning frames of 220 spindles each; 2 $\frac{1}{2}$ inches pitch, = 660 spindles.

Production about 36 bundles, or 240 lbs. of No. 30's per day.

The reeling is generally carried on in the attic above the spinning room, and the number of reels required is about the same as the number of spinning frames.

Summary view.

There are 3200 spindles long line, producing 196 bundles, or, 890 lbs. of yarn per day.

1152	"	long tow,	"	78	"	800	"
2320	"	3 cut line,	"	115	"	340	"
640	"	cut tow,	"	86	"	240	"
7332 spindles				425 bundles	2270 lbs. of yarn per day.		

The waste in line spinning is generally about 10 per cent., and in tow spinning about 25 per cent., so that the quantity of raw flax required to produce the above stated quantity of yarn would be about 20 cwt. of flax for long line and long tow spinning, and about 6 cwt. of flax for cut line and cut tow spinning.

FLAX WEAVING LOOM

the other is provided with a wood sole, and is pressed by a strong spring against the

yarn wound upon the beam *n*. It will be seen that, as the yarn is taken off the beam *n*, and its diameter *c* is continually reduced, the lever *r* moves the fulcrum of the weighted lever *a*, and thus regulates the pressure upon the clamps *m* and *n*, causing an equal tension upon the yarn from the full to the empty beam; *a*, treadles, actuated by the cams *b*, driven by the wheels *c*, *d*, *e*, from the picking shaft *f*, *g*, *g*, shuttle boxes at each end of the going part; *h* *h*, arrangement of levers to conduct equally

ACB

each end of the gears *i* *i*. This loom has also, in addition to the ordinary stopping arrangement connected with the shuttle, one also for relaxing the reed in case the shuttle should be arrested in its course across the warp, whereby the danger, ordinarily incurred by that accident, of breaking many threads in the warp, is avoided; it will also be seen that the hands called picking hands are superseded by the ends of the picking levers striking the shuttle direct; thus, by these improvements, drills are currently woven in this loom at the rate of 120 to 130 picks per minute.

Of late extensive trials have been made to adapt the power-loom to the weaving of light linen fabrics. Previously it had been found that while coarse and strong flax fabrics, such as those made at Dundee, Arbroath, &c., in Scotland, and the drills made at Barnsley, could be produced by power as well and more cheaply than by hand, yet that the lighter fabrics, such as shirtings, cambrics, lawns, &c., would not bear the strain of the power-loom, or at all events that to make them of no good appearance as by the hand loom the manufacturer required to employ a dearer article of yarn, and so found that he could not compete with his neighbours who had hand-loom weavers. The scarcity of the latter in Ireland, during the last three or four years, and the advance in wages caused by the growing prosperity of the country, has directed the serious attention of the trade to the matter, and therefore manufacturers and machine makers have each zealously sought to remedy the defects that existed in the power-loom, as regards its application to the weaving of light linen fabrics, and to give repeated trials to new inventions. The consequence has been that, while four years ago there were only in Ireland fifty-two power-loom making linens of any kind, there are now nearly 3000, and these produce all kinds of flaxen fabrics of good quality, and fairly remunerative to the manufacturer. This branch of the manufacture is, however, as yet in an embryo state.

As respects other details of the subsequent processes which linens undergo before they are placed in the market, and also the general statistics of the entire trade in imports and exports, see BLEACHING, LINEN, &c.—J. M. A.

FLAX SEED. See LINSEED.

FLINT. (*Pierre à fusil*, Fr.; *Feuer stein*, Germ.) The fracture of this fossil is perfectly conchoidal, sometimes glossy, and sometimes dull on the surface. It is very hard, but breaks easily, and affords very sharp-edged splintery fragments; whence it is

a stone which strikes most copious sparks with steel. It is feebly translucent, has so fine and homogeneous a texture as to bear polishing, but possesses little lustre. Its colours are very various, but never vivid. The blackish-brown flint is that usually found in the white chalk. It is often white and opaque, loses its colour in the fire, and becomes greyish-white, and perfectly opaque. Flints occur almost always in nodules or tubercular concretions of various and very irregular forms. These nodules, distributed among the chalk, alongside of one another and almost in contact form extensive beds, interrupted, indeed, by a multitude of void spaces, so as to present, if freed from the earthy matter in which they are imbedded, a species of network with meshes, very irregular both in form and dimension.

The nodules of silex, especially those found in the chalk, are not always homogeneous and solid. Sometimes there is remarked an organic form towards their centre, as a madreporo or a shell, which seems to have served as their nucleus; occasionally the centre is hollow, and its sides are studded over with crystals of quartz, carbonate of iron, pyrites, concretionary silex or calcedony, filled with pulverulent silica nearly pure, or silex mixed with sulphur; a very singular circumstance.

Flints are observed to be generally humid when broken immediately after being dug out of the ground; a property which disappears after a short exposure to the air. When dried they become more brittle and more splintery, and sometimes their surfaces get covered at old fractures with a thin film or crust of opaque silex.

Flints calcined and ground to a powder enter into the composition of all sorts of fine pottery ware.

An important application of this siliceous substance was in the formation of gun-flints, for which purpose it was cut in a peculiar manner. The following characters distinguish good flint nodules from such as are less fit for being manufactured. The best are somewhat convex, approaching to globular; those which are very irregular, knobbed, branched, and tuberoso, are generally full of imperfection. Good nodules seldom weigh more than 20 pounds; when less than 2, they are not worth the working. They should have a greasy lustre, and be particularly smooth and fine grained. The colour may vary from honey yellow to blackish-brown, but it should be uniform throughout the lump, and the translucency should be so great as to render letters legible through a slice about one-fifth of an inch thick, laid down upon the paper. The fracture should be perfectly smooth, uniform, and slightly conchoidal; the last property being essential to the cutting out of perfect gun-flints. Although flint locks are now but rarely employed, the process of cutting the flints to shape possesses much interest.

Four tools are employed by the gun-flint makers.

First, a hammer or mace of iron with a square head, from 1 to 2 pounds weight, with a handle 7 or 8 inches long. The tool is not made of steel, because as hard metal would render the strokes too harsh, or dry, as the workmen say, and would shatter the nodules irregularly, instead of cutting them with a clean conchoidal fracture.

Second, a hammer with 2 points, made of good steel well hardened, and weighing from 10 to 16 ounces, with a handle 7 inches long passing through it in such a way that the points of the hammer are nearer the band of the workman than the centre of gravity of the mace.

Third, the disc hammer or roller, a small solid wheel or flat segment of a cylinder, parallel to its base, only two inches and a third in diameter, and not more than 12 ounces in weight. It is formed of steel not hardened, and is fixed upon a handle 6 inches long, which passes through a square hole in its centre.

Fourth, a chisel tapering and bevelled at both extremities, 7 or 8 inches long, and 2 inches broad, made of steel not hardened; this is set on a block of wood, which serves also for a bench to the workmen. To these 4 tools a file must be added, for the purpose of restoring the edge of the chisel from time to time.

After selecting a good mass of flint, the workman executes the four following operations on it.

1. *He breaks the block.* Being seated upon the ground, he places the nodule of flint on his left thigh, and applies slight strokes with the square hammer to divide it into smaller pieces of about a pound and a half each, with broad surfaces and almost even fractures. The blows should be moderate, lest the lump crack and split in the wrong direction.

2. *He clears or chips the flint.* The principal point is to split the flint well, or to chip off scales of the length, thickness, and shape adapted for the subsequent formation of gun flints. Here the greatest dexterity and steadiness of manipulation are necessary; but the fracture of the flint is not restricted to any particular direction, for it may be chipped in all parts with equal facility.

The workman holds the lump of flint in his left hand, and strikes with the pointed hammer upon the edges of the great planes produced by the first breaking, whereby the white coating of the flint is removed in small scales, and the interior body of the

flint is split here; after which he continues to detach similar small portions from the chosen mass.

These small portions are nearly an inch and a half broad, two inches and a half long, and about one-sixth of an inch thick in the middle. They are slightly convex below, and consequently leave in the part of the lump from which they were separated a space slightly concave, longitudinally bordered by two somewhat projecting straight lines or ridges. The ridges produced by the separation of the first scale must naturally consist of nearly the middle of the subsequent pieces; and such scales alone as have their ridges thus placed in the middle are fit to be made into gun-flints. In this manner the workman continues to split or chip the mass of flint in various directions, until the defect is usually found in the interior render it impossible to make the requisite fracture, or until the piece is too much reduced to sustain the smart blows by which the flint is divided.

2. *He finishes the gun-flint.* Five different parts may be distinguished in a gun-flint. 1. The striking face or bevel part, which is in contact with the hammer of the lock. Its thickness should be from two to three twelfths of an inch; for if it were thicker it would be too liable to break; and if more obtuse, the detonations would be less vivid. 2. The sides or lateral edges, which are always somewhat irregular. 3. The lock or thick part opposite the tapering edge. 4. The under surface, which is smooth and rather concave. And, 5. The upper face, which has a small square plane between the tapering edge and the back, for entering into the upper claw of the clock.

In order to fashion the flint, those scales are selected which have at least one of the above-mentioned longitudinal ridges; the workman fixes on one of the two tapering borders to form the striking edge, after which the two sides of the stone that are to form the lateral edges, as well as the part that is to form the back, are successively placed on the edge of the chisel in such a manner that the convex surface of the flint, which rests on the forefinger of the left hand, is turned towards that tool. Then with the disc hammer he applies some slight strokes to the flint just opposite the edge of the chisel underneath, and thereby breaks it exactly along the edge of the chisel.

4. The finishing operation is the *trimming*, or the process of giving the flint a smooth and equal edge; this is done by turning up the stone and placing the edge of its tapering end upon the chisel, in which position it is completed by five or six slight strokes of the disc hammer. The whole operation of making a gun-flint, which I have used so many words to describe, is performed in less than one minute. A good workman is able to manufacture 1000 good chips or scales in a day (if the flint balls be of good quality), or 500 gun-flints. Hence, in the space of three days, he can easily cleave and finish 1000 gun-flints without any assistance.

Flints form excellent building materials; because they give a firm hold to the mortar by their irregularly rough surfaces, and resist, by their nature, every vicissitude of weather. The counties of Kent, Essex, Suffolk, and Norfolk contain many substantial specimens of flint-masonry.

FLOCK and FLOCKS. The first is finely powdered wool, used when dyed of various colours to prepare paper hangings.

The second is a name given to the refuse or waste of cotton and wool, and is used for stuffing mattresses.

FLOCK PAPER. Paper prepared for walls by being sized in the first instance, either over the whole surface or over special parts, constituting the pattern only, and then powdering over it flock or powdered wool which had been previously dyed.

FLOOKAN or FLUKAN. The name given by the Cornish miners to veins filled wholly with clay. This is usually applied to such veins or lodes as are at right angles, or nearly so, to the true metalliferous lodes.

FLOOR CLOTH MANUFACTURE has become of late years a very large branch of trade. The cloth is a strong somewhat open canvas, woven of flax with a little hemp, and from 6 to 8 yards wide, being manufactured in appropriate looms, chiefly at Dundee. A piece of this canvas, from 60 to 100 feet in length, is secured tight in an upright open frame of wooden bars, in which position it is brushed over with glue size, and rubbed smooth with pumice stones; it next receives the foundation coats of paint, 2 or 3 in number, first on the back side, and then on the front. The foundation paint, made with linseed oil and ochre, or any cheap colouring matter, is too thick to be applied by the brush, and is therefore spread evenly by a long narrow trowel, held in the right hand, from a patch of it laid on just before with a brush in the left hand of the workman. Each foundation coat of the front surface is smoothed by pumice stone when it is hard enough to bear the operation. When both sides are dry, the painted cloth is detached from the frame, coiled round a roller, and in this state transferred to the printing room, where it is spread flat on a table, and variously figured and coloured devices are given to it by wooden blocks, exactly as in the block

printing of calicoes or papers. The blocks of the floor cloth manufacture are formed of two layers of white deal and one of pear tree timber, placed with their grain crossing one another alternately. There is a block for each colour in the pattern, and in each block those parts are cut away that correspond to the impressions given by the others: a practice now well understood in the printing of two or more colours by the press. The faces of the blocks are so indented with fine lines, that they do not take up the paint in a heavy dash from the flat cushion on which it is spread with a brush, but in minute dots, so as to lay on the paint (somewhat thicker than that of the house painter) in a congruity of little dots or teeth, with minute sutures between. Applied in this way, the various pigments lie more evenly, are more slightly, and dry much sooner than if the prominent part of the block which takes up the colour were a smooth surface. The best kinds of floor cloth require from two to three months for their production.

From the use of the sulphate of barytes with the white lead, sometimes to the extent of 75 per cent. of the former, not merely in the foundation paint, but in the subsequent colours with which the canvas is painted, there is a very general complaint that the floor cloths for halls, &c., where they are necessarily exposed to washing, very soon lose their colours and become bare, the barytes washing out, and, of course, removing at the same time the lead and other colours. See WHITE LEAD.

FLOREN. A mining term; tin ore scarcely perceptible in the stone; tin ore stamped very small.—*Pyrie*.

FLOSS, of the puddling furnace, is the fluid glass floating upon the iron produced by the vitrification of the oxides and earths which are present. See IRON.

FLOSS-SILK (*Fiduelle*, *Bourre de soie*, *fleur*, *Pis*) is the name given to the portions of unravelled silk broken off in the flature of the cocoons, which is carded like cotton or wool, and spun into a soft coarse yarn or thread, for making bands, shawls, socks, and other common silk fabrics. The floss or fleur, as first obtained, must be steeped in water, and then subjected to pressure, in order to extract the gummy matter, which renders it too harsh and short for the spinning-wheel. After being dried it is made still more pliant by working a little oil into it with the hands. It is now ready to be submitted to the reeling engine, and it is spun upon the flax wheel.

The female peasants of Lombardy generally wear clothes of homespun floss-silk. Of late years, by improved processes, fine fabrics of this material have been produced, both in England and France. M. Ajac, of Lyons, manufactures a variety of scarfs and square shawls of *bourre de soie*, closely resembling those of *cachemire*.

FLOUR. The finely ground meal of wheat, and of any other corns or *cerealia*. See BRAN.

Since the analyses of grains represent the total chemical constituents of the flour, and the cell in which it is contained, a few analyses from the researches of Way and Ouston are given:—

Adulterations of, to detect. — The first method is by specific gravity. If potato flour be added, which is frequently done in France, since a vessel which contains one pound of wheat flour will contain one pound and a half of the fecula, the proportion of this adulteration may be easily estimated. If gypsum or ground bones be mixed with the flour, they will not only increase its density still more; but they will remain after burning away the meal as ashes.

The second method is by ascertaining the quantity of gluten which the suspected sample will afford, see the article *FLAXEN*. The two following chemical criteria may also be employed.

1st. Nitric acid has the property of colouring wheat flour of a fine orange yellow, whereas it affects the colour neither of fecula nor starch.

2nd. Muratic acid colours good wheat flour of a deep violet, but dissolves fecula or starch, and forms with it a light and colourless viscous fluid, decomposable by alkalis.

Sulphate of iron renders an infusion of pure flour somewhat yellow, and imparts a bottle green to that which is adulterated with bean meal. (*Lamotte*.) Nitric acid and ammonia poured successively on good flour shows nothing remarkable; but bean meal strikes a deep red colour. — (*Idem*.)

The amount of ash left by the flour has been proposed by Louyet as a test of its purity. He says, — Wheat flour yields on the average 0.8 per cent.; rye flour, 1.0; bean and pea meal, 3; linseed meal, 10 per cent. of ash."

FLOWERS. The name formerly given to those substances which were obtained by sublimation; as the flowers of sulphur, the flowers of Benjamin, &c.

FLOWERS, ARTIFICIAL, MANUFACTURE OF. The art of representing by flowers, leaves, plants, &c., vegetable nature in her ornamental productions, constitutes the business of the artificial florist. The Italians appear to have been the first people in Europe who excelled in the art of making artificial flowers; but of late years the French have been most ingenious in this branch of industry.

Ribbons folded in different forms and of different colours were originally employed for imitating flowers, by being attached to wire stems. This limitation soon gave way to that by feathers, which are more delicate in texture, and more capable of assuming a variety of flower-like figures. But a great difficulty was encountered in dyeing them with due vivacity. The savages of South America manufacture perfect feather flowers, derived from the brilliant plumage of their birds, which closely resemble the products of vegetation. The blossoms and leaves are admirable, while the colours never fade.

The Italians employ frequently the cocoons of the silk-worm for this purpose; these take a brilliant dye, preserve their colour, and possess a transparent velvety appearance, suitable for petals. Of late years, the French have adopted the finest cambric for making petals, and the taffeta of Florence for the leaves. M. de Bernardiere employs whalebone in very thin leaves for artificial flowers; and by bleaching and dyeing them of various hues, he has succeeded in making his imitations of nature to be very remarkable.

Gutta percha dissolved in benzole, and freed from all impurities, will when spread out on a sheet of glass dry into a beautifully white and delicate film, of great strength, and capable of receiving any colour. This has been employed in Paris in the manufacture of flowers. Vegetable parchment (paper prepared by the action of sulphuric acid) has been employed for the same purpose in this country. See *VEGETABLE PARCHMENT*.

The colouring matters used in flower dyeing are the following: —

For red; carmine dissolved in a solution of carbonate of potash.

For blue; indigo dissolved in sulphuric acid, diluted and neutralised in part by Spanish whitening.

For bright yellow; a solution of tarmeric in spirit of wine. Cream of tartar brightens all these colours.

For violet; archil, and a blue both.

For lilac; archil.

Some petals are made of velvet, and are coloured merely by the application of the finger dipped in the dye.

FLUATES, more properly *fluorides*. (Eng. and Fr.; *Fluassure*, Germ.) Compounds of fluorine and the metals; as fluor spar, for example, which consists of fluorine and calcium.

Fluor spar consists of —

Fluorine	-	-	-	45.7
Calcium	-	-	-	51.3

Cryolite —

Fluorine	-	-	-	54.2
Sodium	-	-	-	32.8
Aluminium	-	-	-	15.0

Chiolite —

Fluorine	-	-	-	57.53
Sodium	-	-	-	23.78
Aluminium	-	-	-	18.69

Fluolite is fluorine and aluminium, a rare mineral found at Stenngwynne in Cornwall.

FLUKES. See ANCHOR.

FLUORESCENCE, the name given to a peculiar phenomenon rendered evident by many crystals of fluor spar. If we look through a crystal of fluor spar it will appear yellow or green as the case may be; now if we look at it, the light falling upon the surface on which we look, it will appear beautifully blue or purple. Mr. Stokes, to whom we are indebted for a very exact examination of the whole of the phenomena of this class, refers this effect to an alteration of the refraction of the ray by the first surface upon which it falls. Sir John Herschel first drew attention to this peculiar conduction as exhibited in a solution of sulphate of quinine in water slightly acidulated with sulphuric acid. Here we have a perfectly colourless solution when we look through it, which sends back to the eye fine blue rays when we look at the surface on which the solar rays fall. Sir John Herschel referred this to epipolar dispersion, or dispersion from the first surface of the fluid on which the light fell. There are many substances which appear to possess this property of altering the refraction of rays, or are fluorescent. Beyond this brief explanation, we cannot afford space in this dictionary to deal with the subject. We must refer those interested to the *Philosophical Transactions*, in which Mr. Stokes's communications appeared.

FLUORINE. The elementary base of fluoric acid, which has never yet been isolated.

The power of liberating a principle from fluor spar, which would etch glass was known as far back as 1670; Scheele, in 1771, examined fluoric acid, and regarded it as an oxygen compound with an unknown element. Ampere, in 1810, determined the fluoric acid was a compound of hydrogen and fluorine.

Fluorine combines with most of the metals, and with hydrogen, boron, silicon, sulphur, and phosphorus; with chlorine, bromine, iodine, and oxygen it exhibits no tendency to unite.

Symbol, F, equivalent, 19.

FLUOR SPAR. (*Chaux fluatée*, Fr.; *Spaß fluor*, Germ.) This mineral often exhibits a variety of vivid colours. It crystallises in the cubic (monometric) system, with regular octahedral and tetrahedral cleavages; spec. grav. 3.14 to 3.19; H = 4.0; scratches calc spar, but is scratched by a steel point; usually phosphorescent with heat; at the blowpipe decrepitates and fuses into an opaque bead; acted on by the acids with disengagement of a vapour which corrodes glass; its solution affords precipitates with the oxalates, but not with ammonia. Its constituents are, fluorine, 49.7; calcium, 51.3 in 100.

Fluor spar occurs subordinate to metallic veins; as to those of lead, in Derbyshire and Cumberland; of tin and copper, in Cornwall, and in Saxony and Bohemia; but it is found also in masses or veins, either in crystalline rocks, associated with quartz, barytes, &c., as in Auvergne, Forez, Vosges, Norberg in Sweden; Norway; Petersburg; Grouzet, in Scotland, &c.; or among secondary limestones, slates, and sandstones, in Derbyshire, Cumberland, Cornwall, and New Jersey. It exists also in the amygdaloids of Scotland, and in the volcanic products of Monte Somma at Vesuvius. The variously coloured specimens, called Derbyshire spar, are worked upon the turning lathe into vases and other ornamental objects.

A very beautiful variety, which has been much used for ornamental purposes, known from its colour as "Blue John," has been obtained from Tray Cliff near

Castleton, Derbyshire. The beautiful colour of the natural fluor has been successfully imitated by exposing some of the common varieties to heat.

Fluor spar is employed to a considerable extent in the production of hydrofluoric acid and for etching on glass. It is also used by lead smelters as a flux. The beautiful phenomenon of *fluorescence* is so named from the fact that many of the fluor spars have the power in a high degree of thus affecting the rays of light. See FLUOR. REACTOR.

FLUVIATILE (*Fluvius*, a river), belonging to a river.

FLUX (Eng. and Fr.; *Fluss*, Germ.) signifies any substance capable of promoting the fusion of earths or metallic ores by heat. White flux is the residuum of the deflagration, in a red hot crucible, of a mixture of two parts of nitre and one of cream of tartar. It is in fact merely a carbonate of potash. Black flux is obtained when equal parts of nitre and tartar are deflagrated. It owes its colour to the carbonaceous matter of the tartaric acid, which remains unconsumed; the quantity of nitre being too small for that purpose. The presence of the charcoal renders this preparation a convenient flux for reducing calcined or oxidised ores to the metallic state. Limestone, fluor spar, borax, and several earthy or metallic oxides, are employed as fluxes in metallurgy. See METALLURGY.

FLY POWDER. Under this name they sell on the continent the black coloured powder obtained by the spontaneous oxidisation of metallic arsenic in the air. Various preparations of white arsenic are used for the same purpose in this country. King's yellow is much used; it should be made by boiling together sulphur, lime, and white arsenic, but much that is sold is merely arsenic and sulphur mixed.

Objecting on principle to the familiar use of arsenic and dangerous substances, a preference may be given to a substitute for the above, made by boiling quassia chips into a strong decoction and sweetening with loaf sugar. This seems to have deadly power over the flies, who can scarcely quit the liquid without imbibing a deadly potion, and they are seen to fall from the ceilings and walls of the rooms soon afterwards. Many of these compounds for killing flies are supposed by their odour to attract flies into the rooms.

The inconvenience to manufacturers and others from flies, may be obviated in many cases where apartments are required to be kept as free as possible from them, by reference to facts recorded by Herodotus, of fishermen surrounding themselves with their nets to keep off the gnats. We are indebted to William Spence, Esq. F.R.S., for some very curious particulars respecting the common house fly communicated in a paper to the Entomological Society. The common house fly, will not in general pass through the meshes of a net. The inhabitants of Florence and other parts of Italy are aware of this fact, and protect their apartments by hanging a network up at the windows, thus at all times the doors and windows may be kept wide open by hanging a light network over the aperture; the meshes may be of considerable width, say enough for several flies on the wing to pass through, and no fly will attempt to pass, unless there be a strong light (another window opposite, or reflection from a looking-glass). A knowledge of this simple means of protection from flies on the wing may prevent inconvenience from these intruders, and obviate the necessity for poisonous to destroy them.—T. J. P.

FODDER, is the name of a weight by which lead and some other metals were sold in this country; but it is now rarely used. It varied in its amount in different parts of the kingdom, being 19½ cwt. at Hull; 21 cwt. at Newcastle; 22 cwt. at Stockton; 21 cwt. in Derbyshire.

FOILS. Thin sheet copper silvered and burnished, and afterwards coated with transparent colours mixed with isinglass, employed by jewellers to improve the brilliancy of pastes and inferior stones. The foil is inclosed in the setting, and entirely covers the back of the stone, to which it imparts much of its own brilliancy.

FOILS. Thin leaves of metal, usually alloys, of various colours, employed principally for heightening the brilliancy of artificial gems.

FONDUS, is the name given by the French to a particular style of calico printing resembling the rainbow, in which the colours are graduated or melted (*fondus*) into one another, as in the prismatic spectrum. See CALICO PRINTING for a description of the process.

FOOD. See NUTRITION.

FOOTWALL, a mining term. The "wall" or side of the rock under the mineral vein: it is as continuously called the *underlying wall*.

FOOTWAY, a mining term. The ladders by which the miners descend and ascend.

FORGE (Eng. and Fr.; *Forger*, Germ.) is the name either of the furnace, where wrought iron is hammered and fashioned with the aid of heat, or the great workshop where iron is made malleable. The former is called a smith's forge, the latter a shingling mill. See IRON.

Fig. 867 represents a portable track forge, of a very commodious construction. A is the cylindric leather bellows, pressed down by a helical spring, and worked by means of the handle at n, which moves the horizontal piston, with its two attached eccentric levers and chains. t is the pipe which conducts the blast to the nozzle at u. The hearth may be covered with a thin fire-tile or with cinders. v is a vice fixed to the strong rectangular frame. This apparatus answers all the ordinary purposes of a smith's forge; and is peculiarly adapted to ships, and to the execution of engineering jobs upon railways, or in the country. The height is 2 feet 6 inches; the length is 2 feet 9 inches; the width 2 feet. Weight about 2 cwt.

Holzappel describes another portable forge of his own construction, possessing many advantages.

With the manipulations of the forge, it is not the province of this work to deal.

FORK, a mining term. A mine is said to be "in fork," or an engine to have the "water in fork," when all the water is drawn out.

FORMATION. A geological term, which is used to signify a group of rocks, referred to a common origin, or belonging to the same period.

FORMATES. Compounds with formic acid. See *Ure's Dictionary of Chemistry*.

FORMIC ACID. (*Acide Formique, Fr.; Ameisensäure, Germ.*) The acid which exists in the bodies of ants, associated with malic acid.

Formic acid was obtained artificially, originally by Fisher of Leeds in 1670, and subsequently by Dr. Hulse, by distilling red ants.

It may be prepared by boiling 1 part of starch with 4 of sulphuric acid, and 4 of water, allowing the liquor to cool, and adding gradually 4 parts of the black oxide of manganese and distilling. For the reactions which take place see *Ure's Chemical Dictionary*. Its formula is CHGHO . It is a clear colourless fluid, which crystallises below 32° into brilliant plates.

FORMULÆ, CHEMICAL. See **EQUIVALENTS**.

FORMYL. The hypothetical base of formic acid.

FOSSIL. (*fossils*, anything dug from the earth). Formerly all minerals were called fossils, but the word is now restricted to express the remains of animals and plants found buried in the earth.

FOSSIL IVORY. The bones and tusks of elephants and mammoths are found in eastern Siberia, and along the shores of the Arctic sea, in great abundance. The tusks are collected for sale, but it is much less valuable than the recent ivory.

FOUNDING. In foundries attached to blast-furnaces, where from 20 to 30 tons of iron are made *per diem*, the moulds are generally mere troughs cut in the sand into which the melted metal flows and cools in contact with the air. The surfaces of the castings made in this manner present appearances which vary according to the quality of the iron.

The kinds of iron adapted for founding purposes are those which are most fluid when melted, and which contain most carbon, and are called Nos. 1 and 2. They are distinguished by the surface of the pig of iron, which was exposed to the air during cooling, being smooth, and presenting a slightly convex figure. The surfaces of Nos. 3 and 4 pig-iron, and of the white crystalline pig iron (most suitable for making into wrought iron) present a concave figure, and the surfaces are very irregular and pitted with holes. The colour of the fracture, and the closeness of the grain, also indicate the proportion of carbon in pig-iron.

The mixtures of metal, melting temperatures of metal, &c., require the closest observation on the part of the workmen and firemen who practice iron founding, and these mechanics are in the practice of observing differences so minute that they cannot be appreciated by the chemist, or expressed in words.

Machinery has enabled the modern founder, by means of railways, turn-tables,

travelling cranes, and steam-power, to move at will the heaviest masses without confusion and with great expedition; but nothing but the traditions of the factory, and the constant habit of observation will enable him to conduct properly the melting and casting of metal so as to arrive at certain results.

This is proved by the constant failures of those who undertake to make descriptions of castings, of which they have had no previous knowledge.

Each branch of foundry work must be studied in detail, and we can only pretend to indicate those directions in which progress has been and is being made.

Pottery.—The processes of iron smelting and the construction of furnaces having been described under other heads, the remaining part of the business of a foundry, viz., that which relates to the preparation of the moulds and moulding, will now be described.

Moulding.—The art of moulding is one of the most important processes carried on in a foundry, and the success of the founder is directly proportioned to the skill and ingenuity brought to bear upon the production of the patterns and the system of moulding.

Before metals can be cast into the variety of shapes in which they are wanted, patterns must be prepared of wood or metal, and then moulds constructed of some sufficiently infusible material capable of receiving the fluid metal, and retaining it without uniting with it until it has solidified.

A mixture of sand and loam (packed tightly into metal boxes, called *flasks*) is generally chosen as the material for making moulds, and is employed advantageously for several important reasons.

Flasks.—In modern foundries a system has been invented, by which flasks of any dimensions may be constructed by means of bolting together a number of rectangular frames of cast-iron, so arranged as to admit of being easily connected together.

When the particular castings for which the flask has been constructed, or rather compounded, are completed, the separate pieces are unbolted, and are ready to be combined in some new form appropriate to the dimensions of the pattern next to be moulded in them.

The loss of capital, &c., invested in flasks, only occasionally used, is thus saved, as well as loss of time in searching for the size required. The space devoted, on the old system, to the reception of flasks belonging to a foundry was very large, and this may now be appropriated to other purposes.

Sand and loam.—Founders formerly used, on account of price, the description of sand most accessible to them, but at the present time, the convenience and cheapness of railway carriage has enabled special qualities of sand to be delivered to all parts of England.

For founding purposes sand is much improved by the admixture of coke, crushed and reduced to a fine powder, and a mill for this purpose is as necessary in every large foundry as those for grinding and mixing loam.

Moulding sand must be a mixture of a large quantity of silex and a small quantity of alumina—the property of the latter material being to cement the grains of silex together. Loam consists of the same materials mingled in opposite proportions.

The preparation of loam for those purposes for which sand is not adapted, is an important duty in a foundry, for a great quantity of loam cores have to be made, and dried in proper ovens, which is a tedious operation.

Many castings, such as the screws for steamers, are more conveniently cast in moulds constructed of wet loam. These are shaped to the required form when the clay is moist, and then carefully dried afterwards.

Other castings are of such peculiar shapes that they can only be produced in moulds that take in a vast number of pieces. These moulds are then formed of a number of pieces of hardened sand, held together by strips of iron or of plaster, if the sand used is not coherent enough of itself.

Compounds of silex and alumina are very infusible, and when moistened with water and faced with carbonaceous matter, they are capable of receiving the most delicate impressions from the patterns which the founder employs.

Grains of sand are so irregular in shape themselves that they leave innumerable irregular spaces between them, and these intervals form a net work of channels which permit the rapid escape of the gases, which are so violently generated by the contact of hot metal falling upon wet sand.

Machine Castings.—Every year, engineers order castings to be prepared of more difficult and complicated forms, and with greater perfection of surface than they have required before.

The reason of this is, that with the progress of the mechanical arts larger and stronger machines are continually being introduced. In these machines greater steadiness of cast-iron frame work is necessary, than can conveniently be obtained when the frame is made out of a number of pieces of iron cast separately and then bolted together. It would be impossible to mould large frames with pieces projecting on all sides (prepared to receive the moving parts of the machines), and jutting out

in contrary directions, in any flask filled with wet sand, for the pattern never could be removed without destroying the impression. To meet these difficulties the modern ironfounder has had to follow those plans which were first proved practicable by those who have devoted themselves to casting bronze statues. In founding, as in so many other branches of manufacture, the discoveries made in prosecuting the fine arts have been advantageously adopted by those engaged in works of utility.

False Cores.—The introduction of the drawbacks, or false cores, made of sand pressed hard (and admitting of taking to pieces by joints, at each of which a layer of parting sand is prepared), and for figure casting, enables the moulder to work at his leisure, without fearing that his mould may tumble to pieces, and also enables him to fashion these drawbacks or cores into the most complicated forms, with the power to remove them while the pattern is removed, and build them up again round the empty space (formerly occupied by the pattern) with the greatest facility and accuracy.

The workmen, whose occupation is to knead the sand into the forms required by the founder, are termed moulderers, and they form a very numerous body of mechanics, demanding and receiving high wages.

The moulder has often only his sand, his flasks, cranes, and a few simple tools (for smoothing rough places, and for repairing the places in the sand where the mould has broken away during the lifting of the pattern); he has to make proper arrangements for the exit of the atmospheric air which leaves the mould as the fluid metal takes its place; and he is expected to produce an exact copy in metal from any pattern, simple or complicated, which may be brought before him.

It will be evident that to produce a good result with such imperfect appliances as the ordinary moulder uses, a skilful workman must be employed, and time expended in proportion to the difficulty of the operations to be performed.

Where only a few impressions from a model are required, it is not worth while to spend money in making expensive patterns, or providing those appliances which may enable patterns to be moulded with facility and little skill; but where thousands of castings are wanted of one shape, it is expedient to spend money and skill on patterns and tools, and reduce the work of the moulder to its minimum.

Management.—The best managed foundry is not that in which good castings are obtained by the employment of skilled workmen at a great expense, and without trouble or thought on the part of the principal, but rather that in which the patterns have been constructed with a special reference to their being cast with the minimum of skill and the maximum of accuracy. It is only by the forethought and calculation of the manager that subsequent operations can be reduced to their smallest cost; and in the foundry, as in all other manufactories, the true principles of economy are only practised where the head work of one person saves the manual labour of a large number.

Improvements.—The attention of founders has been turned—1st, to the methods by which the labour of making moulds in sand might be reduced; 2nd, to the introduction of improvements in the mode of constructing patterns and moulds; and 3rd, to the manufacture of metallic moulds for those purposes for which they could be applied. A great progress has been made during the last twenty years in these different directions.

Machine Moulding.—In the large industry carried on for the production of cast-iron pipes for the conveyance of water and gas, machinery has been applied so that the operation of pipe-moulding is performed almost without manual labour, with great rapidity and precision. The cost of pipes at the present time is only about 2*l.* per ton above the value of pig-iron, out of which they are made. A sum very small when it is considered that the iron has to be re-melted, an operation involving both a cost of fuel and a loss of 5 to 20 per cent. of the iron in the spout. An ingenious machine for moulding in sand, spur and bevel wheels of any pitch or diameter has been employed in Lancashire; the advantage being that the machine moulding-tool acts directly upon the sand without the intervention of any pattern or mould. In any large foundry there is an enormous accumulation of costly wheel-patterns, taking up a great deal of space, and these can now be dispensed with by substituting the wheel moulding machine. Railway chairs are moulded in a machine; and plough shares, which although only weighing a few pounds each, are sold at the low rate of 5*l.* a ton, are moulded in a machine.

Plate Casting.—Under the next class of improvements the introduction of plate-casting has been the most fruitful of good results.

One great source of expense and trouble in a foundry is the injury done to patterns and to their impressions in the sand by the necessity, under the ordinary system of moulding, of striking the pattern, or pushing it first in one direction and then in another in order to loosen it. Now, the object of the machinist is to construct all his spindles, bearings, bolts, and wheels, of specified sizes, and then to cast the framing of his machine so accurately that the working parts may fit into the frame without any manual labour. In order to effect this, every projection and every aperture in

the casting must be at an exact distance, and this can only be attained by employing such a system as that of plate-casting, where the pattern is attached firmly to a plate, and it is impossible for the moulder to distort or injure the impression. Plate-casting has been long known, but was practically confined for many years to the production of small articles, such as cast nails and rivets.

In a plate-mould for rivet-casting, the shafts of the rivets are attached to one side of the plate, which is $\frac{1}{2}$ in. thick, and planed on both sides. The heads of the rivets are on the opposite side of the plate. The guides on the upper and lower flask admit the plate to fit between them, and when the plate is withdrawn the upper and lower flask close perfectly, and are in all respects like ordinary moulders' flasks. The principle of moulding is very simple, and can be performed without skilled

A, sand.

B B, flask.

R R, rivet pattern.

P, plate.

labour ten times as fast as ordinary moulding, and with far greater accuracy. The plate is inserted between the upper and lower flasks, and sand is filled in; the plate is then withdrawn by simply lifting it; the guides prevent any shaking in this operation; when the flasks are closed the impression of the head of each rivet is exactly perpendicular to its shaft. The first expense of patterns and plates of this description is large, but the accuracy and rapidity of the process of moulding is so advantageous as to cause us to look to the applications of plate-castings becoming very extensive, since the requirements of the machine-maker demand every year better castings at lower prices.

When both sides of a pattern are symmetrical one half only need be attached to the smooth plate, the other face of the plate being left blank. An impression of the pattern must be taken off both in the upper and lower flask, and when these are united the result will be the same as if both sides of the plate had been moulded from. For unsymmetrical patterns both sides of the plate must be employed. The system of using plates with apertures in them, through which patterns could be pushed and withdrawn by means of a lever, was first employed in casting brass nails. A modification of this system has been extensively employed at Woolwich for moulding shot and shells, in the following manner:—

Shell Casting.—A circular aperture is made in a horizontal planed plate of iron, two inches thick. Through this a sphere of iron, of the same diameter as the aperture, is pushed until exactly a hemisphere appears above the plate. The lower flask is put up to the plate, and sand filled in; the lever being relieved the sphere falls by its own weight; the lower flask is removed and the upper flask put on the plate; the sphere is pushed through the plate as before, sand filled in, with great rapidity and accuracy.

The sand cores for filling up that part of the shell which is to be hollow are also carefully and quickly made at Woolwich. The halves of the core-mould, open and shut with a lever, so that the bad plan of striking the core-mould is avoided as completely as the bad plan of striking the pattern is in the process of moulding shot and shell.

Theory of Casting.—Before leaving the subject of the use of sand moulds, we may remark that iron and brass castings with a perfect surface can only be produced when the mould is well dried and heated, so as to drive out any moisture from the apertures between the grains of sand. By this means channels are opened for the rapid escape of the heated air and gas expelled by the entrance of the fluid metal into the mould, and the surface of the metal is not cooled by its contact with damp or cold sand. It is also well to mix charcoal dust, or coke dust, with the sand; and for fine castings to cover the surface of the sand with a coating of charcoal dust. The object of this proceeding is to reduce the oxide which may be present in the metal. This operation of reducing the oxide of a metal instantaneously is performed with the greatest certainty by this simple means, invented, probably, by the earliest metallurgists. By

incorporating a quantity of charcoal or coke-dust with the sand, or facing the sand with carbonaceous matter, any oxide of the metal which may be flowing amongst the pure metal is at once reduced. Sand (being a non-conductor) does not abstract the heat from the fluid metal rapidly, and, therefore, solidification of the metal takes place comparatively regularly and equally throughout the mass; when one part of the casting solidifies before the adjoining part, flaws often occur, and to avoid these the skill of the practical founder is necessary in arranging for the entrance of the metal at the proper point, and for the exit of the air.

We next proceed to the third class of improvements in moulding, that of the extension of the application of metallic moulds.

Metal Moulds.—The practice of casting bronze weapons in moulds made of bronze (blackened over on their surface to prevent the fluid metal uniting with the mould) appears to have been a very general one among the ancients.

Some moulds of this description have been discovered amongst the Celtic (?) remains disseminated in different parts of Europe.

The facility for the escape of the heated air and gases from the sand moulds into which liquid metal is poured, is so much greater than that from moulds of metal, that at the present time neither brass nor iron is poured into metallic moulds, except when a particular purpose is to be attained, viz., that of chilling the surface of the iron and making it as hard as steel. Iron cannot be chilled or hardened in a sand mould.

Chilled Iron.—This process of casting in metal moulds was once supposed to be a modern invention; but it now appears, from the metal moulds discovered among the remains of the Celtic race throughout Europe, that the bronze weapons of the people who preceded the Romans were generally cast in metallic moulds, and not in sand. Chilled castings have been brought to great perfection by Messrs. Ransome, of Ipswich. Their chilled ploughshares and chilled railway chairs are cast in moulds of such a construction that the melted iron comes in contact with iron in those parts of the moulds, where it is wanted to be chilled. A section of the casting shows the effect of chilling.

Zinc.—In casting zinc (a cheap and abundant metal), which fuses at a low temperature, metallic moulds may be most advantageously used. It is, however, necessary to heat the iron or brass mould nearly to the temperature of melting zinc, in order that the rapid abstraction of heat from the fluid metal may be prevented. The preparation of metal moulds, and the casting soft metal in them is now an extensive and important industry on the Continent, for ornamental zinc castings have suddenly come into extensive use in consequence of the discovery of the electrolytic process. When covered with a thin coating of brass or copper by a galvanic battery, zinc may be bronzed so as to present almost the exact external appearance of real bronze at a tenth of the cost.

When metal moulds are used their first cost is very great, as they must be made in numerous separate pieces so as to liberate the castings. The joints and ornaments have to be chased and accurately fitted at a great expense. Their use, however, requires no skill in the workman, and the rapidity with which the zinc is cast, the mould taken to pieces, and the casting removed, renders the operation a very rapid and economical one —A. T.

Such is a general view of the practice of founding. The details, however, which are contained in the original article in the last edition of this dictionary, appear so valuable that that article is retained in addition to the above.

The essential parts of a well-mounted iron foundry, are,

1. Magazines for pig irons of different qualities, which are to be mixed in certain proportions, for producing castings of peculiar qualities; as also for coal, coke, sands, clay, powdered charcoal, and cow-hair for giving tenacity to the loam mouldings.

2. One or more coke ovens.

3. A workshop for preparing the patterns and materials of the moulds. It should contain small edge millstones for grinding and mixing the loam, and another mill for grinding coal and charcoal.

4. A vast area, called properly the foundry, in which the moulds are made and filled with the melted metal. These moulds are in general very heavy, consisting of two parts at least, which must be separated, turned upside down several times, and replaced very exactly upon one another. The casting is generally effected by means of large ladles or pots, in which the melted iron is transported from the cupola where it is fused. Hence the foundry ought to be provided with cranes, having jibs movable in every direction.

5. A stove in which such moulds may be readily introduced, as require to be entirely deprived of humidity, and where a strong heat may be uniformly maintained.

6. Both blast and air furnaces, capable of melting speedily the quantity of cast-iron to be employed each day.

7. A blowing machine to urge the flames in the furnaces.

Fig. 869, represents the general plan of a well-mounted foundry.

a, is a cupola furnace: it is capable of containing 5 tons of cast-iron.

a', is a similar furnace, but of smaller dimensions, for bringing down 1½ tons.

a'', is a furnace like the first, in reserve for great castings.

h h b b, a vast foundry apartment, whose floor to a yard in depth, is formed of sand and charcoal powder, which have already been used for castings, and are ready for being dug up into a substratum, or to be scooped out when depth is wanted for the moulds. There are besides several cylindrical pits, from five to seven yards in depth, placed near the furnaces. They are lined with brick work, and are usually left full of moulding sand. They are emptied in order to receive large moulds, care being had that their top is always below the orifice from which the melted metal is tapped.

These moulds, and the ladles full of melted metal are lifted and transported by the arm of one or more men, when their weight is moderate; but if it be considerable,

869

they are moved about by cranes, whose vertical shafts are placed at *c*, *d*, *e*, in correspondence, so that they may upon occasion transfer the load from one to another. Each crane is composed principally of an upright shaft, embraced at top by a collet, and turning below upon a pivot in a step; next of a horizontal beam, stretched out from nearly the top of the former, with an oblique stay running downwards, like that of a galloway. The horizontal beam supports a movable carriage, to which the tackle is suspended for raising the weights. This carriage is made to glide backwards or forwards along the beam by means of a simple rack and pinion mechanism, whose long handle descends within reach of the workman's hand.

By these arrangements in the play of the three cranes, masses weighing five tons may be transported and laid down with the greatest precision upon any point whatever in the interior of the three circles traced upon fig. 869, with the points *c*, *d*, *e*, as centres.

c, *d*, *e*, are the steps, upon which the upright shafts of the three cranes rest and turn. Each shaft is 16 feet high.

f f, is the drying stove, having its floor upon a level with that of the foundry.

f' f', is a supplementary stove for small articles.

g g g, are the coking ovens.

h is the blowing machine or fan.

i, is the steam-engine, for driving the fan, the loam-edge stoves,

k, and the charcoal mill.

l, are the boiler and the furnace of the engine.

m, workshop for preparing the loam and other materials of moulding.

n, is the apartment for the patterns.

The pig-iron, coals, &c., are placed either under sheds or in the open air, round the above buildings; where are also a smith's forge, a carpenter's shop, and an apartment mounted with vices for chipping and rough cleaning the castings by chisels and files.

Such a foundry may be erected upon a square surface of about 80 yards on each side, and will be capable, by casting in the afternoon and evening of each day, partly in large and partly in small pieces, of turning out from 700 to 800 tons per annum, with an establishment of 100 operatives, including some moulding boys.

Of making the Moulds — 1. Each mould ought to present the exact form of its object.

2. It should have such solidity that the melted metal may be poured into it, and fill it entirely without altering its shape in any point.

3. The air which occupies the vacant spaces in it, as well as the carbonated gases generated by the heat, must have a ready vent; for if they are but partially confined, they expand by the heat, and may crack, even blow up the moulds, or at any rate become dispersed through the metal, making it vesicular and unsound.

There are three distinct methods of making the moulds: —

1. In green sand; 2. In baked sand; 3. In loam.

To enumerate the different means employed to make every sort of mould exceeds the limits prescribed to this work. We shall merely indicate for each species of moulding, what is common to all the operations; and then describe the fabrication of a few such moulds as appear most proper to give general views of this peculiar art.

Moulding in green sand. — The name green is given to a mixture of the sand as it comes from its native bed, with about one twelfth its bulk of coal reduced to powder, and damped in such a manner as to form a porous compound, capable of preserving the forms of the objects pressed upon it. This sand ought to be slightly argillaceous, with particles not exceeding a pin's head in size. When this mixture has once served

for a mould, and been filled with metal, it cannot be employed again except for the coarsest castings, and is generally used for filling up the bottoms of fresh moulds.

For moulding any piece in green sand, an exact pattern of the object must be prepared in wood or metal; the latter being preferable, as not liable to warping, swelling, or shrinkage.

A couple of iron frames form a case or box, which serves as an envelope to the mould. Such boxes constitute an essential and very expensive part of the furniture of a foundry. It is a rectangular frame, without bottom or lid, whose two largest sides are united by a series of cross bars, parallel to each other, and placed from 6 to 8 inches apart.

The two halves of the box carry each corresponding exactly with one another; of which one is pierced with holes, but the other has points which enter truly into the holes, and may be made fast to them by cross pins or wedges, so that the pair becomes one solid body. Within this frame there is abundance of room for containing the pattern of the piece to be moulded with its encasing sand, which being rammed into the frame, is retained by friction against the lateral faces and cross bars of the mould.

When a mould is to be formed, a box of suitable dimensions is taken asunder, and each half, No. 1 and No. 2, is laid upon the floor of the foundry. Green sand is thrown with a shovel into No. 1 so as to fill it; when it is gently pressed in with a rammer. The object of this operation is to form a plane surface upon which to lay in the pattern with a slight degree of pressure, varying with its shape. No. 1 being covered with sand, the frame No. 2 is laid upon it, so as to form the box. No. 2 being now filled carefully with the green sand, the box is inverted, so as to place No. 1 uppermost, which is then detached and lifted off in a truly vertical position; carrying with it the body of sand formed at the commencement of the operation. The pattern remains imbedded in the sand of No. 2, which has been exactly moulded upon a great portion of its surface. The moulder condenses the sand in the parts nearest to the pattern, by sprinkling a little water upon it, and trimming the ill-shaped parts with small iron trowels of different kinds. He then dusts a little well-dried finely-sifted sand over all the visible surface of the pattern, and of the sand surrounding it; this is done to prevent adhesion when he replaces the frame No. 1.

He next destroys the preparatory smooth bed or area formed in this frame, covers the pattern with green sand, replaces the frame 1 upon 2 to reproduce the box, and proceeds to fill and ram No. 1, as he had previously done No. 2. The object of this operation is to obtain very exactly a concavity in the frame No. 1, having the shape of the part of the model impressed coarsely upon the surface formed at the beginning, and which was meant merely to support the pattern and the sand sprinkled over it, till it got imbedded in No. 2.

The two frames in their last position, along with their sand, may be compared to a box of which No. 1 is the lid, and whose interior is adjusted exactly upon the enclosed pattern.

If we open this box, and after taking out the pattern, close its two halves again, then pour in melted metal till it fill every void space, and become solid, we shall obviously attain the wished-for end, and produce a piece of cast iron similar to the pattern. But many precautions must still be taken before we can hit this point. We must first lead through the mass of sand in the frame No. 1, one or more channels for the introduction of the melted metal; and though one may suffice for this purpose, another must be made for letting the air escape. The metal is run in by several orifices at once, when the piece has considerable surface, but little thickness, so that it may reach the remotest points sufficiently hot and liquid.

The parts of the mould near the pattern must likewise be pierced with small holes, by means of wires traversing the whole body of the sand, in order to render the mould more porous, and to facilitate the escape of the air and the gases. Then, before lifting off the frame No. 1, we must tap the pattern slightly, otherwise the sand enclosing it would stick to it in several points, and the operation would not succeed. These gentle jolts are given by means of one or more pieces of iron wire which have been screwed vertically into the pattern before finally ramming the sand into the frame No. 1, or which enter merely into holes in the pattern. These pieces are sufficiently long to pass out through the sand when the box is filled; and it is upon their upper ends that the horizontal blows of the hammer are given; their force being regulated by the weight and magnitude of the pattern. These rods are then removed by drawing them straight out; after which the frame No. 1 may be lifted off smoothly from the pattern.

The pattern itself is taken out, by lifting it in all its parts at once, by means of screw pins adjusted at the moment. This manoeuvre is executed, for large pieces, almost always by several men, who while they lift the pattern with one hand, strike it with the other with small repeated blows to detach the sand entirely, in which it is generally more engaged than it was in that of the frame No. 1. But in spite of all these precautions, there are always some degradations in one or other of the two parts

of the mould, which are immediately repaired by the workman with damp sand, which he applies and presses gently with his trowel, so as to restore the injured form.

Hitherto it has been supposed that all the sand rammed into the box is of one kind; but from economy, the green sand is used only to form the portion of the mould next the pattern, in a stratum of about an inch thick; the rest of the surrounding space is filled with the sand of the floor, which has been used in former castings. The interior layer round the pattern is called in this case, *new sand*.

It may happen that the pattern is too complex to be taken out without damaging the mould, by two frames alone; then three or more are mutually adjusted to form the box.

When the mould, taken asunder into two or more parts, has been properly repaired, its interior surface must be dusted over with wood charcoal reduced to a very fine powder, and tied up in a small linen bag, which is shaken by hand. The charcoal is thus sifted at the moment of application, and sticks to the whole surface which has been previously damped a little. It is afterwards polished with a fine trowel. Sometimes, in order to avoid using too much charcoal, the surfaces are finally dusted over with sand, very finely pulverised, from a bag like the charcoal. The two frames are now replaced with great exactness, made fast together by the ears, with wedged bolts laid truly level, or at the requisite slope, and loaded with considerable weights. When the casting is large, the charcoal dusting, as well as that of fine sand, is suppressed. Every thing is now ready for the introduction of the fused metal.

Moulding in baked or used sand.—The mechanical part of this process is the same as that of the preceding. But when the castings are large, and especially if they are tall, hydrostatic pressure of the melted metal upon the sides of the mould cannot be counteracted by the force of cohesion which the sand acquires by ramming. We must in that case adapt to each of these frames a solid side, pierced with numerous small holes to give issue to the gases. This does not form one body with the rest of the frame, but is attached temporarily to it by bars and wedged bolts. In general no ground coal is mixed with this sand. Whenever the mould is finished, it is transferred to the drying stove, where it may remain from twelve to twenty-four hours at most, till it be deprived of all its humidity. The sand is then said to be *baked*, or *annealed*. The experienced moulder knows how to mix the different sands placed at his disposal, so that the mass of the mould as it comes out of the stove, may preserve its form, and be sufficiently porous. Such moulds allow the gases to pass through them much more readily than those made of *green sand*; and in general the castings they turn out are less vesicular, and smoother upon the surface. Sometimes in a large piece, the three kinds of moulding, that in green sand, in baked sand, and in loam, are combined to produce the best result.

Moulding in loam.—This kind of work is executed from drawings of the pieces to be moulded, without being at the expense of making patterns. The mould is formed of a pasty mixture of clay, water, sand, and cow's hair, or other cheap filamentous matter, kneaded together in what is called the loam mill. The proportions of the ingredients are varied to suit the nature of the casting. When the paste requires to be made very light, horse dung or chopped straw is added to it.

We shall illustrate the mode of fabricating loam moulds, by a simple case such as that of a sugar pan. *Fig. 870* is the pan. There is laid upon the floor of the foundry, an

annular platform of cast-iron, *a, b, fig. 871*; and upon its centre *c*, rests the lower extremity of a vertical shaft, adjunted so as to turn freely upon itself, while it makes a wooden pattern *e, f, fig. 872*, describe a surface of revolution identical with the internal surface reversed of the boiler intended to be made. The outline *e, g*, of the pattern is fashioned so as to describe the surface of the edge of the vessel. Upon the part *a, d, b, d, fig. 872*, of the flat cast-iron ring, there must next be constructed, with bricks laid either flat or on their edge, and clay, a kind of dome, *h, k, fig. 872*, from two to four inches thick, according to the size and weight of the piece to be moulded. The external surface of the brick dome ought to be everywhere two inches distant at least, from the surface described by the arc *e, f*. Before building up the dome to the point *i*, coals are to be placed in its inside upon the floor, which may be afterwards kindled for drying the mould. The top is then formed, leaving at *i*, round the upright shaft

of revolution, only a very small outlet. This aperture, as also some others left under the edges of the iron ring, enable the moulder to light the fire when it becomes necessary, and to graduate it so as to make it last long enough without needing more fuel, till the mould be quite finished and dry. The combustion should be always extremely slow.

Over the brick dome a pasty layer of loam is applied, and rounded with the mould *g, e, f*; this surface is then coated with a much smoother loam, by means of the concave edge of the same mould. Upon the latter surface, the inside of the sugar pan is cast; the line *e, g* having traced, in its revolution, a ledge, *m*. The fire is now kindled, and as the surface of the mould becomes dry, it is painted over by a brush with a mixture of water, charcoal powder, and a little clay, in order to prevent adhesion between the surface already dried and the coats of clay about to be applied to it. The board *g, e, f* is now removed, and replaced by another, *g', e', f'*, *fig. 874*, whose edge *e', f'* describes the outer surface of the pan. Over the surface *e, f*, a layer of loam is applied, which is turned and polished so as to produce the surface of revolution *e', f'*, as was done for the surface *e, f* only in the latter case, the line *e', g'* of the board does not form a new shoulder, but rubs lightly against *m*.

The layer of loam included between the two surfaces *e, f*, *e', f'*, is an exact representation of the sugar pan. When this layer is well dried by the heat of the interior fire, it must be painted like the former. The upright shaft is now removed, leaving the small vent hole through which it passed to promote the complete combustion of the coal. There must be now laid horizontally upon the ears of the platform *d, d*, *fig. 871*, ano-

873

874

875

ther annular platform *p, q*, like the former, but a little larger, and without any cross-bar. The relative position of these two platforms is shown in *fig. 875*. Upon the surface *e', f'*, *fig. 874*, a new layer of loam is laid, two inches thick, of which the surface is smoothed by hand. Then upon the platform *p, q*, *fig. 875*, a brick vault is constructed, whose inner surface is applied to the layer of loam. This contracts a strong adherence with the bricks which absorb a part of its moisture, while the coat of paint spread over the surface *e', f'*, prevents it from sticking to the preceding layers of loam. The brick dome ought to be built solidly.

The whole mass is now to be thoroughly dried by the continuance of the fire, the draught of which is supported by a small vent left in the upper part of the new dome; and when all is properly dry, the two iron platforms are adjusted to each other by pin points, and *p, q* is lifted off, taking care to keep it in a horizontal position. Upon this platform are removed the last brick dome, and the layer of loam which had been applied next to it; the latter of which represents exactly by its inside the mould of the surface *e', f'*, that is, of the outside of the pan. The crust contained between *e, f* and *e', f'* is broken away, an operation easily done without injury to the surface *e, f*, which represents exactly the inner surface of the pan; or only to the shoulder *m*, corresponding to the edge of the vessel. The top aperture through which the upright shaft passed must be now closed; only the one is kept open in the portion of the mould lifted off upon *p, q*; because through this opening the melted metal is to be poured in the process of casting. The two platforms being replaced above each other very exactly, by means of the adjusting pin-points, the mould is completely formed, and ready for the reception of the metal.

When the object to be moulded presents more complicated forms than the one now chosen for the sake of illustration, it is always by analogous processes that the workman constructs his loam moulds, but his sagacity must hit upon modes of executing many things which at first sight appear to be scarcely possible. Thus, when the forms of the interior and exterior do not permit the mould to be separated in two pieces, it is divided into several, which are nicely fitted with adjusting pins. More than two cast-iron rings or platforms are sometimes necessary. When ovals or angular surfaces must be traced instead of those of revolution, no upright shaft is used, but wooden or cast-iron guides made on purpose, along which the pattern cut-out board is slid according to the drawing of the piece. Iron wires and claws are often interspersed through the brick

work to give it cohesion. The core, kernel, or inner mould of a hollow casting is frequently fitted in when the outer shell is moulded. The case of a gas-light retort, *fig.* 876, will illustrate this matter. The core of the retort ought to have the form *o o o*, and be very solid, since it cannot be fixed in the outer mould for the casting, except in the part standing out of the retort towards *m m*. It must be modelled to loam, upon a piece of cast-iron called a *lantern*, made expressly for this purpose. The lantern is a cylinder or a truncated hollow cone of cast iron, about half an inch thick; and differently shaped for every different core. The surface is perforated with holes of about half an inch in diameter. It is mounted by means of iron crossbars, upon an iron axis,

which traverses it in the direction of its length. *Fig.* 877 represents a horizontal section through the axis of the core; *g h* is the axis of the lantern, figured itself at *i h*; *o o* is a kind of disc or dish, perpendicular to the axis, open at *i*, forming one piece with the lantern, whose circumference *o o* presents a curve similar to the section of the core, made at right angles to its axis. We shall see presently the two uses for which this dish is intended. The axis *g h* is laid upon two gudgeons, and handles are placed at each of its extremities, to facilitate the operation in making the core. Upon the whole surface of the lantern, from the point *h* to the collet formed by the dish, a hay cord as thick as the finger is wound. Even two or more coils may be applied, as occasion requires, over which loam is spread to the exact form of the core, by applying with the hand a board, against the dish *o o*, with its edge cut out to the desired shape; as also against another dish, adjusted at the time towards *h*; while by means of the handles a rotatory movement is given to the whole apparatus.

The hay interposed between the lantern and the loam, which represents the crust of the core, aids the adhesion of the clay with the cast iron of the lantern, and gives passage to the holes in its surface, for the air to escape through in the casting.

When the core is finished, and has been put into the drying stove, the axis *g h* is taken out, then the small opening which it leaves at the point *h*, is plugged with clay. This is done by supporting the core by the edges of the dish, in a vertical position. It is now ready to be introduced into the hollow mould of the piece.

This mould executed in baked sand consists of three pieces, two of which, absolutely similar, are represented, *fig.* 878, at *p q*, the third is shown at *r s*. The two similar parts *p q*, present each the longitudinal half of the nearly cylindrical portion of the outer surface of the gas retort; so that when they are brought together, the cylinder is formed; *r s* contains in its cavity the kind of hemisphere which forms the bottom of the retort. Hence, by adding this part of the mould to the end of the two others, the resulting apparatus presents, in its interior, the exact mould of the outside of the retort; an empty cylindrical portion *t t*, whose axis is the same as that of the cylinder *u u*, and whose surface, if prolonged, would be every where distant from the surface *u u*, by a quantity equal to the desired thickness of the retort. The diameter of the cylinder *t t* is precisely equal to that of the core, which is slightly conical, in order that it may enter easily into this aperture *t t*, and close it very exactly when it is introduced to the collet or neck.

The three parts of the mould and the core being prepared, the two pieces *p q*, must first be united, and supported in an upright position; then the core must be let down into the opening *t t*, *fig.* 879. When the plate or disc *o o* of the core is supported upon the mould, we must see that the end of the core is everywhere equally distant from the edge of the external surface *u u*, and that it does not go too far beyond the line *q q*. Should there be an inaccuracy, we must correct it by slender iron slips placed under

the edge of the disc *ee*; then by means of a cast iron cross, and screw bolts *e e*, we fix the core immovably. The whole apparatus is now set down upon *r r*, and we fix with screw bolts the plane surface *g g* upon *r r*; then introduce the melted metal by an aperture *x*, which has been left at the upper part of the mould.

When, instead of the example now selected, the core of the piece to be cast must go beyond the mould of the external surface, as is the case with a pipe open at each end, the thing is more simple, because we may easily adjust and fix the core by its two ends.

In casting a retort, the metal is poured into the mould set upright. It is important to maintain this position in the two last examples of casting; for all the foreign matters which may soil the metal during its flow, as the sand, the charcoal, gases, scoria, being less dense than it, rise constantly to the surface. The hydrostatic pressure produced by a high gate, or filling in aperture, contributes much to secure the soundness and solidity of the casting. This gate piece being superfluous, is knocked off almost immediately after, or even before the casting cools. Very long, and somewhat slender pieces, are usually cast in moulds set up obliquely to the horizon. As the metal shrinks in cooling, the mould should always be somewhat larger than the object intended to be cast. The iron foundry reckons in general upon a linear shrinkage of a ninety-sixth part; that is one-eighth of an inch per foot.

Melting of the cast-iron.—The metal is usually melted in a cupola furnace, of which the dimensions are very various. Fig. 580 represents in plan, section, and elevation,

one of these furnaces of the largest size; being capable of founding 5 tons of cast-iron at a time. It is kindled by laying a few chips of wood upon its bottom, leaving the orifice *c* open, and it is then filled up to the throat with coke. The fire is lit at *c*, and in a quarter or half an hour, when the body of fuel is sufficiently kindled, the tuyère blast is set in action. The flame issues then by the mouth as well as the orifice *c*, which has been left open on purpose to consolidate it by the heat. Without this precaution, the sides, which are made up in argillaceous sand after each day's work, would not present the necessary resistance. A quarter of an hour afterwards, the orifice *c* is closed with a lump of moist clay, and sometimes, when the furnace is to contain a great body of melted metal, the clay is supported by means of a small plate of cast-iron fixed against the furnace. Before the blowing machine is set going, the openings *g g* had been kept shut. Those of them wanted for the tuyères are opened in

succession, beginning at the lowest, the tuyères being raised according as the level of the fused iron stands higher in the furnace. The same cupola may receive at a time from one to six tuyères, through which the wind is propelled by the centrifugal action of an excentric fan or ventilator. It does not appear to be ascertained whether there be any advantage in placing more than two tuyères facing each other upon opposite sides of the furnace. Their diameter at the nozzle varies from 3 to 5 inches. They are either cylindrical or slightly conical. A few minutes after the tuyères have begun to blow, when the coke sticks in the furnace, alternate charges of coke and pig iron must be thrown in. The metal begins to melt in about 20 minutes after its introduction; and successive charges are then made every 10 minutes nearly; each charge containing from 3 cwt. to 5 cwt. of iron, and a quantity proportional to the estimate given below. The amount of the charges varies of course with the size of the furnace, and the speed required for the operation. The pigs must be previously broken into pieces weighing at most 14 or 16 pounds. The vanes of the blowing fan make from 625 to 650 turns per minute. The two cupolas represented *fig. 581*, and another alongside in the plan, may easily melt $6\frac{1}{2}$ tons of metal in 2 $\frac{1}{2}$ hours; that is 2 $\frac{1}{2}$ tons per hour. This result is three or four times greater than what was formerly obtained in similar cupolas, when the blast was thrown in from small nozzles with cylinder bellows, moved by a steam engine of 10 horses power.

In the course of a year, a considerable foundry like that represented in the plan, *fig. 580*, will consume about 300 tons of coke in melting 1240 tons of cast iron; consisting of 940 tons of pigs, of different qualities, and 300 tons of broken castings, gate-pieces, &c. Thus it appears that 48 pounds of coke are consumed for melting every 2 cwt. of metal.

Somewhat less coke is consumed when the fusion is pushed more rapidly, to collect a great body of melted metal for casting heavy articles; and more is consumed when, as in making many small castings, the progress of the founding has to be slackened from time to time; otherwise, the metal would remain too long in a state of fusion, and probably become too cold to afford sharp impressions of the moulds.

It sometimes happens that in the same day, with the same furnace, pieces are to be cast containing several proportions of different kinds of iron; in which case, to prevent an intermixture with the preceding or following charges, a considerable bed of coke is interposed. Though there be thus a little waste of fuel, it is compensated by the improved adaptation of the castings to their specific objects. The founding generally begins at about 3 o'clock, *p.m.*, and goes on till 6 or 8 o'clock. One founder aided by four labourers for charging, &c., can manage two furnaces.

The following is the work of a well-managed foundry in Derby.

200 lbs. of coke are requisite to melt, or bring down (in the language of the founder), 1 ton of cast iron, after the cupola has been brought to its proper heat, by the combusting in it of 9 baskets of coke, weighing, by my trials, 40 pounds each. = 360 lbs.

The chief talent of the founder consists in discovering the most economical mixtures and so compounding them as to produce the desired properties in the castings. One piece, for example, may be required to have great strength and tenacity to bear heavy weights or strains; another must yield readily to the chisel or the file; a third must resist sudden alternations of temperature; and a fourth must be pretty hard.

The filling in of the melted metal is managed in two ways. For strong pieces, whose moulds can be buried in the ground at 7 or 8 yards distance from the furnace, the metal may be run in gutters, formed in the sand of the floor, contained by plates or stones. The clay plug is pierced with an iron rod, when all is ready.

When from the smaller size, or greater distance of the moulds, the melted metal cannot be run along the floor from the furnace, it is received in cast-iron pots or ladles lined with a coat of loam. These are either carried by the hands of two or more men, or transported by the crane. Between the successive castings, the discharge hole of the furnace is closed with a lump of clay, applied by means of a stick, having a small disc of iron fixed at its end.

After the metal is somewhat cooled, the moulds are taken asunder, and the excrescences upon the edges of the castings are broken off with a hammer. They are afterwards more carefully trimmed or chipped by a chisel when quite cold. The loss of weight in founding is about $6\frac{1}{2}$ per cent. upon the pig iron employed. Each casting always requires the melting of considerably more than its own weight of iron. This excess forms the gates, false seams, &c.; the whole of which being deducted, shows that 1 cwt. of coke is consumed for every 3 cwt. of iron put into the furnace; for every 138 cwt. of crude metal, there will be 100 cwt. of castings, 33 of refuse pieces, and 6 of waste.

Fig. 580, Cupola furnace, requires a little further description. It is 3 feet wide within, and 12 $\frac{1}{2}$ feet high. *m m*, solid body of masonry, as a basis to the furnace.

b, octagonal platform of cast iron, with a ledge in which the plates *a a a a* are engaged.

a a, eight plates of cast iron, 1 inch thick, absolutely similar; only one of them is notched at its lower part in *c*, to allow the melted metal to run out, and two of the others have six apertures, *g g g*, &c. to admit the tuyères.

c, orifice for letting the metal flow out. A kind of cast iron gutter, *c*, lined with loam, is fitted to the orifice.

d, hoops of hammered iron, $4\frac{1}{2}$ inches broad; one half of an inch thick for the bottom ones; and a quarter of an inch for the upper ones. The intermediate hoops decrease in thickness from below upwards between these limits.

e, cast iron gutter or spout, lined with loam, for running off the metal.

f f, cylindrical piece of cast iron, for increasing the height and draught of the furnace.

g, side openings for receiving the tuyères, of which there are six upon each side of the furnace. Each of them may be shut at pleasure, by means of a small cast iron plate, *A*, made to slide horizontally in grooves sunk in the main plate, pierced with the holes *g g*.

A A, interior lining of the surface, made of sand, somewhat argillaceous, in the following way. After having laid at the bottom of the furnace a bed of sand a few inches thick, slightly sloped towards the orifice of discharge, there is set upright, in the axis of the cupola, a wooden cylinder of its whole height, and of a diameter a little less than that of the vacant space belonging to the top of the furnace. Sand is to be then rammed in so as to fill the whole of the furnace; after which the wooden cylinder is withdrawn, and the lining of the sand is cut or shaved away, till it has received the proper form.

This lining lasts generally 5 or 6 weeks, when there are six meltings weekly.

i i, cast iron circular plate, through which the mouth of the furnace passes for protecting the lining in *A* during the introduction of the charges.

x x, level of the floor of the foundry. The portion of it below the running out orifice consists of sand, so that it may be readily sunk when it is wished to receive the melted metal in ladles or pots of large dimensions.

The fan distributes the blast from the main pipe to three principal points, by three branch tubes of distribution. A register, consisting of a cast iron plate sliding with friction in a frame, serves to intercept the blast at any moment, when it is not desirable to stop the moving power. A large main pipe of zinc or sheet iron is fitted to the orifice of the slide valve. It is square at the beginning, or only rounded at the angles; but at a little distance it becomes cylindrical, and conducts the blast to the

881

divaricating points. There, each of the branches turns up vertically, and terminates at *b b*, *fig. 881*, where it presents a circular orifice of $7\frac{1}{2}$ inches. Upon each of the upright pipes *b*, the one end of an elbow-tube of zinc *c c c*, *fig. 881*, is adjusted rather loosely, and the other end receives a tuyère of wrought iron *d d*, through the intervention of a shifting hose or collar of leather *e e d*, hooped with iron wire to both the tube and the tuyère. The portion *c c c* may be raised or lowered, by sliding upon the pipe *b*, in order to bring the nozzle of the tuyère *d d*, to the requisite point of the furnace. The portion *c c c* may be made also of wrought iron. A power of 4 horses is adequate to drive the fan, for supplying blast to 3 furnaces.

The founders have observed that the efflux of air was not the same when blown into the atmosphere, as it was when blown into the furnaces; the velocity of the fan, with the same impulsive power, being considerably increased in the latter case. They imagine that this circumstance arises from the blast being sucked in, so to speak, by the draught of the furnace, and that the fan then supplied a greater quantity of air.

The following experimental researches show the fallacy of this opinion. Two water siphons, *e e c, f f f*, made of glass tubes, one-fifth of an inch in the bore, were inserted into the tuyère, containing water in the portions *g g g, h h h*. The one of these siphons for measuring the pressure of the air was inserted at *h*, the other in the centre of the nozzle. The size of this glass tube was too small to obstruct in any sensible degree the outlet of the air. It was found that when the tuyères of the fan discharged into the open air, the expenditure by a nozzle of a constant diameter was proportional to the number of the revolutions of the vanes. It was further found, that when the speed of the vanes was constant, the expenditure by one or two nozzles was proportional to the total area of these nozzles. The following formulae give the volume of air furnished by the fan, when the number of turns and the area of the nozzles are known.

$$\text{Volume} = \frac{25.32 \text{ S n}}{1,000,000} \quad (1)$$

$$\text{Volume} = \frac{0.8667 \text{ S n}}{1,000,000} \quad (2)$$

The volume is measured at 32° Fahr., under a pressure of 29.6 inches barom.

S = is the total area of the orifices of the tuyères in square inches.

n = the number of turns of the vanes in a minute.

After measuring the speed of the vanes blowing into the atmosphere, if we introduce the nozzle of discharge into the orifice of the furnace, we shall find that their speed immediately augments in a notable degree. We might, therefore, naturally suppose that the fan furnishes more air in the second case than in the first; but a little reflection will show that it is not so. In fact, the air which issues in a cold state from the tuyère encounters instantly in the furnace a very high temperature, which expands it, and contributes, along with the solid matters with which the furnace is filled, to diminish the facility of the discharge, and consequently to retard the efflux by the nozzles. The oxygen gas consumed is replaced by a like volume of carbonic acid gas, equally expansible by heat. Reason leads us to conclude that less air flows from the nozzles into the furnace than into the open atmosphere.

The increase in the velocity of the vanes takes place precisely in the same manner, when after having made the nozzles blow into the atmosphere, we substitute for these nozzles others of a smaller diameter, instead of directing the larger ones into the furnace. Hence we may conceive that the proximity of the charged furnace acts upon the blast like the contraction of the nozzles. When the moving power is uniform, and the velocity of the vanes remains the same, the quantity of air discharged must also be the same in the two cases.

Two tuyères, one 5 inches in diameter, the other $4\frac{1}{2}$, and which, consequently, presented a total area of 33½ square inches, discharged air into one of the furnaces, from a fan whose vanes performed 634 turns in the minute. These two nozzles being briskly withdrawn from the furnace, and turned round to the free air, while a truncated paraboloid cone of $3\frac{1}{2}$ inches diameter was substituted for the nozzle of $4\frac{1}{2}$ inches, whereby the area of efflux was reduced to 29.3 square inches, the velocity of the vanes continued exactly the same. The inverse operation having been performed, that is to say, the two original nozzles having been smartly replaced in the furnace, to discover whether or not the moving power had changed in the interval of the experiment, they betrayed no perceptible alteration of speed. From the measures taken to count the speed, the error could not exceed 3 revolutions per minute, which is altogether unimportant upon the number 634.

It follows, therefore, that when the vanes of the fan have the velocity of 654 inches per minute, the expenditure by two nozzles, whose joint area is $35\frac{1}{2}$ square inches, both blowing into a furnace, is to the expenditure which takes place, when the same nozzles blow into the air, as 23.5 is to 29.3; that is, a little more than 4 fifths.

If this be, as is probable, a general rule for areas and speeds considerably different from the above, to find the quantity of air blown into one or more furnaces by the fan, we should calculate the volume by one of the above formula (1) or (2), and take 4-fifths of the result, as the true quantity.

The fan A C, represented (fig. 881), is of the best excentric form, as constructed by Messrs. Braithwaite and Lumsden. It is the circular orifice round the axis by which the air is admitted; and C C P is the excentric channel through which the air is wafted towards the main discharge pipe K. See VENTILATION.

FOUNTAIN. A stream of water rising up through the superficial strata of the earth. See ARTESIAN WELLS.

FOXING, is a term employed by brewers to characterise the souring of beer, in the process of its fermentation or ripening.

FRACTIONAL DISTILLATION. See NAPHTHA (BON HEAD).

FRACTURE of minerals. The fracture of minerals has been grouped under the following heads, there being very few variations from them:—

1. *Conchoidal*; from concha, like a shell, when a mineral breaks with curved concavities; example, flint.

2. *Irreg.*; when the surface of fracture is rough, with numerous small elevations and depressions.

3. *Splintery*; when the broken surface exhibits protruding points.

4. *Harkly*; when the elevations are sharp or jagged, as iron.

FLAME, a mining term. See ORE DRESSING.

FRANKFORT BLACK; is a black used in copper-plate printing. It is said to be a compound obtained from grape and vine lees, peach kernels, and bone shavings. It is, doubtful, whether the finest black is not a soot produced from the combustion of some of these bodies. The preparation is, however, made much of a mystery.

FRANKINCENSE. The spontaneous exudations of the *Abies cereba*, the Norway spruce fir.

FRANKLINITE. A somewhat remarkable mineral, which is found at Hamburg, N. J., with red oxide of zinc and garnet in granular limestone. Its composition has been determined to be—

	1.	2.	3.
Oxide of iron	66.0	68.88	66.12
Oxide of manganese	18.0	16.17	11.19
Oxide of zinc	17.0	10.91	21.77

Franklinite was at first employed for the production of zinc; but for that purpose it did not answer commercially. It is, however, now employed in combination with iron, as it is said, with much advantage. Major Farrington of New Jersey thus speaks of it:—"Many experiments have been made under my superintendence upon the ores of Franklinite, and I have also witnessed several others of an interesting character made by other parties in mixing Franklinite with pig iron in the puddling furnace, and also a mixture of franklinite pig with other irons in their conversion to wrought iron. The result in all cases has been a great improvement in the quality of iron as manufactured. The most marked and, as I consider, the most valuable result is obtained by using from 10 to 15 per cent. of the weight of pig iron to be puddled with pulverised Franklinite ore in the furnace at each heat. Iron of the most inferior quality when thus treated, is converted into an article of No. 1 grade. The volatile nature of zinc at a high temperature, combining with the sulphur, phosphorus, and other volatile constituents of the coal, or that may be in the iron, being carried off mechanically, I consider is one of the causes of the improvement; the manganese also of the ore combines with silica at a high temperature, and pig iron that contains silica is thus freed from it. The great advantage to be obtained by using the pulverised ore in the puddling furnace is, that a high grade of iron may be made; and where reheating has been hitherto deemed indispensable, one heating is found sufficient for such uses as wire billets, nuts, bolts, horseshoe iron, and nails. A particular selection of fuel is not required, coke and charcoal can be dispensed with, and bituminous or anthracite coal used."

FREESTONE. A term used to denote any stone which is capable of being worked freely in every direction, and, which has no tendency to break in one direction more than another. In the counties of Wicklow and Dublin, and also in Cornwall, the term is applied to granite which works freely.—H. W. B.

FREEZING. (*Congelation*, Fr.; *Gefrierung*, Germ.) The three general forms, solid, liquid, and gaseous, under one or other of which all kinds of matter exist, are

referrible to the influence of heat, modifying, balancing, or subduing the attraction of cohesion. Nearly every solid may be liquefied, and every liquid may be vaporised, by a certain infusion of heat, whether this be regarded as a moving power, or an elastic essence. The converse of this proposition is equally true; for many gases, till lately styled permanent, may be liquefied, nay, even solidified, by diminution of their temperature, either alone, or aided by a sufficient mechanical condensation, to bring their particles within the sphere of aggregative attraction. When a solid is transformed into a liquid, and a liquid into a gas or vapour, a quantity more or less considerable of heat is absorbed, or becomes latent, to use the term of Dr. Black. When the opposite transformation takes place, the heat absorbed is again emitted, or what was latent becomes sensible. See HEAT for the more recent hypotheses.

The production of cold is a curious and interesting branch of physical inquiry. A few general laws may be distinctly named.

If a solid body suddenly liquefies, without the application of external heat, it abstracts from the surrounding bodies the heat necessary for its liquefaction.

When a salt is dissolved in water cold is produced.

If a liquid vaporises, the vapour is produced at the expense of the heat of some neighbouring body.

When spirits of wine, or ether, is thrown on the body, a sensation of coldness is produced from the liquids vaporising by robbing the body of heat.

By placing water in a porous vessel, and exposing it to the sun, it becomes very cold. The solar heat-rays occasion a rapid evaporation of the water which has filtered through the pores of the vessel, and some heat is taken by the process from the fluid in the interior.

If air is allowed suddenly to expand, it takes heat from the surrounding bodies, or produces cold.

The most familiar method of producing intense cold is by means of freezing mixtures. A great number of those were invented by Mr. Walker; the principal results are contained in the following tables:—

L—Table, consisting of Frigorific Mixtures, having the power of generating or creating cold without the aid of ice, sufficient for all useful and philosophical purposes, in any part of the world at any season.

Frigorific Mixtures without Ice.

MIXTURES.	Thermometer sinks.	Deg. of cold produced.
Nitrate of ammonia - - - 1 part Water - - - - - 1	From + 50° to + 4°	46°
Muriate of ammonia - - - 5 parts Nitrate of potash - - - 5 Water - - - - - 16	From + 50° to + 10°	40
Muriate of ammonia - - - 5 parts Nitrate of potash - - - 5 Sulphate of soda - - - 8 Water - - - - - 16	From + 50° to + 4°	46
Sulphate of soda - - - 3 parts Dilute nitric acid - - - 2	From + 50° to - 3°	53
Nitrate of ammonia - - - 1 part Carbonate of soda - - - 1 Water - - - - - 1	From + 50° to - 7°	57
Phosphate of soda - - - 2 parts Dilute nitric acid - - - 4	From + 50° to - 12°	62
Sulphate of soda - - - 8 parts Hydrochloric acid - - - 5	From + 50° to 0°	50
Sulphate of soda - - - 5 parts Dilute sulphuric acid - - - 4	From + 50° to + 3°	47
Sulphate of soda - - - 6 parts Muriate of ammonia - - - 4 Nitrate of potash - - - 2 Dilute nitric acid - - - 4	From + 50° to - 10°	60
Sulphate of soda - - - 6 parts Nitrate of ammonia - - - 5 Dilute nitric acid - - - 4	From + 50° to - 14°	64

II. — Table consisting of Frigorific Mixtures, composed of ice, with chemical salts and acids.

Frigorific Mixtures with Ice.

MIXTURES.		Thermometer sink.	Deg. of cold produced.			
Snow, or pounded ice	- 2 parts	From any temperature	to -5°	•		
Muriate of soda	- 1					
Snow, or pounded ice	- 5 parts		to -12°	•		
Muriate of soda	- 2					
Muriate of ammonia	- 1		to -18°	•		
Snow, or pounded ice	- 24 parts					
Muriate of soda	- 10	to -25°	•			
Muriate of ammonia	- 5					
Nitrate of potash	- 5					
Snow, or pounded ice	- 12 parts	From any temperature	to -25°	•		
Muriate of soda	- 5 t					
Nitrate of ammonia	- 5					
Snow	- 3 parts				From $+32^{\circ}$ to -23°	55
Dilute sulphuric acid	- 2					
Snow	- 8 parts				From $+32^{\circ}$ to -27°	59
Muriatic acid	- 5					
Snow	- 7 parts		From $+32^{\circ}$ to -30°	62		
Dilute nitric acid	- 4					
Snow	- 4 parts		From $+32^{\circ}$ to -40°	72		
Muriate of lime	- 5					
Snow	- 2 parts		From $+32^{\circ}$ to -50°	62		
Cryst. muriate of lime	- 3					
Snow	- 3 parts		From $+32^{\circ}$ to -51°	83		
Potash	- 4					

N. B. — The reason for the omissions in the last column of the preceding table is, the thermometer sinking in these mixtures to the degree mentioned in the preceding column, and never lower, whatever may be the temperature of the materials at mixing.

To produce these results in a satisfactory manner, it is necessary to cool previously to the experiments, the vessels in which the mixtures are made.

The most intense cold that is as yet known is that from the evaporation of a mixture of solid carbonic acid and sulphuric ether, by which a temperature of 166° Fahr. below the freezing point of water is produced. By means of this intense cold, assisted by mechanical pressure several of the gaseous bodies have been condensed into liquids, and in some instances solidified.

Sir John Herschel, some years since, recommended the following method for obtaining at moderate cost large quantities of ice.

A steam engine boiler was to be sunk into the earth, and the quantity of water which it was desired to freeze placed in it. By means of a condensing pump, several atmospheres of air were forced into the boiler, and then everything was allowed to remain for a night, or until the whole had acquired the temperature of the surrounding earth. Then, by opening a stop cock, the air expanding escaped with much violence, and the water being robbed of its heat to supply the expanding air, the temperature of the whole was so reduced, that a mass of ice was the result.

The following process for producing cold has been patented and exhibited in this country.

In a reservoir, or what may with propriety be called a boiler, was placed a quantity of sulphuric ether. This reservoir was placed in a long vessel of saline water, this fluid by the arrangement being made to flow from one end of the trough to the other, that is to and from the reservoir. In this water was placed a number of vessels, the depth and breadth of the trough, but of only two inches in width, and these were filled with the water to be frozen.

A steam engine was employed to pump the air from the reservoir; this being done, of course the ether boiled, and the vapour of the ether was removed by the engine as fast as it was formed. The heat required to vaporise the ether was derived from the saline water in the trough, and this again took the heat from the water in the cells; thus eventually every cell of water was converted into ice. The ether was, after it had passed through the engine, condensed by a refrigeratory of the ordinary kind.

The statement made by the patentee was very satisfactory, as it regarded the cost of production. An apparatus of this kind is of course intended for hot countries only, where ice becomes actually one of the necessities of life.

A peculiar physical fact connected with the freezing of water has been made available to some important uses. Water in freezing really rejects everything it may contain—even air, and hence solid ice is actually *pure* water. This may be easily proved. Make a good freezing mixture, and place some water in a flask, and while it is undergoing consolidation by being placed in the frigorific compound, gently agitate it with a feather. Now, if the water contains spirit, acid, salt, or colouring matter, either of them are alike rejected, and the solid obtained, when washed from the matter adhering to its surface is absolutely pure solid water.

This philosophic fact, although it has only been subjected to examination within the last few years, has been long known.

Byron, in his 13th Canto of *Don Juan*, has the following allusion to it:—

"I'll have another figure in a trice
What say you to a bottle of champagne?
Frozen into a very vinous ice,
Which leaves few drops of that immortal sap,
Yet in the very centre, past all price,
Almost a liquid glassful will remain;
And this is stronger than the strongest grape
Could e'er express in its expanded shape."

The old nobles of Russia, when they desired a more intoxicating drink than usual, placed their wines or spirit in the ice of their frozen rivers, until all the aqueous portion was frozen; when they drank the ardent fluid accumulated in the centre. This plan has been employed also for concentrating lemon juice and the like. For some further matters connected with this peculiar condition, see *STEAM BOILERS* and *WATER*.

FRENCH BERRIES. The berries of the *Rhamnus cathartica*, and other species of the *Banethorn*. The true French berries, which should be four-seeded, belong to the first named; all the two-seeded berries are obtained from other and inferior kinds.

FRENCH CHALK. A steatite; a soft magnesian mineral.

FRENCH POLISH. There are numerous methods given for the preparation of this polish, one of the best is probably the following: 1½ lbs. of shell lac dissolved in a gallon of spirits of wine without heat. Another recipe is 12 ounces of shell lac, 2 ounces of gum elemi, and 3 ounces of copal to 1 gallon of spirits of wine.

FRICTION. The resistance to motion which depends on the structure of the surfaces in contact. Friction is usually divided into two kinds: *sliding friction* and *rolling friction*. The questions involved in the consideration of friction are purely engineering, and cannot therefore be treated here. One very important element may however be named, as showing the importance of exact science in connection with the improvements in mechanics. By friction heat is evolved. It is found by accurate experiment, that the quantity of heat evolved is exactly sufficient to reproduce the effect caused in overcoming the friction. — *Joule and Thomson*.

FRUIT. See *EXAMEN* and *GLASS*.

FUCUS. See *ALGÆ*. In the *Fucus serratus* and *ceramoides* silver has been detected, *Malaguto* has stated, to the extent of inches, in the ashes of these plants. It has also been stated that these and some other plants contain lead and copper.

FUD, or WOOLLEN WASTE, is the refuse of the new wool taken out in the scurbling process, and is mixed with the mungo for use. See *MUNGO*.

FUEL. (*Combustible*, Fr; *Brennstoff*, Germ.)

Such combustibles as are used for fires or furnaces. Wood, Tar, Coal, are familiar examples. Fuels differ in their nature, and in their power of giving heat, it is therefore of much importance to ascertain the heat-giving power. Numerous excellent experiments have been made for the purpose of determining with exactness the heating values of fuels of different kinds. Lavoisier and Laplace, in an extensive examination carried out by them, used the well known *Calorimeter*, that is, they determined the value of the heat by the quantity of ice melted in a given time. Count Rumford subsequently measured the quantity of heat by the increase of temperature in a given quantity of water. The quantity of heat which will melt 1 lb of ice at 0° Cent. being just sufficient according to Laplace to raise the temperature of a pound of water to 75° Cent., or according to the experiments of Regnault, to 79° Cent. Clement and Desormes have also shown, that an equal weight of aqueous vapour, whatever may be its temperature and tension, is always produced by one and the same amount of heat.

As far as we can within the limits of the present work, we shall endeavour to present a full practical view of the subject, giving each class of fuels under their several heads.

I. *Wood*, which is divided into hard and soft. To the former belong the oak.

the beech, the alder, the birch, and the elm; to the latter, the fir, the pine of different sorts, the larch, the linden, the willow, and the poplar.

Under like dryness and weight, different woods are found to afford very different degrees of heat and combustion. Moisture diminishes the heating power in three ways: by diminishing the relative weight of the ligneous matter, by wasting heat in its evaporation, and by causing slow and imperfect combustion. If a piece of wood contain, for example, 25 per cent. of water, then it contains only 75 per cent. of fuel, and the evaporation of that water will require $\frac{1}{3}$ part of the weight of the wood. Hence the damp wood is of less value in combustion by $\frac{1}{3}$, or $\frac{1}{4}$ than the dry. The quantity of moisture in newly felled wood amounts to from 20 to 50 per cent.; birch contains 30, oak 35, beech and pine 39, alder, 41, fir 43. According to their different natures, woods which have been felled and cleft for 12 months contain still from 20 to 25 per cent. of water. There is never less than 10 per cent. present, even when it has been kept long in a dry place, and though it be dried in a strong heat, it will afterwards absorb 10 or 12 per cent. of water. If it be too strongly kiln dried, its heating powers are impaired by the commencement of carbonisation, as if some of its hydrogen were destroyed.

The following table, compiled from the researches of Count Rumford, will place these points clearly before us.

One pound of the following woods when burnt will heat:	Pounds of water from 60° to 100° Cent.		
	Ordinary condition.	Slightly dried.	Strongly dried.
Lime tree - - - -	34.708	38.533	40.131
Beech - - - -	33.798	- -	36.744
Elm - - - -	30.205	- -	34.083
Oak - - - -	25.590	29.210	29.855
Ash - - - -	30.666	33.720	35.449
Sycamore - - - -	- -	- -	36.117
Fir - - - -	30.322	34.000	37.379
Poplar - - - -	31.601	- -	37.161

From every combustible the heat is diffused either by radiation or by direct communication to bodies in contact with the flame. In a wood fire the quantity of radiating heat is, to that diffused by the air, as 1 to 3; or it is one fourth of the whole heating power.

II. *Charcoal*.—The different charcoals afford, under equal weights, equal quantities of heat. We may reckon, upon an average, that a pound of dry charcoal is capable of heating 75 pounds of water from the freezing to the boiling point; but when it has been for some time exposed to the air, it contains at least 10 per cent. of water, which is partially decomposed in the combustion into carburetted hydrogen, which causes flame, whereas pure dry charcoal emits none.

Winkler gives the following as the results obtained by him with charcoal from various sources:

Charcoal from:	Pounds of water heated from 60° to 100° Cent. by 1 pound of charcoal.	Air required for perfect combustion.	Pounds of fuel reduced by 1 pound of charcoal.
Poplar - - - -	On an average 75.7.	On an average 293.3 cubic feet at 19° Cent.	33.56
Sycamore - - - -			33.23
Fir - - - -			33.51
Ash - - - -			33.23
Birch - - - -			33.71
Oak - - - -			33.71
Elm - - - -			33.26
Willow - - - -			33.49
Pine - - - -			33.53

A cubic foot of charcoal from soft wood weighs upon an average from 8 to 9 pounds, and from hard wood 12 to 13 pounds; and hence the latter is best adapted to maintain a high heat in a small compass. The radiating heat from charcoal fires constitutes one third of the whole emitted.

III. *Turf or peat*.—One pound of this fuel will heat according to its quality, from 19 to 42 pounds of water from freezing to boiling. Its value depends upon its com-

pactness and freedom from earthy particles; and its radiating power is to the whole heat it emits in burning as 1 to 3.

According to Berthier, the following results were obtained from peat:—

Source of the Peat.	Pounds of water heated by 1 pound of peat from 60° to 100° Cent.
From Troyes - - - - -	18.1
" département de la Somme - - - - -	27.9
" " de la Marne - - - - -	29.2
" " de la Vauges - - - - -	34.0
" " des Landes - - - - -	34.6

Winkler gives 26.0 as the evaporative power of the worst Hanoverian peat, and 42.6 as that of the best.

Peat obtained from the Bog of Allen gave, according to Griffith (the discrepancies between the results we do not understand).—

	Pounds of water heated from 60° to 100° Cent.
Upper peat - - - - -	62.7
Lower peat - - - - -	54.6
Pressed peat - - - - -	29.0

IV. *Coal*.—The varieties of coal are almost indefinite, and give out very various quantities of heat in their combustion. The carbon is the heat giving constituent, and it amounts, in different coals, to from 75 to 95 per cent. One pound of good coal will, upon an average, heat 60 pounds of water from the freezing to the boiling point. Small coal gives out three-fourths of the heat of the larger lumps. The radiating heat emitted by burning pitcoal is greater than that by charcoal.

V. *The coke of coal*.—The heating power of good coke is to that of pitcoal as 75 to 69. One pound of the former will heat 65 pounds of water from 32° to 212°; so that its power is equal to nine-tenths of that of wood charcoal.

Berthier gives as the results of his trials:—

	Pounds of water heated by 1 pound of coal from 60° to 100° C.
Dowlais coal - - - - -	72.0
Glamorgao - - - - -	70.7
Newcastle - - - - -	70.0
Derbyshire - - - - -	61.6
Lancashire (cannel) - - - - -	58.2
Durham - - - - -	71.6
Coke (St. Etienne) - - - - -	65.6
Do. gas from Paris - - - - -	50.3

VI. *Carburetted hydrogen or coal gas*.—One pound of this gas, equal to about 24 cubic feet, disengages in burning as much heat as will raise 76 pounds of water from the freezing to the boiling temperature.

In the following table the fourth column contains the weight of atmospherical air, whose oxygen is required for the complete combustion of a pound of each particular substance.

Species of combustible.	Pounds of water which a pound can heat from 60° to 212°.	Pounds of boiling water evaporated by 1 pound.	Weight of atmosphere at 32°, to burn 1 pound.
Perfectly dry wood -	35.00	6.36	5.96
Wood in its ordinary state -	26.00	4.72	4.47
Wood charcoal - - -	73.00	13.27	11.46
Pitcoal - - - - -	60.00	10.90	9.26
Coke - - - - -	65.00	11.81	11.46
Turf - - - - -	30.00	5.45	4.60
Turf charcoal - - -	64.00	11.63	9.86
Carburetted hydrogen gas -	76.00	13.81	14.38
Oil - - - - -			
Wax } - - - - -	76.00	14.18	15.00
Tallow }			
Alcohol of the shops -	52.60	9.36	11.60

The quantity of air stated in the fourth column, is the smallest possible required to burn the combustible, and is greatly less than would be necessary in practice, where

much of the air never comes into contact with the burning body, and where it consequently never has its whole oxygen consumed. The heating power stated in this second column is also the maximum effect, and can seldom be realised with ordinary boilers. The draught of air usually carries off at least $\frac{1}{4}$ of the heat, and more if its temperature be very high when it leaves the vessel. In this case it may amount to one half of the whole heat, or more; without reckoning the loss by radiation and conduction, which however may be rendered very small by enclosing the fire and flues within proper non-conducting and non-radiating materials.

It appears that, in practice, the quantity of heat which may be obtained from any combustible in a properly mounted apparatus, must vary with the nature of the object to be heated. In heating chambers by stoves, and water boilers by furnaces, the efficient heat in the chimney, which constitutes the principal waste, may be reduced to a very moderate quantity, in comparison of that which escapes from the best constructed reverberatory hearth. In heating the boilers of steam engines, one pound of coal is reckoned adequate to convert $7\frac{1}{2}$ pounds of boiling water into vapour; or to heat 41 $\frac{1}{2}$ pounds of water from the freezing to the boiling point. One pound of fir of the usual dryness will evaporate 4 pounds of water, or heat 22 pounds to the boiling temperature; which is about two-thirds of the maximum effect of this combustible. According to Watt's experiments upon the great scale, one pound of coal can boil off with the best built boiler, 9 pounds of water; the deficiency from the maximum effect being here $\frac{1}{4}$, or nearly one sixth. See the *Tables at the end of this article*.

In many cases the hot air which passes into the flues or chimneys may be beneficially applied to the heating, drying, or roasting of objects; but care ought to be taken that the draught of the fire be not thereby impaired, and an imperfect combustion of the fuel produced. For, at a low smothering temperature, both carbonic oxide and carburised hydrogen may be generated from coal, without the production of much heat in the fireplace.

To determine exactly the quantity of heat disengaged by any combustible in the act of burning, three different systems of apparatus have been employed: 1, the calorimeter of Lavoisier and Laplace, in which the substance is burned in the centre of a vessel whose walls are lined with ice, and the amount of ice melted measures the heat evolved; 2, the calorimeter of Watt and Rumford, in which the degree of heat communicated to a given body of water affords the measure of temperature; and 3, by the quantity of water evaporated by different kinds of fuel in similar circumstances.

The first and most celebrated, though probably not the most accurate apparatus for measuring the quantity of heat transferable from a hotter to a colder body, was the calorimeter of Lavoisier and Laplace. It consisted of three concentric cylinders of tin plate, placed at certain distances asunder; the two outer interstitial spaces being filled with ice, while the innermost cylinder received the hot body, the subject of experiment. The quantity of water discharged from the middle space by the melting of the ice in it, served to measure the quantity of heat given out by the body in the central cylinder. A simpler and better instrument on this principle would be a hollow cylinder of ice of proper thickness, into whose interior the hot body would be introduced, and which would indicate by the quantity of water found melted within it the quantity of heat absorbed by the ice. In this case the errors occasioned by the retention of water among the fragments of ice packed into the cylindric cell of the tin calorimeter, would be avoided. One pound of water at 172° Fahr., introduced into the hollow cylinder described, will melt exactly one pound of ice; and one pound of oil heated to 172° will melt half a pound. — *Ure*.

The method of refrigeration, contrived at first by Meyer, has been in modern times brought to great perfection by Dulong and Petit. It rests on the principle, that two surfaces of like size, and of equal radiating force, lose in like times the same quantity of heat when they are at the same temperature. Suppose, for example, that a vessel of polished silver, of small size, and very thin in the metal, is successively filled with different pulverised substances, and that it is allowed to cool from the same elevation of temperature; the quantities of heat lost in the first instant of cooling will be always equal to each other; and if for one of the substances, the velocity of cooling is double of that for another, we may conclude that its capacity for heat is one half, when its weight is the same; since by losing the same quantity of heat, it sinks in temperature double the number of degrees.

The method of mixtures. — In this method two bodies are always employed; a hot body, which becomes cool, and a cold body, which becomes hot, in such manner that all the caloric which goes out of the former is expended in heating the latter. Suppose, for example, that we pour a pound of quicksilver at 212° F., into a pound of water at 32° ; the quicksilver will cool and the water will heat, till the mixture by stirring acquires a common temperature. If this temperature was 122° , the water and mercury would have equal capacities, since the same quantity of heat would produce in an equal

mass of these two substances equal changes of temperature, viz., an elevation of 90° in the water and a depression of 90° in the mercury. But in reality, the mixture is found to have a temperature of only $37\frac{1}{2}^{\circ}$, showing that while the mercury loses $174\frac{1}{2}$ the water gains only $5\frac{1}{2}$; two numbers in the ratio of about 32 to 1; whence it is concluded, that the capacity of mercury is $\frac{1}{32}$ of that of water. Corrections must be made for the influence of the vessel and for the heat dissipated during the time of the experiment.

If our object be to ascertain the relative heating powers of different kinds of fuel, we need not care so much about the total waste of heat in the experiments, provided it be the same in all; and therefore they should be burned in the same furnace, and in the same way. But the more economically the heat is applied, the greater certainly will

852

there be in the results. The apparatus, *fig. 852*, is simple and well adapted to make such comparative trials of fuel. The little furnace is covered at top, and transmits its burned air by *c*, through a spiral tube immersed in a cistern of water, having a thermometer inserted near its top, and another near its bottom, into little side orifices, *a* & *a*, while the effluent air escapes from the upright end of the tube *b*. Here also a thermometer bulb may be placed. The average indication of the two thermometers gives the mean temperature of the water. As the water evaporates from the cistern, it is supplied from a vessel placed alongside of it. The experiment should be begun when the furnace has acquired an

equality of temperature. A throttle valve *ntc* serves to regulate the draught, and to equalise it in the different experiments by means of the temperature of the effluent air. When the water has been heated the given number of degrees, which should be the same in the different experiments, the fire may be extinguished, the remaining fuel weighed, and compared with the original quantity. Care should be taken to make the combustion as vivid and free from smoke as possible.

The following calorimeter, founded upon the same principle as that of Count Rumford, but with certain improvements, may be considered as an equally correct instrument for measuring heat with any of the preceding, but one of much more general application, since it can determine the quantity of heat disengaged in combustion, as well as the latent heat of steam and other vapours.

It consists of a large copper bath, *e, f* (*fig. 853*), capable of holding 100 gallons of

853

Scale about $\frac{1}{2}$ inch to the square foot.

water. It is traversed four times, backwards and forwards, in four different levels, by a zig-zag horizontal flue or flat pipe *d*, *e*, nine inches broad and one deep, ending below in a roiled pipe at *c*, which passes through the bottom of the copper bath *e, f*, and receives there into it the top of a small black lead furnace *b*. The innermost crucible contains the fuel. It is surrounded at the distance of one inch by a second crucible, which is enclosed at the same time by the sides of the outermost furnace;

the strata of stagnant air between the crucibles serving to prevent the heat from being dissipated into the atmosphere round the body of the furnace. A pipe *a*, from a pair of cylinder double bellows, enters the ash-pit of the furnace at one side, and supplies a steady but gentle blast, to carry on the combustion, kindled at first by half an ounce of red-hot charcoal. So completely is the heat which is discharged by the burning fuel absorbed by the water in the bath, that the air discharged at the top orifice *g* has usually the same temperature as the atmosphere.

The vessel is made of copper, weighing two pounds per square foot; it is $5\frac{1}{2}$ feet long, $1\frac{1}{2}$ wide, 2 deep, with a bottom $5\frac{1}{2}$ feet long, and $1\frac{1}{2}$ broad, upon an average, including the zig-zag tin plate flue, and a rim of wrought iron, it weighs altogether 85 pounds. Since the specific heat of copper is to that of water as 94 to 1,100, the specific heat of the vessel is equal to that of 8 pounds of water, for which, therefore, the exact correction is made by leaving 8 pounds of water out of the 600 or 1,000 pounds used in such experiment.

In the experiments made with former calorimeters of this kind, the combustion was maintained by the current or draft of a chimney open at bottom, which carried off at the top orifice of the flue a variable quantity of heat, very difficult to estimate.

When the object is to determine the latent heat of steam and other vapours, they may be introduced through a tube into the top orifice *g*, the latent heat being deduced from the elevation of temperature in the water of the bath, and the volume of vapour expended from the quantity of liquid discharged into a measure glass from the bottom outlet *c*. In this case, the furnace is of course removed.

The heating power of the fuel is measured by the number of degrees of temperature which the combustion of one pound of it, raises 600 or 1,000 pounds of water in the bath,—the copper substance of the vessel being taken into account.

It must be borne in mind that a coal which gives off much unburnt carbonated hydrogen gas does not afford so much heat, since in the production of the gas a great deal of heat is carried off in the latent state.

The economy of fuel, as exhibited in the celebrated pumping engines of Cornwall, will be dealt with under the proper head. See STEAM ENGINE. And in reference to the ordinary uses of fuel for domestic and other purposes, see STOVE.

PATENT FUEL. Under this name a great many attempts have been made to utilise waste material. In countries where charcoal is abundant charcoal dust mixed with pitch has been employed, and attempts have been made to utilise the immense quantities of saw-dust produced in the north of Europe, by mixing it with clay and tar. Passing over the several kinds of artificial fuel which have been made on the continent, the productions of this character made in this country must be described.

Wylam's patent fuel is small coal and pitch moulded together into bricks by pressure. The pitch is obtained by the distillation of coal tar from which naphtha and a peculiar oil are separated, leaving the pitch. This pitch is ground fine and mixed with small coal, and in this state it is passed, by a very ingenious application of the Archimedean screw, through a retort maintained at a dull red heat, by which it is softened for being moulded, which is effected by a kind of brick-making machine under enormous pressure.

Warlich's patent fuel is similar in character, but he adds a little common salt or alum to prevent the evolution of too much smoke, and the fuel bricks are subjected to a temperature of 400° F. for eight hours, by which the more volatile constituents are driven off.

Wood's fuel is prepared by mixing small coke or coal in a heated state with tar or pitch in a common pug-mill, after which it is moulded in the ordinary manner.

Bessemer's process consists merely in exposing coal-dust to a temperature of 600° F. By this the bituminous matter of the coal becomes softened, and the whole can be pressed into a firm block.

Grout's patent. This fuel is composed of coal-dust and coal-tar pitch; these materials are mixed together, under the influence of heat, in the following proportions:—20 lbs. of pitch to 1 cwt. of coal-dust, by appropriate machinery, consisting of crushing-rollers for breaking the coal in the first instance sufficiently small so that it may pass through a screen, the meshes of which do not exceed a quarter of an inch asunder; 2ndly, of mixing-pans or cylinders, heated to the temperature of 220° , either by steam or heated air; and, 3rdly, of moulding machines, by which the fuel is compressed, under a pressure equal to five tons, into the size of a common brick; the fuel bricks are then whitewashed, which prevents their sticking together, either to the coal bunkers or in hot climates. The advantages of these artificial fuels over coal may be stated to consist, first, in its efficacy in generating steam; secondly, it occupies less space; that is to say, 500 tons of it may be stowed in an area which will contain only 400 tons of coal; thirdly, it is used with much greater ease by the stokers or firemen than coal, and it creates little or no dirt or dust, considerations of some importance

when the delicate machinery of a steam-engine is considered; fourthly, it produces a very small proportion of clinkers, and thus it is far less liable to choke and destroy the furnace bars and boilers than coal; fifthly, the ignition is so complete that comparatively little smoke, and only a small quantity of ashes, are produced by it; sixthly, from the mixture of the patent fuel, and the manner of its manufacture, it is not liable to enter into spontaneous ignition.

A great many other persons have either patented processes for the preparation of artificial fuel, or published suggestions. These are so nearly alike that a few of them only require any notice.

Cobbolt agitates peat in water to separate the earthy matter, and then allows the peat to subside, and consolidates it.

Godwin makes brick of mud or clay with pitch or coal.

Oram employs tar, coals, and mud.

Hill takes the residuary matter after the distillation of peat, and mixes it with pitch.

Holland mixes lime or cement with tar and small coals.

Kauwme cements small coal together by a solution of salicats of soda.

From the Admiralty Coal Inquiry's Report we obtain the following analyses of several of the more important artificial fuels:—

Name of Fuel.	Specific Gravity of Fuel.	Carbon.	Hydrogen.	Sulphur.	Oxygen.	Ash.
Wartlich's	1.15	90.02	5.56	1.62	. . .	2.91
Livingstone's . . .	1.18	85.07	4.13	1.45	2.03	4.52
Lyon's	1.13	86.56	4.56	1.29	2.07	4.66
Bell's	1.14	87.89	5.22	0.71	0.42	4.90
Holland and Green's .	1.30	70.14	4.65	13.73
Wylam's	1.10	79.91	5.69	1.25	6.65	4.54

The following returns of trials at Woolwich will place the question of fuel, so far as coal and patent fuel are concerned, in the best possible view.

Report of Trials of Coals at Woolwich Dockyard, between the 9th February, 1848, and the 31st March, 1858.

Description of the Fuel used.	Number of Trials from which the Average Result was obtained.	Pounds of Water evaporated by 1 lb. of fuel consumed, corrected from 100° Fahr. to the Temperature of the Feed Water.	Cubic Feet of Water evaporated per Hour, each trial from 100° Fahr. to the Temperature of the Feed Water.	Per centage of Carbon.	Per centage of Ash.	Per centage of sulphur in ash.	Remarks.

[illegible]

FULGURATION designates the sudden brightening of the melted gold and silver in the cupel of the assayer, when the last film of vitreous lead and copper leaves their surface.

FULLER'S EARTH (*Terre à foulon, Argile, Sæctique, Fr.; Walkerde, Germ.*) In geology this term is applied to the clayey deposit which intervenes between the calcareous strata commonly known as the Bath or Great Oolite, and the inferior Oolite. A sandy argillaceous earth is met with in the upper part of the clay in question, to which the name Fuller's earth was given from its adaptability for fulling or cleansing cloth, when first woven, from grease and other impurities. The term thus limited originally to a particular stratum was subsequently applied to the entire formation by Dr. William Smith in his classification of the British strata, and has ever since retained its place in geological nomenclature. The fuller's earth above mentioned was formerly procured in considerable quantities from the Downs, to the south of Bath, whence it was sent to the cloth factories of Gloucestershire. Of late years, however, an artificial substitute has been found in a chemical preparation, and the demand for the natural production has decreased so far, that little or none of it is now procured in the West of England. The fuller's earth of Reigate is found in strata of a much more recent date than those alluded to above, and forms a part of the Lower Greensand. — See **GREENSAND**.

From Reigate 12,000 tons of dried fuller's earth are raised annually. There are two varieties, called the blue and yellow; their analyses are respectively —

	Blue.	Yellow
Alumina	18	11
Silica	42	44
Lime	4	5
Magnesia	2	2
Oxide of Iron	6	10
Soda	3	5

The other places from which fuller's earth has been obtained, are — Penenden Heath, Maidstone, Frome, Lonsdale, Coombe Hay, English Coombe, and Duncorn Hill in Gloucestershire, and at one locality in Bedfordshire. — H. W. H.

FULLING. The art of cleansing, scouring, and pressing woollen manufactures. The object is to render them stronger and firmer. It is called also *milling*, because the cloths are scour'd by a water mill.

The principal parts of a fulling mill, are the wheel with its trundle, which gives motion to the tree or spindle whose teeth communicate that motion to the rammers or beaters, which fall into troughs, wherein the cloth is put, with the fuller's earth.

William and Ogle introduced in 1825 some new fulling machinery, designed to act in a similar way to the ordinary stocks, in which cloths are beaten, for the purpose of washing and thickening them; but the standard and the bed of the stocks are made of iron instead of wood, as heretofore; and a steam vessel is placed under the bed, for heating the cloths during the operation of fulling; whereby their appearance is said to be greatly improved.

Fig. 234 is a section of the fulling machine or stocks; *a*, is a cast-iron pillar, made hollow for the sake of lightness; *b*, is the bed of the stocks, made also of iron, and polished smooth, the side of the stock being removed to show the interior; *c*, is the lever that carries the beater *d*. The cloths are to be placed on the bed *b*, at bottom, and water allowed to pass through the stock, when by the repeated blows of the beater *d*, which is raised and let fall in the usual way, the cloths are beaten, and become cleansed and full'd.

A part of the bed at *e* is made hollow, for the purpose of forming a steam box, into which steam from a boiler is introduced by a pipe with a stop-cock. This steam heats the bed of the stock, and greatly facilitates, as well as improves, the process of cleansing and fulling the cloths.

The smoothness of the surface of the polished metal, of which the bed of the stock is constituted, is said to be very much preferable to the roughness of the surface of wood of which ordinary fulling stocks are made, as by these iron stocks less of the nap

or felt of the cloth is removed, and its appearance when finished is very much superior to cloth folded in ordinary stocks.

In the operation of folding, the cloths are turned over on the bed by the falling of the beaters, but this turning over of the cloths will depend in a great measure upon the form of the front or breast of the stock. In these improved stocks, therefore, there is a contrivance by which the form of the front may be varied at pleasure, in order to suit cloths of different qualities; *f*, is a movable curved plate, constituting the front of the stock; its lower part is a cylindrical rod, extending along the entire width of the bed, and being fitted into a recess, forms a hinge joint upon which the curved plate moves; *g*, is a rod attached to the back of the curved plate *f*, with a screw thread upon it; this rod passes through a nut *h*, and by turning this nut, the rod is moved backward or forward, and consequently, the position of the curved plate altered.

The nut *h*, is a wheel with teeth, taking into two other similar toothed wheels, one on each side of it, which are likewise the nuts of similar rods jointed to the back of the curved plate *f*; by turning the central wheel, therefore, which may be done by a winch, the other two wheels are turned also, and the curved plate moved backward or forward. At the upper part of the plate there are pins passing through curved slots, which act as guides when the plate is moved.

FULMINATING MERCURY, $C^N Hg^O$ + Ag. (dried at 212°). The well known compound used for priming percussion caps. It was analysed many years ago by Liebig, and subsequently, by Gay-Lussac. Although chemists have long been acquainted with the true composition of fulminic acid, and the formula of fulminating mercury has also been rendered almost certain, no accurate analysis of the latter compound was made public until 1853, when M. Schischkoff published his celebrated paper on the fulminates. It is singular that Liebig and Schischkoff were independently engaged at the same time in investigating the products of decomposition of the fulminates. The formula of fulminic acid, and also that of fulminating mercury, had been deduced from the very accurate analysis of fulminating silver made by Gay-Lussac and Liebig. A great number of processes for the preparation of fulminating mercury have been published. The following are the best as regards economy and certainty.

1. One part of mercury is to be dissolved in 10 parts of nitric acid, sp. gr. 1.4, and the solution at a temperature of 180° F. is to be poured into 8.7 parts of alcohol, sp. gr. 0.830. — *Dr. Ure.*

2. One part of mercury is to be dissolved in 12 parts of nitric acid, of sp. gr. 1.3. To the solution (as soon as it has cooled to 55° F.), 8 parts of alcohol, sp. gr. 0.837, are to be added; the vessel containing the mixture is to be heated in boiling water until thick white fumes begin to form. The whole is then set in a cool place to deposit the crystals of fulminate. — *Crematwohl.*

3. One part of mercury is to be dissolved in 12 parts of nitric acid, sp. gr. 1.340 to 1.345, in a flask capable of holding 14 times the quantity of fluid used. When the metal is dissolved, the solution is decanted into a second vessel containing 5.7 parts of alcohol, of 90° to 92° (*Tralles*), then immediately poured back into the first vessel, and agitated to promote absorption of the nitrous acid. In five to ten minutes gas bubbles begin to rise, and there is formed at the bottom of the vessel a strongly refracting, specifically heavier liquid, which must be mixed with the rest by gentle agitation. A moment then arrives when the liquid becomes black from separation of metallic mercury, and an extremely violent action is set up, with evolution of a thick white vapour, and traces of nitrous acid; this action must be moderated by gradually pouring in 5.7 parts more of the same alcohol. The blackening then immediately disappears, and crystals of fulminating mercury begin to separate. When the fluid has become cold, all the fulminating mercury is found at the bottom. By this method not a trace of mercury remains in solution. — *Liebig.*

The fulminate in all these processes is to be collected on filters, washed with distilled water, and dried. The violent reaction which takes place when the solution of mercury reacts on the alcohol is essential to the success of the operation.

With regard to the economy of the above methods, it has been found that 1 part of mercury yields the following proportions of fulminate: —

1st process	-	-	-	-	-	-	-	-	1.30
2nd "	-	-	-	-	-	-	-	-	1.25
3rd "	-	-	-	-	-	-	-	-	1.54

C. G. W.

FULMINATING SILVER, $C^N Ag^N O^1$. This salt corresponds in constitution to the fulminate of mercury; it may also be prepared by analogous processes, merely substituting silver for mercury. *Preparation.*—1. 1 part of silver is to be dissolved in 24 parts of nitric acid, sp. gr. 1.5, previously mixed with an equal weight of water.

To the solution is to be added alcohol equal in weight to nitric acid. *Produce*, 1.5 parts of fulminating silver. 2. 1 part of silver is to be dissolved in 20 parts of nitric acid, sp. gr. 1.33. To the solution is to be added 27 parts of alcohol, sp. gr. 0.832. The mixture is to be heated to boiling, and, as soon as it shows signs of becoming turbid, it is to be removed from the fire, and a quantity of alcohol, equal in weight to the first, is to be poured in. The liquid is now to be allowed to become perfectly cold, when the fulminate will be found at the bottom of the vessel. *Produce*, equal to the silver employed. 3. 1 part of silver is to be dissolved in ten times its weight of nitric acid, sp. gr. 1.36. To the solution is to be added 20 parts of alcohol, sp. gr. 0.83. The mixture is to be treated as in the second mode of preparation, except that no more alcohol is to be added. The produce should be in fine crystals. Whichever mode of preparation be selected, it is absolutely necessary, in order to avoid fearful accidents, that the following precautions be attended to. The beakers or flasks employed must be two or three times larger than is required to hold the ingredients, for if, owing to frothing or boiling over, any of the fluid happened to find its way to the outside, and dry there, an explosion might ensue. Care must also be taken that the highly inflammable vapours given off during the preparation do not come near any flame. The salt, when formed, must be received on a filter, and well washed with cold water. It is safer to dry it spontaneously, or over oil of vitriol, for although it will endure a heat above that of boiling water before exploding, yet when warm, the slightest touch with a hard substance is often sufficient to cause a terrible detonation. A spatula of pasteboard or very thin wood should be employed to transfer it into its receptacle. Fulminating silver should not be kept in glass vessels, for fear of the salt finding its way between the cork or stopper, the slightest movement with a view of opening the vessel, being then sufficient to cause an accident. Small paper boxes are the safest to keep it in.

Fulminating silver gives a more violent detonation than the corresponding mercurial compound. The presence of roughness or granular particles on the substances with which it may be in contact, assists greatly in causing it to explode.

Although giving so violent an explosion when alone, it may be burnt without danger when mixed with a large excess of oxide of copper, as in the ordinary process of organic analysis. It then gives off a mixture of two volumes of carbonic acid, and one volume of nitrogen. Gay-Lussac and Liebig made an analysis of the salt in this manner, with the annexed results:—

Experiment				Calculation.

For further remarks on the fulminates, see FULMINATING MERCURY.—C. G. W.

FULMINIC ACID, $C^2N^2HPO^2$. The acid contained in fulminating mercury; which see.

FUMIGATION is the employment of fumes or vapours to purify articles of apparel, and goods or apartments supposed to be imbued with some infectious or contagious poison or fumes. The vapours of vinegar, the fumes of burning sulphur, explosion of gunpowder, have been long prescribed and practised, but they have in all probability little or no efficacy. The diffusion of such powerful agents as chlorine gas, muriatic acid gas, or nitric acid vapour, should alone be trusted to for the destruction of malarious effluvia. See DISINFECTANTS.

FUR. (*Fouurre*, Fr; *Felz*, Germ.) Fur may be strictly distinguished as the short fine soft air of certain animals, growing thick on the skin, and distinguished from the hair which is longer and coarser. The term is, however, used sometimes very loosely, and includes those skins which are covered with hair. Fur is one of the most perfect non-conductors of heat, and consequently we find the animals of the colder regions of the earth clothed with this substance, and hence man has adopted it as the warmest of clothing.

To the admirable report made by Messrs. J. A. Nicholay and James R. Bevington, on the furs of the Great Exhibition, we are mainly indebted for the following particulars.

THE RUSSIAN SABLE (*Mustela sibirica*). In the reign of Henry VIII., by a law to regulate the expenses of different classes, and to distinguish them by peculiarity of costume, the use of sable was confined to the nobility above the rank of Esquire. It is stated that 25,000 skins are annually collected in the Russian territories. The fur is brown, with some grey spots on the head; the darker varieties are the most valuable, a single skin of a fine dark colour being sold for as much as nine pounds, though the

average value does not exceed two or three. The Russian sable is sometimes confounded with the Hudson's Bay sable, but to the furrier the former is easily distinguishable from the length and fullness, as well as the darker colour, of the fur.

HUDSON'S BAY SABLE (*Mustela Canadensis*). As the natural colour of this skin is much lighter than the prevailing taste, it is the practice to dye many of them a darker colour, and the furs thus treated are scarcely inferior to the Russian or true sable. Not less than 120,000 skins are annually imported into this country.

PINE MARTEN or BAUM (*Mustela abietum*). The animals producing this skin are found in extensive forests in the north of Europe. The skins are distinguished from the stone marten by the yellow colour of the throat. These skins are dyed to imitate real sable.

STONE MARTEN (*Mustela pennina*). This is frequently called French sable, from the fact that the French furriers excel in dyeing this skin. The stone marten is distributed through most European countries. The under fur is a bluish white, with the top hairs a dark brown, the throat being generally a pure white, by which it is distinguished.

FISHER. These skins are larger than the sables, and the fur is longer and fuller; about 11,000 of these skins are annually brought from America. The tail, which is long, round, and gradually tapering to a point, was formerly used as the common ornament to a national cap worn by the Jew merchants of Poland.

MINK (*Mustela vison*). There were 245,000 skins of this little animal brought to this country in 1850. The fur resembles sable in colour, but is considerably shorter and more glossy.

ERMINE (*Mustela erminea*). This animal is similar in form and habit to the common weasel of this country, but in Siberia, Russia, and Norway, from whence the skins are imported; the little animal during winter becomes as white as the snowy regions it inhabits, and is esteemed the whitest fur known, though in summer its dress is a dingy brown. The tail of the skin, of which the lower half is jet black is usually introduced as an ornament to the purely white fur. In Edward III.'s reign, the use of ermine was restricted to the royal family.

FITCH or POLECAT (*Mustela putorius*), produced throughout Europe and in our own country. This animal has a soft black fur with a rich yellow ground. The natural smell of this fur is unpleasant and difficult to overcome.

NORTH AMERICAN SABLE (*Mephitis Americana*). These skins are imported by the Hudson's Bay Company. The animal from which it is obtained is allied to the polecat of Europe. The fur is a soft black, with two white stripes running from the head to the tail. This fur is not much used in this country.

KOLIKERY (*Mustela Siberica*). The Tartar sable, which is of a bright yellow colour. It is sometimes used in its natural state, but is more frequently dyed brown to imitate other sable, to which it bears a strong resemblance. It is remarkable for the uniformity of its colour, having no spot or difference of shade in any part of the body. The tail which is of the same colour, is exclusively used for the best artists' pencils.

MINK RAT or MRSQUASH (*Fiber sibiricus*), an inhabitant of the swamps and rivers of America. About a million skins are brought to this country annually. The fur resembles that of the beaver, and was used by hat manufacturers. The skins are also dyed by the furrier, and manufactured into many cheap and useful articles.

NETTIE or COYON (*Myopotamus coypus*). This animal is larger than, but somewhat similar to, the musquash; it inhabits the banks of rivers in Buenos Ayres and Chili. But few of these skins are now imported.

HAMSTER (*Cricetus vulgaris*), a native of Germany, where not less than 100,000 skins are annually collected. It has a poor, short, and coarse fur, which is almost exclusively used for cloak linings by the Greeks. The colour of the back is a reddish brown, the belly black, with a few light spots.

PRAWITZKY. The skin of this animal is marked like tortoise shell; it is brought from the southern extremities of Asiatic Russia. It is chiefly used by the Russians for cloak lining.

BEAVER (*Castor Americanus*). This beautiful fur is sometimes used for articles of dress. In order to prepare the skin for this appropriation, the coarse hairs are removed, and the surface cut by a very ingenious machine, somewhat similar to that used in dressing cloth. The skin thus prepared has a beautiful appearance, not unlike the costly South Sea otter, and has the advantage of durability and lightness.

OTTER (*Lutra vulgaris*, *Lutra Canadensis*). Of the British otter about 500 skins are collected annually. The large quantity used by the Russians and Chinese is derived principally from North America.

SEA OTTER (*Enhydra marina*). The sea otter has a very thick, soft, woolly fur, and is most highly prized by the Russians and Chinese, to whom most of the skins

are exported. The animal is found in the North Pacific from Kamtschka to the Yellow Sea, on the Asiatic coasts, and from Alaska to California on the American coast.

SEAL (*Phoca*). There are numerous varieties of these animals, which are found on the western coasts of these islands, and in immense numbers on the shores of Labrador, Greenland, and Newfoundland. The greater portion of the skins imported are tanned and enamelled with black varnish for ladies' shoes; other descriptions are well adapted for fur. Before they can be used as a fur, it is necessary to remove the very coarse hairs which cover a beautifully fine and silky fur. By shaving the felt to half its natural substance, the roots of the coarse hairs are cut through, and they easily fall out, but the same effect is produced by the natural process of fermentation, which ensues when the skins are properly prepared and allowed to remain together. This fur is rarely used in its natural state, but is dyed a deep randyke brown, when it has the appearance of the richest velvet.

The skins of the fox, the wolverine (*Gulo luteus*), the bear, the hare, and the rabbit, scarcely require notice.

The **SQUIRREL**, especially the Siberian squirrel, is much sought for. It is said that 15,000,000 of these skins are annually collected in Russia, and of these, 3,000,000 are sent to this country.

CHINCHILLA (*Chinchilla lanigera*). There are two varieties of Chinchilla, the produce of South America. Our chief supply is from Buenos Ayres and Arica. The skins from the former locality are of a silvery grey. Those from Arica are the darkest and best coloured skins.

RACCOON (*Procyon lotor*), this fur is used for lining coats.

CAT (*Felis domesticus*). In Holland, the cat is bred for its fur; it is fed on fish and carefully tended until the fur arrives at perfection.

CANADA LYNX (*Felis Canadensis*). This fur is not much used in this country, but it is prepared and exported for the American market.

The importance of the trade in furs and skins will be rendered evident from the preceding accounts of the Imports and Exports. It would have been desirable to have separated the furs, strictly so called, from the skins, but this has not been found practicable with anything like accuracy; the returns are therefore given under the heads adopted by the Customs.

Furs are subject to injury by several species of moths, whose instinct leads them to deposit their eggs at the roots of the fine hair of animals.

Linnæus mentions five species that prey upon cloth and furs, of which *Tinea pellionella*, *T. vestimentella* and *T. tapetella* are the most destructive. No sooner is the worm hatched than it eats its path through the fur, and continues increasingly destructive until it arrives at its full growth, and forms itself a silken covering, from which, in a short time, it again emerges a perfect moth.

Another cause of the decay of fur is, the moisture to which they are frequently exposed; the delicate structure of the fine under fur cannot be preserved when any dampness is allowed to remain in the skin. This fact is well known to the leather manufacturer, who, having wetted his skins, allows them to remain in a damp cellar

for a few days, for the purpose of removing the hair which is pulled out with the greatest facility, after remaining only one week in a moist condition. It follows from these observations, that to preserve the fur it is necessary to keep them dry, and to protect them from moths; if exposed to rain or damp, they must be dried at a moderate distance from the fire; and when put by for the summer should be combed and beaten with a small cane, and very carefully secured in a dry brown paper or box, into which moths cannot enter. During the summer they should be examined once a month to be again beaten and aired, if the situation in which they have been placed be at all damp. With these precautions, the most valuable furs may be preserved uninjured for many years.

FURNACE. The various descriptions of furnaces employed in the different metallurgical processes will be found described in the articles devoted to the metals. See *IRON, COPPER, &c. &c.*, and *METALLURGY*.

FUR-SKIN DRESSING. Fur-skins are usually dressed by placing them in their dried state in closed tubs with a little salt batter, where they undergo a treading operation with men's feet until they are sufficiently soft, and bend easily. The skins if large are sewn up, the fur being turned inwards; but if small skins, such as ermine, are being dressed, they require no sewing. This sewing is preparatory to the greasing with butter or lard, and is intended to protect the fur from the grease, and to promote the softening in the succeeding treading operation. The skins are next wetted, and their flesh is removed, or they are fleshed. See *CURRYING*. They are again subjected to treading in tubs containing sawdust, that from mahogany being preferred; and afterwards in tubs containing plaster of Paris, or whitening, sprinkled between the skins. The main object of this is to remove the grease which has been used in the previous processes. They are then beaten with a stick, and combed; when the dressing is completed. M. Pierre Thirion proposed to soften the skins, not by treading, but by beating stocks, of a construction like the falling mill. They are next sewn up, and again filled in a strong vessel, where they are forced upwards by the beaters, turned over and over, and thus speedily softened. They are now fleshed, and then returned to the beating stocks, and mahogany or other sawdust is sprinkled upon the fur, before the beating is renewed. They are next placed in a heated barrel, furnished within with radial pins for turning the goods over and over, in order that they may be acted upon by various dry substances, which are thrown into the barrel, and absorb the fat from the skins. Through the hollow shaft of the barrel steam is introduced, which heats the skins, softening the fat, which is then absorbed by sand, flour, or any other desiccative powder. It is proper to take the skins out of the barrel from time to time, to comb them. Such as have been sufficiently acted upon may then be set aside. They are lastly freed from the dust by being subjected to a grated cylinder in a state of rotation, and then combed by hand.

FUSEL OIL. During the rectification of corn or grape spirits there is always separated a fiery fetid oil of nauseous odour and taste. It is this substance which is the cause of the unpleasant effects which are produced upon most persons by even a small quantity of insufficiently rectified whiskey or brandy. Any spirit which produces sickness on the addition of four or five times its volume of water may be suspected to contain it. By repeated rectification every trace may be removed.

Fusel oil invariably consists of one or more homologues of the vinic alcohol ($C^{11}H^{23}O$), mixed with variable quantities of the latter substance and water. The nature of fusel oil varies much with the source from whence it is obtained. That which is ordinarily sold in this country for the purpose of yielding pear essence consists mainly of the amylic alcohol ($C^{11}H^{23}O$), mixed with from one-fourth to one-fifth of spirit of wine.

The progress of organic chemistry has been greatly assisted by the researches which have been made upon fusel oil, almost all the amylin compounds hitherto obtained having been directly or indirectly obtained from it.

To obtain fusel oil in a state of purity it is necessary, in the first place, to rectify it fractionally. By this means it will be found that much alcohol can be removed at once. If a great quantity of water and very little vinic alcohol be present, the simplest mode of purification is to shake it with water, by which means common alcohol is removed in solution, while the amylic alcohol, owing to its comparative insolubility, may be easily separated by the tap-funnel. After drying over chloride of calcium, it is to be again rectified once or twice, only that portion distilling at about $289^{\circ} 6'$ Fahr. (142° Cent.) being received. The product of this operation is pure amylic alcohol, from which an immense number of derivations of the amylic series can be obtained. By treatment with sulphuric acid and bichromate of potash it is converted into valerianic acid. In this manner all the valerianic acid, now so much employed in medicine is prepared. By distilling amylic alcohol with sulphuric acid and acetate of potash, we obtain the acetate of amylic, commercially known as jargonelle pear essence.

The foreign fusel oils obtained from the grape mare contain several homologues

higher and lower in the series than the amyl alcohol. In fact, it would appear that during the fermentation of grapes there are formed, not only alcohols, but ethers and acids.

M. Chancel, by repeatedly rectifying the dehydrated and more volatile portions of the residues of the distillation of grape marc alcohol, succeeded in isolating a fluid boiling at 205° Fahr. This proved to be pure propionic alcohol. M. Wurtz has also been able to obtain the butylic alcohol by rectifying certain specimens of fusel oil.

All fusel oils are not so complex. The author of this article has repeatedly examined specimens of English and Scotch fusel oil, which did not contain anything save the ethylic and amyl alcohol, accompanied by small portions of the acids, which are procured by their oxidation. M. Chancel has given the following equations, which explain the manner in which saccharine matters break up into homologous alcohols under the influence of ferments. I have reduced the unitary notation employed by him into the ordinary formulae used in this country, in order to render the relations as clear as possible to the reader.

M. Chancel appears to consider the last equation as indicating the necessity of propionic alcohol being always formed whenever amylic alcohol is generated, but this is not in accordance with the results of those chemists who have examined crude amylic alcohol repeatedly for propionic alcohol, but without finding any. The formation of these interesting homologues appears therefore to depend upon special circumstances connected with the fermentation.

The caproic alcohol is also contained in certain varieties of fusel oil.

In order to assist those who may wish to examine the fluid alluded to, the following table of the physical properties of the alcohols up as high as the caproic has been inserted:—

Table of the Physical Properties of some Homologous Alcohols found in Fusel Oils.

Name.	Observations.	Formula.	Boiling Point.	Specific Gravity.	Vapour Density.	
					Experiment.	Calculation.
Methylic	Dumas and Peligot	$C^2H^4O^2$	132°	0.7941 at 4°	1.170	1.1672
Ethylic	Gay-Lussac	$C^4H^8O^4$	172°	0.794 at 4°	1.463	1.4616
Propionic	Chancel	$C^6H^{12}O^6$	205°	" "	2.020	2.0200
Butylic	Wurtz	$C^8H^{16}O^8$	214°	" "	"	2.684
Amylic	Stalar and Dumas	$C^{10}H^{20}O^{10}$	271°	0.814 at 4°	3.147	3.0444
Caproic	Faget	$C^{12}H^{24}O^{12}$	284°	0.8320 at 27°	3.820	3.8208

Fusel oil, in addition to these homologous alcohols, contains several fatty acids. The following list contains the acids found in fusel oil, with the name of the observer.

Name of Acid.	Formula.	Observer.
Formic	$C^2H^4O^4$	Wethrill
Acetic	$C^4H^8O^6$	Kent
Valerianic	$C^6H^{12}O^8$	Kent
Caproic	$C^8H^{16}O^{10}$	Wethrill
Heptanthylic	$C^{10}H^{20}O^{12}$	Mulder, Wethrill
Caprylic	$C^{12}H^{24}O^{14}$	Wethrill
Capric	$C^{14}H^{28}O^{16}$	Rowny
Margaric	$C^{16}H^{32}O^{18}$	Kolbe

Fusel oil has been patented as a solvent for quinine, but its odour, and more especially that produced by its oxidation, so persistently adheres to anything with which it has been in contact, that great care is requisite in the purification. It is remarkable that at the first instant of smelling most specimens of fusel oil, the odour is not unpleasant, but in a very few seconds it becomes exceedingly repulsive, and provokes coughing.—C. G. W.

FUSERS. See SAFETY FUSERS.

FUSIBILITY. That property by which solids assume the fluid state under the influence of heat. With a few exceptions, such as carbon and some organic bodies, all substances appear capable of assuming the fluid state. Although we do not appear to have actually fused charcoal by means of the voltaic battery, the diamond has been fused and converted from a crystalline gem into a mass of opaque coke.

Thenard has thus grouped the metals:—

1. Fusible below a red heat:—*Mercury, potassium, sodium, tin, bismuth, lead, tellurium, uranium, zinc, antimony, cadmium.*

2. Infusible below a red heat:—*Silver, copper, gold, cobalt, iron, manganese, nickel, palladium, molybdenum, uranium, tungsten, chromium, titanium, cerium, osmium, iridium, rhodium, platinum, columbium.*

Ponillet has, in his admirable treatise on heat, given the following table of the fusing points of various substances:—

Names.	Centigrade.	Names.	Centigrade.
Mercury	—39	Bismuth	202
Oil of turpentine	—10	Lead	320
Ice	0	Zinc	350
Tallow	33 to 38	Antimony	432
Acetic acid	43	Bronze	900
Spermoceti	49	Silver, very pure	1000
Stearine	49 to 43	Standard gold	1150
Margaric acid	53 to 60	Very fine gold	1250
Unbleached wax	61	White cast iron, very fusible	1050
White wax	68	White cast iron, second fusion	1200
Stearic acid	70	Grey cast iron, very fusible	1100
Phosphorus	43	Grey cast iron, second fusion	1300
Potassium	59	Manganese cast iron	1250
Sodium	90	The more fusible steels	1300
Iodine	107	The less fusible steels	1400
Sulphur	114	Soft iron (French)	1500
Tin	230	English hammered iron	1600

FUSIBLE METAL. See ALLOY.

This alloy owes its peculiar property of melting at a comparatively low temperature to the presence of bismuth.

8 parts of bismuth, 3 of lead, 3 of tin	- melt at 212° F.
2 do. 1 do. 1 do.	- do. 201° F.
3 do. 3 do. 2 do.	- do. 199° F.
8 do. 5 do. 4 of tin, and 1 of type metal	is an alloy

much used on the continent for producing casts of metals by the *châche* process. A mixture of bismuth, lead, tin, and antimony is used in this country for obtaining copies from wood blocks. Mr. Cowper used 1 of bismuth and 2 of tin to make the alloy most suitable for rose engine and eccentric turned pattern, to be printed from after the manner of letter press.

The soft solders used by pewterers consist of tin, lead, and bismuth in various proportions; indeed, bismuth enters to a greater or a less extent into all the soft solders.

Fusible metal has also been employed as a sort of safety valve for steam boilers. By adjusting the proportions of the above named metals, an alloy can be made which will melt at any required temperature; therefore, when the boiler rose to this temperature, the metal plug gave way and the steam escaped.

FUSTIAN is a species of coarse thick tweeled cotton, and is generally dyed of an olive, leaden, or other dark colour. Besides the common fustian, which is known by the name of pillow (probably pilaw), the cotton stuffs called corduroy, velvet, velveteen, thickset, used for men's wearing apparel, belong to the same fabric. The commonest kind is merely a tweel of four, or sometimes five leaves, of a very close stout texture, and very narrow, sellem exceeding 17 or 18 inches in breadth. It is cut from the loom in half pieces, or ends as they are usually termed, about 35 yards

long, and after undergoing the subsequent operations of dyeing, dressing, and folding, is ready for the market.

The draught and cording of common fustian is very simple, being generally a regular or unbroken twell of four or five leaves. Below are examples of a few different kinds, selected from those most general in Lancashire.

The number of leaves of heddles are represented by the lines across the paper, and the cording by the ciphers in the little squares, those which raise every leaf being distinguished by these marks, and those which sink them left blank, as more particularly explained in the article TEXTILE FABRIC.

When the material is silk, it is called velvet, when cotton, velveteen. A common tweeled cloth, when composed of silk is called satin; when of cotton, fustian or jean; of woollen, plaiding, serge, or kerseymere.

No. 1.—Pillow Fustian.

1	0	1	1	1	1	1	1
1	0	1	1	1	1	1	1

Of the above, each contains four leaves of heddles or beards: that represented by No. 1 is wrought by four treddles, and that which is distinguished by No. 2, by five; the succession of inserting the threads of warp into the heddles will be discovered by the figures between the lines, and the order in which the treddles are to be successively pressed down by the figures below.

No. 3.—Double Jean.

1	0	1	1	1	1	1	1

1	0	1	1	1	1	1	1
1	0	1	1	1	1	1	1

These, like the former, are wrought with leaves. No. 3 requires four, and No. 4 five treddles. The succession of inserting the threads of warp, and of working the treddles, are marked by the respective numbers between and under the lines, as in the former example. Both are fabrics of cloth in very general use and estimation as low priced articles.

No. 5.—Best Thicksett.

1	0	1	1	1	1	1	1
1	0	1	1	1	1	1	1
1	0	1	1	1	1	1	1

In these the succession of drawing and working are marked like the former. The next are examples of patterns wrought with six leaves. No. 9 has eight, and No. 10 five heddles.

No. 2.—Double Cord-rope.

[illegible]

No. 10.—Genoa Thickset.

[illegible]

In both these the warp is inserted into the beddles the same way. The difference is entirely in the application of the cords, and in the succession of pressing down the treadsles. We now give four specimens of the flushed and cut work, known by the name of velvetten. They are also upon six leaves, and the difference is solely in the curling and in the treading.

The additional varieties of figure which might be given are almost endless, but the limits of this article will not admit a further detail. Those already given are the articles in most general use. The varieties of fancy may be indulged to great extent, but it is universally found, that the most simple patterns in every department of ornamental weaving, are those which attract attention and command purchasers. We shall therefore only add an example of king's cord, or corduroy, and of Dutch cord, with one of Genoa and one of common velvet, to show the peculiarities.

After the fustian cloth is taken from the loom-beam, it is carried to the cutter, who rips up the surface-threads of web, and produces thereby a hairy-looking stuff.

Preparatory to its being cut, the cloth is spread evenly upon a table about six feet long, upon each end of which a roller mounted with a ratchet-wheel is fixed, the one to give off, and the other to wind up the piece, in the above six-foot lengths.

The knife is a steel rod about two feet long, and three-eighths of an inch square, having a square handle at the one end; the other end is tapered away to a blade, as thin as paper. To prevent this point from turning downwards and injuring the cloth, its under side is covered by a guide which serves to stiffen it, as well as to prevent its lower edge from cutting the sustian.

The operative (male or female) grasps the handle in the right hand, and inserting the projecting point of the guide under the web, pushes the knife smartly forward through the whole length of six feet, with a certain dextrous movement of the shoulder and right side, balancing the body meanwhile, like a fencer, upon the left foot. This process is repeated upon every adhesive line of the web.

The next process to which sustians are exposed is steeping in hot water, to take out the dressing paste. They are then dried, reeled, and brushed by a machine, &c. From twenty to thirty pieces, each eighty yards long, may be brushed in an hour. The breadth of the cloth is twenty inches. The maceration is performed by immersing the banded pieces in tanks of water, heated by waste steam; and the washing by means of a reel or winch, kept revolving rapidly under the action of a stream of cold water, for an hour or longer.

After being thus ripped up, it is taken to the brushing or teasing machine, to make it shaggy.

This consists of a series of wooden rollers, turning freely upon iron axes, and covered with tin-plate, rough with the burr of punched holes; and blocks of wood, whose concave under surfaces are covered with card-cloth or card-brushes, and which are made to traverse backwards and forwards in the direction of the axes of the revolving rollers, during the passage of the cloth over them.

After they are brushed in the machine, the goods are singed by passing their cut surface over a cylinder of iron, laid in a horizontal direction, and kept red hot by a fire. They are now brushed again by the machine, and once more passed over the singeing surface. The brushing and singeing are repeated a third or even occasionally a fourth time, till the cord acquires a smooth polished appearance.

The goods are next steeped, washed, and bleached by immersion in solution of chloride of lime. They are then dyed by appropriate chemical means. After which they are padded (imbued by the padding machine of the calico printers) with a solution of glue, and passed over steam cylinders to stiffen them.

Smooth sustians, when cropped or shorn before dyeing, are called mol-shins; but when shorn after being dyed, are called beverteen; they are both twined sustians. Canton is a sustian with a fine cord visible upon the one side, and a satiny surface of yarns running at right angles to the cords upon the other side. The satiny side is sometimes smoothed by singeing. The stuff is strong, and has a very fine aspect.

FUSTIC, or YELLOW WOOD. (*Rhus jaune*, Fr.; *Gelbbholz*, Germ.) The old fustic of the English dyer. It is the wood of the *Morus tinctoria*. It is light, not hard, and pale yellow with orange veins; it contains two colouring matters, one resinous, and another soluble in water. Chevreul has given the name of *morin* to the colouring matter obtained from fustic. It is procured by boiling ground fustic in distilled water, passing the decoction rapidly through a filter, and allowing the liquid to stand for several days, when the colouring matter (*morin*) is precipitated.

The decoctions of fustic in water are brightened by the addition of a little glue, and still more so by curdled milk. This wood is rich in colour, and imparts permanent dyes to woollen stuffs, when aided by proper mordants. It unites well with the blue of the indigo vat, and Saxon blue, in producing green of various shades. Alum, tartar, and solution of tin, render its colour more vivid; sea salt and sulphate of iron deepen its hue. From 5 to 6 parts of old fustic are sufficient to give a lemon colour to 16 parts of cloth. This wood is often employed with sulphate of iron in producing olive and brownish tints, which agree well with its dull yellow. For the same reason it is much used for dark greens.

The bichromates of potash and of lead, have nearly superseded the use of fustic, but still, it is employed for producing some green in cotton yarn, and in light cotton fabrics, as gazees and muslins.

FUSTIC, Young. (*Fustet*, Fr.) The wood of the *Rhus cotinus*, a shrub which grows principally in the south of France and in Italy, called also *l'acétun romain*. This wood contains a large quantity of yellow colouring matter, named *fusticic*. This colouring matter has a strong attraction for oxygen, which affects its use as a dye, rendering it very fugitive. It is rarely used alone, but as an assistant to strike some particular tint.

G.

GABRONITE, is a yellowish stony substance, of a greasy lustre and sp. gr. = 2.74; affording no water by calcination; fusible at the blow pipe into an opaque glass; soluble in muriatic acid; solution affords hardly any precipitate by oxalate of ammonia. This mineral is distinguished by the large quantity of soda which it contains; its constituents being, silica, 34; alumina, 24; soda, 17.25; magnesia, 1.3; oxide of iron, 1.25; water 2. It is most probably a variety of Scapolite.

GAD. A miner's tool, a pointed wedge having its sides at a parabolic figure.

GADIDÆ. The cod-fish family. Beyond the value of the cod-fish as an article of food, the cod liver oil is now an important manufacture. See **COD**.

GADOLINITE, called also Yttrite and Ytterbyite; is a mineral of a black, brownish, or yellowish colour, granular, or compactly vitreous, and conchoidal fracture; of sp. gr. 4.0 to 4.3, readily scratching glass; at the blow pipe it forms an opaque glass, sometimes with intumescence, but does not fuse into a bead. It efforls, with acids, a solution that lets fall, with caustic soda, a precipitate partly resolvable in carbonate of ammonia. It is remarkable for containing from 45 to 55 per cent. of the earth yttria; its remaining constituents being silica, 25.8; oxide of cerium, 17.92; oxide of iron, 11.43. This mineral is very rare, is found in the neighbourhood of Fahlun and Ytterby, in Sweden; also at Disko, in Greenland; in trap, near Galway; in granite, in Ceylon; and in the south of Norway. Its peculiar constituent was discovered by Professor Gadolin, after whom it is named.

GALACTOMETER, or **LACTOMETER**, is an instrument to ascertain the quantity of milk; an article often sophisticated in various ways. Fresh milk, rich in cream, has a less specific gravity than the same milk after it has been skimmed; and milk diluted with water becomes proportionally lighter. Hence, when our purpose is to determine the quantity of cream, the galactometer may consist merely of a long graduated glass tube standing upright upon a scale. Having filled 100 measures with the recent milk, we shall see, by the measures of cream thrown up, its value in this respect. A delicate long ranged glass hydrometer, graduated from 1.000 up to 1.060 affords the most convenient means of detecting the degree of watery dilution, provided the absence of thickening materials has been previously ascertained by filtration. Good fresh milk indicates from 1.030 to 1.032; when the cream is removed, 1.035 to 1.037. When its density is less than 1.024, we may infer it has been thinned with water.

GALLIAXUM is a gum-resin, which occurs sometimes in yellow shining tears, easily agglutinated; of a strong durable smell; an acid and bitter taste; at other times in lumps. It exudes either spontaneously or from incisions made into the stem of the *buden galliæum*, a plant of the family of *umbellifers*, which grows in Africa, particularly in Ethiopia. It contains 67 of resin; 19.3 of gum; 6.4 of volatile oil and water; 7.5 of woody fibres and other impurities; with traces of acid malate of lime.

GALENA (*Plumb sulfur*, Fr.; *Bleiglantz*, Germ.) is a sulphide (sulphuret) of lead. It is of a lead-grey colour, crystallises in the cubic system, and is susceptible of cleavages parallel to the faces of the cube; sp. gr. 7.532; cannot be cut; fusible at the blow pipe with exhalation of sulphureous vapours; is easily reduced to metallic lead. Nitric acid first dissolves it, and then throws down sulphate of lead in a white precipitate; the solution affording with plates of zinc brilliant laminæ of lead (*arbor Saturni*). It consists of sulphur 13; lead 85; with a little iron, and generally a small quantity of silver. This is the richest ore of lead, and it occurs in almost every geological formation, in veins, in masses, or in beds. Galena in powder, called *Alquifoux*, is employed as a glass for coarse earthenware. See **LEAD**.

GALIPOT, is a name of a white resin solid viscid resin, found on fir-trees; or an inferior sort of turpentine, poor in oil.

GALL OF ANIMALS. See **Ox GALL**.

GALL OF GLASS, called also **SANDIVER**, is the neutral salt skimmed off the surface of melted crown glass; which, if allowed to remain too long, is apt to be re-absorbed in part, and to injure the quality of the metal, as the workmen call it. See **GLASS**.

GALLATES; salts consisting of gallic acid combined with bases; the most important being that with oxide of iron, constituting a principal part of the black dye.

GALLERY, in mining, in some districts, an underground horizontal excavation.

GALLIARD, a north of England term for a hard, smooth, flinty grit.

GALLIC ACID is the peculiar acid extracted from gall-nuts. See **GALL-NUTS**.

GALLIPOLI OIL is a coarse olive oil, containing more or less mucilage, imported

from a seaport so named, of the province of Otranto, in the kingdom of Naples. See OLIVE OIL.

GALL-NUTS, or **GALLS** (*Noir de Galle*, Fr.; *Galläpfel*, Germ.), are excrescences found upon the leaves and leaf-stalks of a species of oak, called *Quercus infectoria*, which grows in the Levant. They are produced in consequence of the puncture of the female of the gall wasp (*Cynips folii quercus*), made in order to deposit her eggs; round which the juice of the tree exudes, and dries in concentric portions. When the insect gets fully formed, it eats through the nut and flies off.

The Levant galls are of two different appearances and qualities: the first are heavy, compact, imperforated, the insect not having been sufficiently advanced to eat its way through the shell; prickly on the surface; of a blackish or bluish green hue; about the size of a musket ball. These are called *black*, *blue*, or *Aleppo* galls. The second are light, spongy, pierced with one or more holes; smooth upon the surface, of a pale greyish or reddish yellow colour, generally larger than the first, and are called *white* galls; but they are inferior to the former, and great care should be taken in the purchase of the best quality, for these are often dyed by dishonest traders to imitate the best blue Aleppo galls, but this fraud may be detected by the small hole made by the insect in the white galls, so that if the blue galls have holes, we may be sure they are not genuine.

Besides the galls of the Levant, others come from Dalmatia, Illyria, Calabria, &c.; but they are of inferior quality, being found upon the *Quercus cerris*; they are smaller, of a brownish colour, and of inferior value. The further south the galls are grown, they are reckoned the better.

Galls consist principally of three substances; tannin, or tannic acid; yellow extractive; and gallic acid. Their decoction has a very astringent and unpleasant bitter taste. The following are their habitudes with various reagents:—

Litmus paper is powerfully reddened.

Stannous chloride (*protomuriate of tin*) produces an Isabel yellow precipitate.

Alum; a yellowish grey precipitate.

Acetate of lead; a thick yellowish white precipitate.

Acetate of copper; a chocolate brown precipitate.

Ferric sulphate (red sulphate of iron); a blue precipitate.

Sulphuric acid; a dirty yellowish precipitate.

Acetic acid brightens the muddy decoction.

The galls of the *Quercus cerris* and common oak (*Galles d'épine*, Fr.; *Knoepfern*, Germ.) are of a dark-brown colour, prickly on the surface, and irregular in shape and size. They are used chiefly for tanning in Hungary, Dalmatia, and the southern provinces of the Austrian states, where they abound.

Tannin or tannic acid is prepared as follows: Into a long narrow glass adapter tube, shut at its lower orifice with a cotton wick, a quantity of pounded galls are put, and slightly pressed down. The tapering end of the tube being inserted into a matrass or bottle, the vacant upper half of the tube is filled with anphoric ether, and then closed with a ground-glass stopper. Next day there will be found in the bottle a liquid in two distinct strata; of which the more limpid occupies the upper part, and the other, of a spry consistence and amber colour, the lower. More ether must be filtered through the galls, till the thicker liquor ceases to augment. Both are now poured into a funnel, closed with the finger, and after the dense liquor is settled at the bottom, it is steadily run off into a capsule. This, after being washed repeatedly with ether, is to be transferred into a stove chamber, or placed under the receiver of an air pump to be evaporated. The residuary matter swells up in a spongy crystalline form of considerable brilliancy, sometimes colourless, but more frequently of a faintly yellowish hue.

This is pure tannin, which exists in galls to the amount of from 40 to 45 per cent. It is indispensable that the ether employed in the preceding process be previously agitated with water, or that it contain some water, because by using anhydrous ether, not a particle of tannin will be obtained.

Tannic acid is a white or yellowish solid, inodorous, extremely astringent, very soluble in water and alcohol, much less so in sulphuric ether, and uncrystallisable. Its watery solution, out of contact of air, undergoes no change; but if, in a very dilute state, it be left exposed to the atmosphere, it loses gradually its transparency, and lets fall a slightly greyish crystalline matter, consisting almost entirely of gallic acid. For procuring this acid in a perfectly pure state, it is merely necessary to treat that solution thus changed with animal charcoal, and to filter it in a boiling state, through paper previously washed with dilute muriatic acid. The gallic acid will fall down in crystals as the liquid cools.

If the preceding experiment be made in a graduated glass tube containing oxygen over mercury, this gas will be absorbed, and a corresponding volume of carbonic acid

gas will be disengaged. In this case the liquor will appear in the course of a few weeks as if traversed with numerous crystalline colourless needles of gallic acid.

Tannin or tannic acid consists of carbon, 51.56; hydrogen, 4.20; oxygen, 44.24.

From the above facts it is obvious that gallic acid does not exist ready formed in gall-nuts, but that it is produced by the reaction of atmospheric oxygen upon the tannin of these concretions.

Gallic acid is a solid, feebly acidulous and atypic to the taste, inodorous, crystallising in silky needles of the greatest whiteness; soluble in about 100 times its weight of cold, and in a much smaller quantity of boiling water; more soluble in alcohol than in water, but little so in sulphuric ether.

Gallic acid does not decompose the salts of protoxide of iron, but it forms, with the sulphate of the peroxide, a dark blue precipitate, much less insoluble than the tannate of iron.

Galls imported in 1857:—

GALVANISED IRON. This is the name, improperly given, first in France, and subsequently adopted in this country, to iron coated with zinc by a peculiar patent process.

In 1837 Mr H. W. Crawford patented a process for zincing iron. In the "*Repository of Patent Inventions*" his process is thus described:—Sheet iron, iron castings, and various other objects in iron are cleaned and scoured by immersion in a bath of water, acidulated with sulphuric acid, heated in a leaden vessel, or used cold in one of wood, just to remove the oxide. They are then thrown into cold water, and taken out one at a time to be scoured with sand and water with a piece of cork, or more usually with a piece of the husk of the cocoa nut, the ends of the fibres of which serve as a brush, and the plates are afterwards thrown into cold water.

Pure zinc covered with a thick layer of sal-ammoniac is then melted in a bath, and the iron, if in sheets, is dipped several sheets at a time in a cradle or grate. The sheets are slowly raised to allow the superfluous zinc to drain off, and are thrown whilst hot into cold water, on removal from which they only require to be wiped dry.

Thick pieces are heated before immersion in a reverberatory furnace, to avoid cooling the zinc. Chains are similarly treated, and on removal from the zinc require to be shaken until cold to avoid the links being soldered together. Nails and small articles are dipped in muriatic acid, and dried in a reverberatory furnace, and then thrown altogether in the zinc, covered with the sal ammoniac, left for one minute, and taken out slowly with an iron skimmer; they come out in a mass soldered together, and for their separation are afterwards placed in a crucible and surrounded with charcoal powder, then heated to redness and shaken about until cold for their separation. Wire is reeled through the zinc, into which it is compelled to dip by a fork or other contrivance. It will be understood that the zinc is melted with a thick coat of sal-ammoniac to prevent the loss of zinc by oxidation.

Mr. Mallet coated iron with zinc by the following process:—

The plates are immersed in a cleansing bath of equal parts of sulphuric or muriatic acid and water, used warm; the works are then hammered and scrubbed with emery and sand to detach the scales, and to thoroughly clean them; they are then immersed in a "preparing bath" of equal parts of saturated solutions of muriate of zinc and sal-ammoniac, from which the works are transferred to a fluid metallic bath, consisting of 302 parts of mercury and 1292 parts of zinc, both by weight, to every ton weight of which alloy is added above one pound of either potassium or sodium, the latter being preferred. As soon as the cleaned iron-works have attained the melting heat of the triple alloy, they are removed, having become thoroughly coated with zinc. At the proper fusing temperature of this alloy, which is about 680° Fahr., it will dissolve a plate of wrought iron of an eighth of an inch thick in a few seconds.

Morewood and Rogers's galvanised tinned iron is prepared under several patents. Their process is as follows:—

The sheets are pickled, scoured, and cleaned just the same as for ordinary tinning.

A large wooden bath is then half filled with a dilute solution of muriate of tin, prepared by dissolving metallic tin in concentrated muriatic acid, which requires a period of two or three days. Two quarts of the saturated solution are added to 500 or 600 gallons of the water contained in the bath. Over the bottom of the bath is first spread a thin layer of finely granulated zinc, then a cleaned iron plate, and so on, a layer of granulated zinc and a cleaned iron plate alternately, until the bath is full; the same is then driven together with the fluid constitute a weak galvanic battery, and the tin is deposited from the solution so as to coat the iron with a dull uniform layer of metallic tin in about two hours.

The tinned iron is then passed through a bath containing flint sand, covered with sal ammoniac mixed with earthy matter, to lessen the volatility of the sal ammoniac, which becomes as fluid as treacle. Two iron rollers are moved below the surface of the sand, are fixed to the bath and are driven by machinery to carry the plates through the fluid metal at any velocity previously determined. The plates are removed one by one from the tinning bath, drained for a short time, and passed at once, whilst still wet, by means of the rollers, through the bath as described. The plates take up a very regular and smooth layer of zinc, which, owing to the pressure of the tin beneath, assumes its natural crystalline character, giving the plate an appearance resembling that known as the *moiré métallique*.—See *Hunt's Handbook to the Great Exhibition*.

It is stated that galvanised iron plates cut with shears so as to expose the central iron become sined round the edges, and at the holes where the nails were driven. We are also informed that *ungalvanised* iron will, if moist when near galvanised plate, become sined, and that telegraph wires, where cut through, become coated by the action of the rain-water on the galvanised portions of the surfaces.

It has been stated that the galvanised iron is not more durable than unprotected iron; that, indeed, when the zinc is by any accident removed the destruction is more rapid than ordinary. We have made especial inquiries, and find that in *forges* where there is any escape of sulphur vapour the galvanised iron does not stand well; but that under all ordinary circumstances it has the merit of great durability in addition to its other good qualities.

GALVANO-PLASTIC. The German name of Electro-metallurgy.

GAMBIER, or GAMBIER. The Malay name of an extract obtained from the *Uncaria Gambier*. It is the *Terra Japonica* of tanners.

Two methods of obtaining gambir are described, one consists in boiling the leaves in water, and inspissating the decoction; the other, which yields the best gambir, consists in infusing the leaves in warm water, by which a fecula is obtained, which is inspissated by the heat of the sun and formed into cakes. The best gambir is made at Rhin, in the Isle of Brittany, in the Eastern Archipelago; and the next best is that of Lingin. It is principally imported from Singapore, and is used principally for tanning, under the name of *Terra Japonica*. The *Mimosa catechu* yields a different extract from the gambir, but catechu and gambir are often confounded.

The imports have been 1856, 8536 tons; 1857, 11,047 tons.

GAMBIER CATECHU. See CATECHU.

GAMBOGE (*Gomme Gutte*, Fr.; *Gutti*, Germ.) Gamboge appears to have been first brought from China about 1603, and its oriental name was said to be *Githurmon*.

It is generally supposed to be produced from the *Hebradendron gambogodes* of Graham, and the *Nanthochymus ovalifolius* of Roxburgh. In Ceylon the gamboge is obtained by wounding the bark of the tree in various places with a sharp stone, when the flowers begin to appear. Gamboge is imported from Siam, by way of Singapore and Penang. It is known in three forms. In rolls or solid cylinders; in pipes or hollow cylinders in cakes or amorphous masses. Gamboge in small quantities is also obtained in Ceylon.

Gamboge consist of—

Resin	-	-	-	-	-	-	742
Soluble gum	-	-	-	-	-	-	218
Moisture	-	-	-	-	-	-	48

1008

Gamboge is employed as an artist's colour; it is used to colour varnishes and lacquers, and it is administered medicinally.

We imported in 1857, 248 cwts.

GAMMAM. A dye stuff, so called, from Tunisia. Examples were sent to this country in 1851, but it does not appear to have been introduced since that time.

GANGUE. A word derived from the German *gange*, a vein or channel. It signifies the mineral substance which either encloses or usually accompanies any metallic

ore in the vein. Quartz, lamellar carbonate of lime, sulphate of baryta, sulphate and fluate of lime, generally form the gangues; but a great many other substances become such when they predominate in a vein. In mineral works the first thing is to break the mixed ore into small pieces, in order to separate the valuable from the useless parts, by processes called stamping, picking, sorting. See MINING.

GARANCIN. See MANNER.

GARANCEUX. See MADON.

GARLIC. *Allium sativum*. This plant is well known, and is much used in flavouring sauces.

It is found by analysis to contain an acrid volatile oil, gum, woody fibre, albumen, water, with sulphur, starch, and saccharine matter. The oil of garlic is a sulphide of allyle, $\text{AUS} = \text{C}_2\text{HS}$.

GARNET. (*Graat*, Fr.) Garnet is a silicate of some base, which may be lime, magnesia, oxide of iron, &c.

There are six sub-species of garnet, viz. :—

I. *Alumina-lime garnet*, consisting of the silicates of alumina and lime.

II. *Alumina-magnesia garnet*, consisting of the silicates of alumina and magnesia.

III. *Alumina-iron garnet*, consisting of the silicates of alumina and iron.

IV. *Alumina-manganese garnet*, consisting of the silicates of alumina and manganese.

V. *Iron-lime garnet*, consisting of the silicates of iron and lime.

VI. *Lime-chrome garnet*, consisting of the silicates of lime and oxide of chromium.

I. Lime-garnet, or grossular, is composed of silica, 40.1; alumina, 22.7; lime, 37.2 = 100.0. Colour, pale greenish, clear red, and reddish orange, cinnamon colour. Before the blowpipe, fuses to a slightly greenish glass or enamel; soluble, when powdered, in concentrated muriatic acid.

This section comprises cinnamon-stone or Esonite, grossular or Wiluite, Romanovite, topazolite, and succinite.

II. Magnesia-garnet is of a deep coal-black colour, with a resinous lustre. The variety from Arendal is composed of silica, 42.45; alumina, 22.47; protoxide of iron, 9.29; protoxide of manganese, 6.27; magnesia, 13.41; lime, 6.53 = 100.44.—(*Wächtermeister*.) Before the blowpipe, easily fusible, forming with intumescence a dark greyish-green globule, which is non-magnetic.

III. Iron-garnet comprises the almandine or precious garnet, alchochroite, and common garnet. It is composed of silica, 36.3; alumina, 20.5; protoxide of iron, 43.2 = 100.0. Before the blowpipe, fuses rather easily with an iron reaction.

IV. Manganese-garnet, or spessartine, is of a brownish-red colour, and is composed of silica, 35.53; alumina, 18.06; protoxide of iron, 14.97; protoxide of manganese, 30.96 = 99.78. (Analysis of M. garnet from Haddam, U. S., by *Seydort*.) Before the blowpipe, gives a manganese reaction.

V. Iron-lime garnet includes apome, colophonite, melanite, and pyrenite. These vary in colour from dark red, brownish-black, to black, and possess a shining lustre, which is sometimes resinous, as in colophonite.

Analysis of the apome of Altena. —Silica, 33.64; lime, 29.22; protoxide of iron, 30.00; protoxide of manganese, 3.01; potash, 2.35 = 100.22.—(*Wächtermeister*.)

VI. Lime-chrome garnet, or uvarovite, is of an emerald-green colour. Sp. gr., 3.418. Before the blowpipe it is infusible alone, but with borax affords a chrome-green glass. It occurs at Ussersk, in Russia.

Analysis by *Erdmann*. —Silica, 36.93; alumina, 5.69; peroxide of iron, 1.96; oxide of chrome, 21.84; magnesia, 1.54; carbonate of lime, 31.66; oxide of copper, a trace = 99.58.

The garnet varies greatly in transparency, fracture, and colour; but when the colours are rich, and the stone is free from flaws, it constitutes a valuable gem, which may be distinguished by the following properties :—

The colour should be blood or cherry-red; on the one hand often mixed more or less with blue, so as to present various shades of crimson, purple, and reddish violet, and on the other hand, with yellow, so as to form orange-red and hyacinth brown.

The stones vary in size from the smallest pieces that can be worked to the size of a nut. When above that size they are scarcely ever free from flaws, or sufficiently transparent for the purposes of the jeweller.

The garnets of commerce are procured from Bohemia, Ceylon, Pegu, and the Brasile. By jewellers they are classed as Syrian, Bohemian, or Cingalese, rather from their relative value and fine-ness, than with any reference to the country from which they are supposed to have been brought.

Those most esteemed are called Syrian garnets, not because they come from Syria, but after Syrian, the capital of Pegu, which city was formerly the chief mart for the finest garnets. The colour of the Syrian garnet is violet purple, which, in some rare

instance, was with that of the finest oriental amethyst, but it may be distinguished from the latter by acquiring an orange tint by candle-light. The Syrian garnet may also be distinguished from all the other varieties of garnet in preserving its colour (even when of considerable thickness and unassisted by foil), unmixed with the black tint which usually obscures this gem. The Bohemian garnet is generally of a dull pappy-red colour, with a very perceptible hyacinth-orange tint when held between the eye and the light. When the colour is a full crimson it is called pyrope, or fire-garnet, a stone of considerable value when perfect and of large size.

The best manner of cutting the pyrope is *en cabochon*, with one or two rows of small facets round the girdle of the stone. The colour appears more or less black when the stone is cut in steps, but when not *en cabochon*, the points on which the light falls display a brilliant fire-red.

Garnet is easily worked, and when facet-cut is nearly always (on account of the depth of its colour) formed into thin tables, which are sometimes concave or hollowed out on the under side. Cut stones of this latter description, when skilfully set, with a bright silver foil, have often been sold as rubies.

The garnet may be distinguished from corundum or spinel by its duller colour. Coarse garnets reduced to a fine powder are sometimes used as a substitute for emery in polishing metals.

Rubies as garnet. See PYROPE.—H. W. B.

GAS. (*Gas*, Fr.; *Gas*, Germ.) The generic name of all such elastic fluids as are not firm under a considerable pressure, at the zero of Fahrenheit. Oxygen, hydrogen, and nitrogen, are permanent gases; many of the other vaporiform bodies have been condensed by the joint power of cold and mechanical force. See *Ure's Dictionary of Chemistry*.

GAS HOLDER. A vessel for containing and preserving gas, of which various forms are described by chemical writers.

GAS, LAI OXIGÈNE. *Protoxide of Nitrogen*; also *Protoxide of Azote*, and *Nitrous Oxide*. This gas is always prepared from the nitrate of ammonia; it was first described by Priestley, in 1776, and carefully studied by Davy. This gas is chiefly remarkable for the peculiar intoxication which it produces when breathed. It is not to be used without much caution. If it is not very pure, serious consequences may ensue; and even when absolutely pure, the editor has seen the nitrous oxide produce very distressing effects. It is not used in the arts. See *Ure's Dictionary of Chemistry*.

GASOMETER. means properly a measure of gas, though it is employed often to denote a recipient of gas of any kind. See COAL-GAS.

GAS-PIPES. When the illumination by gas was first introduced in the large way by Aaron Manly, Esq., then of the Horsley Iron Works, the old musket barrels, laid by in quiet retirement from the fatigues of the last war, were employed for the conveyance of gas, and by a curious coincidence, various iron foundries destined in a great measure from the manufacture of iron ordnance, and took up the peaceful employment of casting pipes for gas and water.

The breach-ends of the musket-barrels were breeched and tapped, and the muzzles were screwed externally, to connect the two without detached sockets. From the rapid increase of gas illumination, the old gun-barrels soon became scarcer, and new tubes with detached sockets, made by the old barrel-forgers, were first resorted to. This led to a series of valuable contrivances for the manufacture of the wrought iron tubes, commencing with the Russell's patent, in 1824, under which the tubes were first bent up by hand hammers and swages, to bring the edges near together; and they were welded between semi-circular swages, fixed respectively in the anvil, and the face of a small tilt-hammer worked by machinery, by a series of blows along the tube either with or without a mandrel. The tube was completed on being passed between rollers with half-round grooves, which forced it over a conical or egg-shaped piece at the end of a long bar to perfect the interior surface.

Various steps of improvements have been since made; for instance, the skelp was bent at two squeezes, first to the semi-cylindrical, and then to the tubular form preparatory to welding, between a swage tool five feet long worked by machinery. The whole process was afterwards carried on by rollers, but abandoned on account of the unequal velocity at which the greatest and least diameters of the rollers travelled.

In the present method of manufacturing the patent welded tube, the end of the skelp is bent to the circular form, its entire length is raised to the welding heat in an appropriate furnace, and as it leaves the furnace almost at the point of fusion it is dragged by the chain of a draw bench, after the manner of wire, through a pair of tongs with two bell-mouthed jaws, these are opened at the moment of introducing the end of the skelp, which is welded without the agency of a mandrel.

By this ingenious arrangement wrought-iron tubes may be made from the diameter of six inches internally, and about one-eighth to three-eighths of an inch thick, to as

small as one quarter inch diameter and one-tenth bore; and so admirably is the joining effected in those of the best description, that they will withstand the greatest pressures of gas, steam, or water to which they have been subjected, and they admit of being bent both in the heated and cold state almost with impunity. Sometimes the tubes are made one upon the other when greater thickness is required, but these stout pipes and those larger than three inches are comparatively but little used. — (*Holtzapffel*.)

CASSING, in order to remove the hairy filaments from net-lace and other woven fabrics, they are passed over a large number of minute jets of gas, and between rollers.

GAULT, a local term in some parts of England for clay, has been adopted into geological nomenclature to denote the argillaceous strata which separate the upper and lower greenlands. It is a dark blue or grey clay, used for making bricks and tiles; it affords a poor agricultural soil, which is generally converted into pasture. — *H. W. H.*

GAULTHERIA OIL. **WINTHROP'S OIL**, which see.

GAULTHERINE. When the powdered bark of *betula lenta* is exhausted with cold alcohol of 91° it can afford no more oil. The fluid which contains the gaultherine has a slightly bitterish taste, and by evaporation it forms a dry gummy mass, which at a high heat leaves a coally residual. Oil of vitriol dissolves the gaultherine with a red colour and the flavour of the oil.

GAUZE WIRE CLOTH is a textile fabric, either plain or twilled, made of brass, iron, or copper wire, of very various degrees of fineness and openness of texture. Its chief uses are for sieves and safety lamps.

GAY-LUSSITE, is a white mineral of vitreous fracture, which crystallises in oblique rhomboidal prisms; specific gravity from 1.93 to 1.95; scratches gypsum, but is scratched by calc spar; affords water by calcination; it consists of carbonic acid, 28.66; soda, 20.44; lime, 17.70; water, 32.30; clay, 1.04. It is, in fact, by my analysis, a hydrated soda-carbonate of lime in atomic proportions. This mineral occurs abundantly in insulated crystals, disseminated through the bed of clay which covers the *urum*, or native semicircular carbonate of soda, at Lagunilla in Columbia.

GELATINE (Eng. and Fr.; *Gallert*, *Lern*, Germ.) is an animal product which is never found in the humours, but it may be obtained by boiling with water the soft and solid parts; as the muscles, the skin, the cartilages, bones, ligaments, tendons, and membranes. Isinglass consists of from 86 to 93 per cent. of gelatine. This substance is very soluble in boiling water; the solution forming a tremulous mass of jelly when it cools. Cold water has little action upon gelatine. Alcohol and tannin precipitate gelatine from its solution; the former by abstracting the water, the latter by combining with the substance itself into an insoluble compound, of the nature of leather. No other acid, except the tannic, and no alkali, possesses the property of precipitating gelatine. But chlorine and certain salts render its solution more or less turbid, as the nitrate and bi-chloride of mercury, the proto-chloride of tin, and a few others. Sulphuric acid converts a solution of gelatine at a boiling heat into sugar. Gelatine consists of carbon, 47.86; hydr. gen., 7.91; oxygen, 27.21.

Gelatine is produced by boiling the skin of animals in water, which in its crude but solid state is called *glue*, and when a tremulous semi liquid, *size*. See those articles.

A fine gelatine for culinary uses is prepared and sold as Nelson's patent gelatine. It is thus prepared:—After washing the parings, &c., of skin, he scores their surfaces, and then digests them in a dilute caustic soda lye during ten days. They are next placed in an air-tight vat, lined with cement, kept at a temperature of 70° Fahr., then washed in a revolving cylinder apparatus with plenty of cold water, and afterwards exposed to the fumes of burning sulphur (sulphurous acid) in a wooden chamber. They are now squeezed to expel the moisture, and finally converted into soluble gelatine, by water in earthen vessels, enclosed in steam cases. The fluid gelatine is purified by straining it at a temperature of 100° or 120° Fahr.

A sparkling gelatine has been prepared under a patent granted to Messrs. J. and G. Cox, of Edinburgh. By their process the substance is rendered perfectly pure, while it possesses a gelatinising force superior even to isinglass. It makes a splendid calves'-feet jelly and a milk-white blanc-mange. The patentees also prepare a semi-solid gelatine, resembling figulines, which readily dissolves in warm water, as also in the mouth, and may be employed to make an extemporaneous jelly.

The gelatine of bones may be extracted best by the combined action of steam and a current of water trickling over their crushed fragments in a properly constructed apparatus. When the gelatine is to be used as an alimentary article, the bones ought to be quite fresh, well preserved in brine, or to be dried strongly by a stove. Bones are best crushed by passing them between grooved iron rolls. The

cast-iron cylinders in which they are to be steamed, should be three times greater in length than in diameter. To obtain 1000 rations of gelatinous soup daily, a charge of four cylinders is required; each being 3½ feet long, by 14 inches wide, capable of holding 70 lbs. of bones. These will yield each hour about 20 gallons of a strong jelly, and will require nearly 1 gallon of water in the form of steam, and 5 gallons of water to be passed through them in the liquid state. The 5 quarts of jelly produced hourly by each cylinder proceeds from the 1 quart of steam-water and 4 quarts of percolating water.

The boiler should furnish steam of about 223° Fahr., at a pressure of about 4 lbs. on the square inch.

In fig. 865 A, B, C, D, represents a vertical section of the cylinder; a, n, i, x, a

865

section of the basket or cage, as filled with the burned bones, inclosed in the cylinder; k, c, c, the pipe which conducts the steam down to the bottom of the cylinder; l, a, a pipe for introducing water into the interior; n, a stopcock for regulating the quantity of water (according to the force of the steam pressure within the apparatus), which should be 3½ quarts per hour; x is a tube of tin plate fitting tightly into the part a of the pipe l; it is shut at x, and perforated below with a hole; it is inserted in its place, after the cage full of bones has been introduced. Fig. 866 is an elevation of the apparatus. A, B, C, D, represent the four cylinders, raised about 20 inches above the floor, and fixed in their seats by screws; h, h, are the lids; g, g, tubulures or valves in

the lids; i, ring junction of the lid; p, a thermometer; f, f, stop-cocks for drawing off the jelly; n, n small gutters of tin-plate; m, the general gutter of discharge

866

into the cistern b; o, a block and tackle for hoisting the cageful of bones in and out. Fig. 867 is an end view of the apparatus; n, the main steam pipe; a, b, c, e, branches that conduct the steam to the bottom of the cylinder; o, the tackle for raising the cage; x, stopcock; n, small gutter; m, main conduit; b, cistern of reception.

When a strong and pure jelly is wished for, the cylinder charged with the bones is to be wrapped in blanket stuff, and whenever the pressure ceases to drop, the stopcock

which admits the cold water is to be shut, as also that at the bottom of the cylinder, which is to be opened only at the end of every hour, and so little as to let the gelatinous solution run out, without allowing any of the steam to escape with it.

Butchers' meat contains on an average in 100 pounds, 24 of dry flesh, 56 of water, and 20 of bones. These 20 pounds can furnish 6 pounds of alimentary substance in a dry state; whence it appears that, by the above means, one fourth more nutritious matter can be obtained than is usually got. A keen dispute has been carried on for some time in Paris, between the partisans and adversaries of gelatine as an article of food. It is probable that both parties have pushed their arguments too far. Calf's-foot jelly is still deemed a nutritious article by the medical men of this country, at least, though it is not to be trusted to alone, but should have a due admixture or interchange of fibrice, albumen, caseine, &c. See NUTRITION.

French Gelatine is sold in cakes, marked, like those of common glue, with the nets in which they have been dried. This gelatine is made at Paris, from the cuttings of skins used for making white kid gloves; it is coloured red, green, and blue, as well as solid colourless.

Swiss gelatin's patent system is a pure form of gelatine, prepared from the skins of calves cut into very thin slices and treated simply with water at or about 500°.

D'Arcet, in his *Recherches sur les Substances nutritives que renferment les Os*, states, that in Paris, bones of all kinds are first digested with hydrochloric acid to extract the phosphate of lime, and then boiled in water under pressure. In this way a nutritious soup is prepared for the hospitals and other pauper establishments. See ISOMALASE.

GEMS are precious stones, which, by their colour, limpidity, luster, brilliant polish, purity, and rarity, are sought after as objects of dress and decoration. They form the principal part of the crown jewels of kings, not only from their beauty, but because they are supposed to comprise the greatest value in the smallest bulk; for a diamond, no larger than a nut or an acorn, may be the representative sign of the territorial value of a whole country, the equivalent in commercial exchange of a hundred fortunes acquired by a few tools and privations.

Among these beautiful minerals mankind have agreed in forming a select class, to which the title of *gems* or *jewels* has been appropriated; while the term *precious stone* is more particularly given to substances which often occur under a more considerable volume than *fine stones* ever do.

Diamonds, sapphires, emeralds, rubies, topazes, hyacinths, and chrysoberyls, are reckoned the most valuable *gemms*.

Crystalline quartz, jasper, opalescent, or of various hues, amethyst, lapis lazuli, malachite, jasper, agate, &c., are ranked in the much more numerous and inferior class of ornamental stones. These distinctions are not founded upon any strict philosophical principle, but are regulated by a conventional agreement, not very well defined; for it is impossible to subject these creatures of fashion and taste to the rigid subdivisions of science. We have only to consider the value currently attached to them, and take care not to confound two stones of the same colour, but which may be very differently prized by the *virtuosos*.

Since it usually happens that the true gems are in a cut and polished state, or even set in gold or silver, we are thereby unable to apply to them the criteria of mineralogical and chemical science. The cutting of the stone has removed or masked its crystalline character, and circumstances rarely permit the phenomena of double or single refraction to be observed, while the test by the blowpipe is inadmissible. Hence the only scientific resources that remain are the trial by electricity, which is often inconclusive; the degree of hardness, a criterion requiring great experience to the person who employs it; and, lastly, the proof of specific gravity, unquestionably one of the surest means of distinguishing the really fine gems from ornamental stones of similar colour. This proof can be applied only to a stone that is not set; but the richer gems are usually dismounted when offered for sale.

This character of specific gravity may be applied by any person of common intelligence with the aid of a small hydrostatic balance. If, for example, a stone of a fine crimson-red colour be offered for sale as an oriental ruby; the purchaser must ascertain

if it be not a Siberian tourmaline, or ruby spinel. Supposing its weight in air to be 100 grains, if he finds it reduced to 69 grains when weighed in water, he concludes that its bulk is equal to that of 31 grains of water, which is its loss of weight. Now, a real sapphire which weighs 100 grains in air, would have weighed 74.6 in water; a spinel ruby of 100 grains would have weighed 72.2 in water, and a Siberian tourmaline of 100 grains would have weighed only 69 grains in water. The quality of the stone in question, is therefore, determined beyond all dispute, and the purchaser may be thus protected from fraud. See the GEMS respectively.

GEMS, ARTIFICIAL. These are glasses, the material of which they are composed being called *Strass*.

Strass, the paste or glass which generally forms the principal ingredient of imitation *gem*, is called after the name of a German jeweller, by whom it was invented, at the commencement of the last century. It is composed of silica, potash, borax, the various oxides of lead, and sometimes of arsenic: chemically it may be regarded as a double silicate of potash and lead.

The silica may be furnished either by rock crystal, white sand, or flint: but, of these, the first is to be preferred, one of the principal considerations in these preparations being the extreme purity of the materials or ingredients employed. In this manufacture, which is of more importance, and attended with greater difficulty than most persons imagine, perfect success (independently of the choice of materials) depends upon the care taken, and the precautions to be observed. No crucibles should be used but those which have been proved, both as regards their composition, their power of withstanding the strongest heat, and their impenetrability to the action of metallic oxides.

All the substances to be melted should be first pulverised, and even ground with the greatest care. It should be remembered that the most perfect mixture can only be effected by numerous siftings, and that a separate sieve should be used for each ingredient, and never be made to serve for different substances. When mixed, the materials should be put in a crucible placed in the middle of a cylindrical furnace terminated in a dome, the height of which should be 7 feet 6 inches, and its diameter 4 feet 3 inches. The fuel should consist as much as possible of thoroughly dry wood, chopped very small. The melting should be effected by means of a heat raised by degrees, and then steadily maintained, especially at the maximum temperature; then when over the melting has been thoroughly accomplished, which cannot be in less than from twenty to thirty hours, the crucible must be allowed to cool very slowly.

The art of imitating precious stones in paste has amazingly improved since the time of *Strass*, as was shown by the results of the great Paris exposition of 1855. The imitations, especially as regards certain colours, have little to be desired; but there is something still in that respect in which the imitation is far from being perfect.

Now that it is proved that the alkalies and vitrifiable earths are oxides of the metals, all that has to be done to obtain the finest effects, is to combine them skilfully, and in their present form with other artificially prepared metallic oxides, which have undergone the process of vitrification.

Experiments ought to be made with all oxidisable and vitrifiable substances, with the different salts, fluorates, phosphates, phosphoric acid, &c.

The following are some of the mixtures generally known, but it must be observed here that each artist has his own processes, ingredients, and proportions.

Mixtures for *Strass*.

Observations. For topaz, No. 1, the clearest and most transparent glass of antimony should be used. Frequently this mixture only yields an opaque mass, translucent on the edges, and transmitting in thin fragments a red colour when held between the eye and the light. In that case rubies may be made of it.

To make them, a portion of the topaz material is taken, and mixed with eight parts of fine strass: these are melted in a Hessian crucible for thirty hours in a potter's furnace, and the result is a beautiful yellow glass-like strass, which, when cut, produces an imitation of the finest oriental rubies.

These may be made of another tint by using the following proportions:—

Strass, 2411.25; oxide of manganese, 61.310.

In the emerald, No. 1, by increasing the proportion of chrome or oxide of copper, and mixing with it oxide of iron, the green shade may be varied, and the peridot or deep tinted emerald may be imitated.

The manufacture of artificial gems has acquired an extreme development; immense factories are established at Septmoncel in the Jura, furnishing employment to more than 100 work-people, who produce fabulous quantities.

Many ingenious persons in Paris vie with one another in bringing to perfection the most perfect processes, and produce truly surprising results. M. Savary especially, in his magnificent collections, and his perfect imitation of celebrated diamonds, has arrived at a degree of excellence which, apparently, can scarcely be surpassed.

We have alluded only to these imitations of gems in glass of which a large portion of the cheap jewellery is formed. Some very successful attempts have been made to manufacture true gems by an artificial process. M. Ebelmen has done much in this direction, and M. Henri Sainte Claire Deville and M. Henri Caton communicated to the Academy of Sciences of Paris, in April 1858, a process which they had discovered for the production of a number of the gems which belong to the corundum class, as the ruby, sapphire, &c. Essentially, the process consisted in exposing the fluoride of aluminium, mixed with a little charcoal and boracic acid, in a black lead crucible, protected from the action of the air, to a white heat for about an hour. For details of the process see *Comptes Rendus, Annales de Chimie*.

GENEVA. A grain spirit flavoured with juniper berries, manufactured extensively in Holland; hence it is frequently called *HOLLANDIA*.

GENTIAN. *Gentiana lutea*. The common or yellow gentian, which is said to owe its name to Gentius king of Illyria, who introduced it as a medicine about 170 years before Christ.

The roots of the gentian are collected and dried by the peasants of Switzerland, the Tyrol, and in the Auvergne.

The bitter of the gentian is agreeable and aromatic; it is much used in medicine, and has on some occasions been employed instead of hops in beer.

GEODE. A rounded nodule of stone, containing a cavity usually lined with crystals. Geodes frequently consist of agate, calcined, &c.

GEOGNOSY, γη, the earth, and γνωσις, knowledge.—means the science of the substances which compose the earth's crust. It originated with the German mineralogists.

GEOLOGY, γη, the earth, and λογος, a discourse. The science which treats of the structure of the earth, and of the causes which have produced its present physical features.

GERHARDT'S ANHYDROUS ACETIC ACID. See ACETIC ACID, and refer to Ure's *Dictionary of Chemistry*.

GERMAN BLACK. See FRANKFURT BLACK.

GERMAN SILVER. See ALLOY and COPPER. M. Gerold, of Vienna, stated that

the proportion of the metals in this alloy should vary according to the uses for which it is destined. When intended as a substitute for silver, it should be composed of 25 parts of nickel, 25 of zinc, and 50 of copper. An alloy better adapted for rolling consists of 25 of nickel, 20 of zinc, and 60 of copper. Castings, such as candlesticks, bells, &c., may be made of an alloy, consisting of 20 of nickel, 20 of zinc, and 60 of copper; to which 3 of lead are added. The addition of 2 or 3 of iron (in the shape of tin plate) renders the alloys much whiter, but, at the same time, harder and more brittle.

Kefenstein has given the following analysis of the genuine German silver, as made from the original ore found in Hildburghausen, near Suhl, in Henneberg:—

Copper	-	-	-	-	-	-	-	-	40.4
Nickel	-	-	-	-	-	-	-	-	31.6
Zinc	-	-	-	-	-	-	-	-	26.4
Iron	-	-	-	-	-	-	-	-	2.6
									100.0

Chinese pakfoo, a white alloy, according to the same authority, consists of 5 parts of copper, alloyed with 7 parts of nickel, and 7 parts of zinc.

The best alloy for making bearings, bushes, and steps for the steel or iron gudgeons, and pivots of machinery to run in, is said to consist of 90 parts of copper, 5 of zinc, and 5 of antimony.

GERMAN STEEL. A metal made of a white iron in forges where charcoal is employed, the ore used being either bog-iron ore or the sparry carbonate.

GERMAN TINIER. See AMADOR.

GERMINATION. (Eng. and Fr.; *Das Keimen*, Germ.) The first indication of vital force in the embryo plant. The seed being placed in the soil, a proper temperature existing, and a due quantity of water being supplied, a chemical action is established, and heat is developed. In fact, a slow combustion takes place, during which oxygen is combined with carbon, and carbonic acid is liberated. The starch of the grain, by the process of germination, is converted into sugar by taking into combination one equivalent of the elements of water. While this operation is progressing, the embryo enlarges, sending down its root radicle into the soil, and forcing upwards, towards the light, the cotyledons or leaf lobes, and the plumule.

These phenomena of the commencement of vegetable life can be well studied in the process of *Malting*, in which the barley, by the conversion of its starch into sugar, becomes malt.

The direct action of sunlight is injurious to the germinating seed, consequently it is a law of nature that a dark soil should be the bed in which this remarkable operation commences, and is continued until the first leaves appear above the soil. In the process of malting (which see), care is taken that the floors upon which the germination is established are but dimly illuminated.

GEROPIGA. A factitious liquor, imported from Portugal and used in this country for the adulteration of wines. It is sometimes spelt *JERRICA*. It appears to be a compound of unfermented grape juice, brandy, sugar, and colouring matter. This compound is used even more extensively in the United States than in this country. — (M'Culloch.)

GIG MACHINES, are rotatory drums, mounted with thistles or wire teeth for teasing cloth. See WOOLLEN MANUFACTURE.

GILDING. (*Dorure*, Fr.; *Vergoldung*, Germ.) This art consists in covering bodies with a thin coat of gold, which may be done either by mechanical or chemical means. The mechanical mode is the application of gold leaf or gold powder to various surfaces, and their fixation by various means. Thus gold may be applied to wood, plaster, pasteboard, leather; and to metals, such as silver, copper, iron, tin, and bronze; so that gilding, generally speaking, includes several arts, exercised by very different classes of tradesmen.

I. MECHANICAL GILDING. — Oil gilding is the first method under this head, as oil is the fluid most generally used in the operation of this mechanical art. The following process has been much extolled at Paris.

1. A coat of *imprimario* is to be given first of all, namely, a coat of white lead paint, made with drying linseed oil, containing very little oil of turpentine.

2. Calcined ceruse is to be ground very well with unboiled linseed oil, and tempered with essence of turpentine, in proportion as it is laid on. Three or four coats of this hard put are to be applied evenly on the ornaments, and the parts which are to be most carefully gilded.

3. The *Gold colour* is then to be smoothly applied. This is merely the drops of the colours, ground and tempered with oil, which remain in the little dish in which painters

clean their brushes. This substance is extremely rich and glossy; after being ground up, and passed through fine linen cloth, it forms the ground for gold leaf.

4. When the gold colour is dry enough to catch hold of the leaf gold, this is spread on the cushion, cut into pieces and carefully applied with the point knife, pressed down with cotton, and on the small ornaments with a fine brush.

5. If the gildings be for outside exposure, as balconies, gratings, statues, &c., they must not be varnished, as simple oil gilding stands better; for when it is varnished, a bright sun-beam acting after heavy rain, gives the gilding a jagged appearance. When the objects are inside uses, a coat of spirit varnish may be passed over the gold leaf, then a glow from the gilder's chafing dish may be given, and finally a coat of oil varnish. The workman who causes the chafing dish to glide in front of the varnished surface, must avoid stopping for an instant opposite any point, otherwise he would cause the varnish to boil and blister. This heat brings out the whole transparency of the varnish, and lustre of the gold.

Oil Gilding is employed with varnish polish, upon equipages, mirror-frames, and other furniture. The following method is employed by eminent gilders at Paris:—

1. White lead, with half its weight of yellow ochre, and a little litharge, are separately ground very fine; and the whole is then tempered with linseed oil, thinned with essence of turpentine, and applied in an evenly coat, called *impression*.

2. When this coat is quite dry, several coats of the hard tint are given, even as many as 10 or 12, should the surface require it for smoothing and filling up the pores. These coats are given daily, leaving them to dry in the interval in a warm sunny exposure.

3. When the work is perfectly dry, it is first softened down with pumice stone and water, afterwards with worsted cloth and very finely powdered pumice, till the hard tint give no reflection, and be smooth as glass.

4. With a camel's hair brush, there must be given lightly and with a gentle heat, from 4 to 5 coats at least, and even sometimes double that number, of fine lac varnish.

5. When these are dry, the grounds of the pannels and the sculptures must be first polished with shave-grass (*de la préle*); and next with putty of tin and tripoli, tempered with water, applied with woollen cloth; by which the varnish is polished till it shines like a mirror.

6. The work thus polished is carried into a hot place, free from dust, where it receives very lightly and smoothly, a thin coat of gold colour, much softened down. This coat is passed over it with a clean soft brush, and the thinner it is the better.

7. Whenever the gold colour is dry enough to take the gold, which is known by laying the back of the hand on a corner of the frame work, the gilding is begun and finished as usual.

8. The gold is smoothed off with a very soft brush, one of camel's hair for example; ie, of three fingers' breadth; after which it is left to dry for several days.

9. It is then varnished with a spirit of wine varnish; which is treated with the chafing dish as above described.

10. When this varnish is dry, two or three coats of copal, or oil of varnish, are applied, at intervals of two days.

11. Finally, the pannels are polished with a worsted cloth, imbued with tripoli and water, and lustre is given by friction with the palm of the hand, previously softened with a little olive oil, taking care not to rub off the gold.

In this country, *Burnished gilding* is practised by first giving a ground of size whitening, in several successive coats; next applying gilding size; and then the gold leaf, which is burnished down with agate, or a dog's tooth.

Gilding à l'estemper of the French, is the same as our burnished gilding. Their process seems to be very elaborate, and the best consists of 17 operations; each of them said to be essential.

1. *Encollage*, or the *Glue coat*. To a decoction of worm-wood and garlic in water, strained through a cloth, a little common salt, and some vinegar are added. This composition, as being destructive of worms in wood, is mixed with as much good glue; and the mixture is spread in a hot state, with a brush of bear's hair. When plaster or marble is to be gilded, the salt must be left out of the above composition, as it is apt to attract humidity in damp places, and to come out as a white powder on the gilding. But the salt is indispensable for wood. The first glue coating is made thinner than the second.

2. *White preparation*. This consists in covering the above surface, with 8, 10, or 12 coats of Spanish white, mixed up with strung size, each well worked up with the brush, and in some measure incorporated with the preceding coat, to prevent their peeling off in scales.

3. *Stopping up the pores*, with thick whiting and glue, and smoothing the surface with dog-skin.

4. *Polishing the surface* with pumice-stone and very cold water.

5. *Reparation*; to which a skilful artist retouches the whole.

6. *Chasing*; with a damp linen rag, and then a soft sponge.

7. *Wiping*. This is rubbing with horse's tail (*ash-c-grass*) the parts to be yellowed, in order to make them a fir.

8. *Yellowing*. With this view *yellow ochre* is carefully ground in water, and mixed with transparent colorless size. The thinner part of this mixture is applied hot over the white surface with a fine brush, which gives it a fine yellow hue.

9. *Ungraining*; consists in rubbing the whole work with shave-grass, to remove any granular appearance.

10. *Coat of azzette; trencher coat*. This is the composition on which the gold is to be laid. It is composed of Armenian bole, 1 pound; bloodstone (hematite), 2 ounces; and as much galena; each separately ground in water. The whole are then mixed together, and ground up with about a spoonful of olive oil. The *azzette* well made and applied gives beauty to the gilding. The *azzette* is tempered with a white sheep-skin glue, very clear and well strained. This mixture is heated and applied in three successive coats, with a very fine hog-haired brush.

11. *Rubbing*, with a piece of dry, clean linen cloth; except the parts to be burnished, which are to receive other two coats of *azzette* tempered with glue.

12. *Graining*. The surface being damped with cold water (used in summer) has then the gold leaf a place to it. The hollow grounds must always be gilded before the plain part. Water is dexterously applied by a soft brush, immediately behind the gold leaf, before laying it down, which makes it lie smoother. Any excess of water is then removed with a dry brush.

13. *Burnishing*, with bloodstone.

14. *Darkening*. This consists in passing a thin coat of glue, slightly warmed, over the parts that are not to be burnished.

15. *Menting*; that is, moistening any broken points with a brush, and applying bits of gold leaf to them.

16. *The vermeil coat*. Vermeil is a liquid which gives lustre and fire to the gold; and makes it resemble *or-moulu*. It is composed as follows: 2 ounces of annotta, 1 ounce of gamboge, 1 ounce of vermillion, half an ounce of dragon's blood, 2 ounces of salt of tartar, and 16 grains of saffron, are boiled in a litre (2 pints English) of water, over a slow fire, till the liquid be reduced to a fourth. The whole is then passed through a silk or muslin sieve. A little of this is made to glaze lightly over the gold, with a very soft brush.

17. *Repassing*; is passing over the dead surfaces a second coat of drenching glue, which must be hotter than the first. This finishes the work, and gives it strength.

Leaf gilding, on paper or vellum, is done by giving them a coat of gum water or fine size, applying the gold leaf ere the surfaces be hard dry, and burnishing with agate.

Gold lettering, on bound books, is given without size, by laying the gold leaf on the leather, and imprinting it with hot brass type.

The edges of the leaves of books are gilded, while they are in the press where they have been cut smooth, by applying a solution of minglass in spirits, and laying on the gold when the edges are in a proper state of dryness. The French workmen employ a ground of Armenian bole, mixed with powdered sugar-candy, by means of white of egg. This ground is laid very thin upon the edges, after fine size or gum water has been applied; and when the ground is dry it is rubbed smooth with a wet rag, which moistens it sufficiently to take the gold.

Japanese' gilding is done by sprinkling or daubing with wash leather, some gold powder over an oil sized surface, mixed with oil of turpentine. This gives the appearance of frosted gold. The gold powder may be obtained, either by precipitating gold from its solution in *aqua regia* by a solution of pure sulphate of iron, or by evaporating away the mercury from some gold amalgam.

II. *CHEMICAL GILDING*, or the application of gold by chemical affinity to metallic surfaces.

A compound of copper with one seventh of brass is the best metal for gilding on a copper by itself being too soft and dark coloured. Ordinary brass, however, answers very well. We shall describe the process of wash gilding, with M. l'Arget's late improvements, now generally adopted in Paris.

Wash gilding, consists in applying evenly an amalgam of gold to the surface of a copper alloy, and dissipating the mercury with heat, so as to leave the gold film fixed. The surface is afterwards burnished or denuded at pleasure. The gold ought to be

quite pure, and laminated to facilitate its combination with the mercury; which should also be pure.

Preparation of the amalgam.—After weighing the fine gold, the workman puts it in a crucible, and as soon as this becomes faintly red, he pours to the crucible a quantity of mercury; which is about 8 to 1 of gold. He stirs up the mixture with an iron rod, bent backwards at the end, leaving the crucible on the fire till he perceives that all the gold is dissolved. He then pours the amalgam into a small earthen dish containing water, washes it with care, and squeezes out of it with his fingers all the running mercury that he can. The amalgam that now remains on the sloping sides of the vessel is so putty as to preserve the impression of the fingers. When this is squeezed in a shaggy leather bag, it gives up much mercury; and remains an amalgam, consisting of about 33 of mercury, and 57 of gold, in 100 parts. The mercury which passes through the bag, under the pressure of the fingers, holds a good deal of gold in solution; and is employed in making fresh amalgam.

Preparation of the mercurial solution.—The amalgam of gold is applied to brass, through the intervention of pure nitric acid, holding in solution a little mercury.

100 parts of mercury, and 110 parts by weight of pure nitric acid, specific gravity 1.33, are to be put into a glass matrass. On the application of a gentle heat the mercury dissolves with the disengagement of fumes of nitrous gas, which must be allowed to escape to the chimney. This solution is to be diluted with about 25 times its weight of pure water, and bottled up for use.

1. *Annealing.*—The workman anneals the piece of brass after it has come out of the hands of the turner and engraver. He sets it among burning charcoal, or rather pots, which have a more equal and lively flame; covering it quite up, so that it may be oxidised as little as possible, and taking care that the thin parts of the piece do not become hotter than the thicker. This operation is done in a dark room, and when he sees the piece of a cherry red colour, he removes the fuel from about it, lifts it out with long tongs, and sets it to cool slowly in the air.

2. *The decapage.*—The object of this process is to clear the surface from the coat of oxide which may have formed upon it. The piece is plunged into a bucket filled with extremely dilute sulphuric acid; it is left there long enough to allow the coat of oxide to be dissolved, or at least loosened; and it is then rubbed with a hard brush. When the piece becomes perfectly bright, it is washed and dried. Its surface may, however, be still a little variegated; and the piece is therefore dipped in nitric acid, specific gravity 1.33, and afterwards rubbed with a long-haired brush. The addition of a little common salt to the dilute sulphuric acid would probably save the use of nitric acid, which is so apt to produce a new coat of oxide. It is finally made quite dry (after washing in pure water), by being rubbed well with tanners' dry bark, sandast, or bran. The surface should now appear somewhat depolished; for when it is very smooth, the gold does not adhere so well.

3. *Application of the amalgam.*—The gilder's *scratch-brush* or pencil, made with fine brass wire, is to be dipped into the solution of nitrate of mercury, and is then to be drawn over a lump of gold amalgam, laid on the sloping side of an earthen vessel, after which it is to be applied to the surface of the brass. This process is to be repeated, dipping the brush into the solution, and drawing it over the amalgam, till the whole surface to be gilded is coated with its just proportion of gold. The piece is then washed in a body of water, dried, and put to the fire to volatilise the mercury. If one coat of gilding be insufficient, the piece is washed over anew with amalgam, and the operation recommenced till the work prove satisfactory.

4. *Volatilisation of the mercury.*—Whenever the piece is well coated with amalgam, the gilder exposes it to glowing charcoal, turning it about, and heating it by degrees to the proper point; he then withdraws it from the fire, lifts it with long pincers, and, seizing it in his left hand, protected by a stuffed glove, he turns it over in every direction, rubbing and striking it all the while with a long-haired brush, in order to equalise the amalgam. He now restores the piece to the fire, and treats it in the same way till the mercury be entirely volatilised, which he recognises by the hissing sound of a drop of water let fall on it. During this time he repairs the defective spots, taking care to volatilise the mercury very slowly. The piece, when thoroughly coated with gold, is washed, and scrubbed well with a brush in water acidulated with vinegar.

If the piece is to have some parts burnished, and others dead, the parts to be burnished are covered with a mixture of Spanish white, bruised sugar-candy, and gum dissolved in water. This operation is called in French *epargner* (*protecting*). When the gilder has protected the burnished points, he dries the piece, and carries the heat high enough to expel the little mercury which might still remain on it. He then plunges it, while still a little hot, in water acidulated with sulphuric acid, washes it, dries it, and gives it the burnish.

5. *The burnish* is given by rubbing the piece with burnishers of hematite (blood-

stone). The workman dips his burner in water sharpened with vinegar, and rubs the piece always in the same direction backwards and forwards, till it exhibits a fine polish and a complete metallic lustre. He then washes it in cold water, dries it with fine linen cloth, and completes the operation by drying it slowly on a grating placed above a basket of burning charcoal.

6. The *gilding* is given as follows. The piece, covered with the protection on those parts that are to be burnished, is attached with an iron wire to the end of an iron rod, and is heated strongly so as to give a brown line to the *epargne* by its partial carbonisation. The gilded piece assumes thus a fine tint of gold; and is next coated over with a mixture of sea salt, nitre and alum, fused in the water of crystallisation of the latter salt. The piece is now restored to the fire, and heated till the saline crust which covers it becomes homogeneous, nearly transparent, and enters into true fusion. It is then taken from the fire and suddenly plunged into cold water, which separates the saline crust, carrying away even the coat of *epargne*. The piece is lastly passed through very weak nitric acid, washed in a great body of water, and dried by exposure either to the air, over a drying stove, or with clean linen cloths.

7. *Of or-molu colour.*—When it is desired to put a piece of gilded bronze into or-molu colour, it must be less scrubbed with the scratch-brush than usual, and made in some back again by heating it more strongly than if it were to be deadened, and allowing it then to cool slowly. The or-molu colouring is a mixture of hematite, alum, and sea salt. This mixture is to be thinned with vinegar, and applied with a brush so as to cover the gilded bronze, with reserve of the burnished parts. The piece is then put on glowing coals, dried a little by the bellows, and allowed to heat till the colour begins to blacken. The piece ought to be so hot that water sprinkled on it may cause a hissing noise. It is then taken from the fire, plunged into cold water, washed, and next scrubbed with a brush dipped in vinegar, if the piece be smooth, but if it be chased, weak nitric acid must be used. In either case, it must be finally washed in a body of pure water, and dried over a gentle fire.

8. *Of red gold colour.*—To give this hue, the piece after being coated with amalgam, and heated, is in this hot state to be suspended by an iron wire, and tempered with the composition known under the name of gibber's wax; made with yellow wax, red ochre, verdigris, and alum. In this state it is presented to the flame of a wood fire, is heated strongly, and the combustion of its coating is favoured by throwing some drops of the wax mixture into the burning fuel. It is now turned round and round over the fire, so that the flame may act equally. When all the wax of the colouring is burned

away, and when the flame is extinguished, the piece is to be plunged in water, washed, and scrubbed with the scratch-brush and pure vinegar. If the colour is not beautiful, and quite equal in shade, the piece is coated with verdigris dissolved in vinegar, dried over a gentle fire, plunged in water, and scrubbed with pure vinegar, or even with a little weak nitric acid if the piece exhibit too dark a hue. It is now washed, burnished, washed anew, wiped with linen cloth, and finally dried over a gentle fire.

The following is the outline of a complete gilding factory, as now fitted up at Paris.

Figs. 838, 839, front elevation and plan of a complete gilding workshop. 1. Furnace of *epargne*, or draught, serving at the same time to heat the deadening pan (*poisson au mord*).

2. Ash pit of this furnace.

3. Chimney of the furnace constructed of bricks, as far as the construction of the

great chimney a of the forge, and which is terminated by a summit pipe rising 2 or 3 yards above this contraction.

n. Forge for annealing the pieces of bronze; for drying the gilded pieces, &c.

c. Chimney of communication between the annealing forge n, and the space v below the forge. This chimney serves to carry the noxious fumes into the great vent of the factory.

o. Bucket for the brightening operation.

a. Forge for passing the amalgam over the piece.

s. Stiff for the brushing operations.

r. Coal cellarets.

q. Forge for the deadening process.

u. Furnace for the same.

m. An opening into the furnace of *appel*, by which vapours may be let off from any operation by taking out the plug at m.

t. Cask in which the pieces of gilded brass are plunged for the deadening process. The vapours rising thence are carried up the general chimney.

j. Casement with glass panes, which serves to contract the opening of the hearths, without obstructing the view. The casement may be rendered movable to admit larger objects.

h. Curtains of coarse cotton cloth, for closing at pleasure, in whole or part, one or several of the forges or hearths, and for quickening the current of air in the places where the curtains are not drawn.

q. Opening above the draught furnace, which serves for the heating of the *poisson* on mat (deadening pan).

Gilding on polished iron and steel.—If a nearly neutral solution of gold in muriatic acid be mixed with sulphuric ether, and agitated, the ether will take up the gold, and float above the denser acid. When this auriferous ether is applied by a hair pencil to brightly polished iron or steel, the ether flies off, and the gold adheres. It must be fixed by polishing with the burnisher. This gilding is not very rich or durable. In fact the affinity between gold and iron is feeble, compared to that between gold and copper or silver. But polished iron, steel, and copper, may be gilded with heat, by gold leaf. They are first heated till the iron takes a bluish tint, and till the copper has attained to a like temperature; a first coat of gold leaf is now applied, which is pressed gently down with a burnisher, and then exposed to a gentle heat. Several leaves either single or double are thus applied in succession, and the last is burnished down cold.

Mr. Elkington obtained a patent, in June, 1834, for gilding copper, brass, &c., by means of potash or soda combined with carbonic acid, and with a solution of gold. Diaville, says he, 5 oz. troy of fine gold in 52 oz. avoirdupoise of nitro-muriatic acid of the following proportions: viz. 21 oz. of pure nitric acid, of spec. grav. 1.45, 17 oz. of pure muriatic acid, of spec. grav. 1.15, with 14 oz. of distilled water.

The gold being put into the mixture of acids and water, they are to be heated in a glass or other convenient vessel till the gold is dissolved; and it is usual to continue the application of heat after this is effected, until a reddish or yellowish vapour ceases to rise.

The clear liquid is to be carefully poured off from any sediment which generally appears, and results from a small portion of silver, which is generally found in alloy with gold. The clear liquid is to be placed in a suitable vessel of stone; pottery ware is preferred. Add to the solution of gold 4 gallons of distilled water, and 20 pounds of bicarbonate of potash of the best quality; let the whole boil moderately for 2 hours, the mixture will then be ready for use.

The articles to be gilded having been first perfectly cleaned from scale or grease, they are to be suspended on wires, conveniently for a workman to dip them in the liquid, which is kept boiling. The time required for gilding any particular article will depend on circumstances, partly on the quantity of gold remaining in the liquid, and partly on the size and weight of the article; but a little practice will readily give sufficient guidance to the workman.

Supposing the articles desired to be gilded be brass or copper buttons, or small articles for gift toys, or ornaments of dress, such as earrings or bracelets, a considerable number of which may be strung on a hoop, or banded piece of copper or brass wire, and dipped into the vessel containing the boiling liquid above described, and moved therein, the requisite gilding will be generally obtained in from a few seconds to a minute; this is when the liquid is in the condition above described, and depending on the quality of the gilding desired; but if the liquid has been used some time, the quantity of gold will be lessened, which will vary the time of operating to produce a given effect, or the colour required, all of which will quickly be observed by the workman; and by noting the appearance of the articles from time to time, he will

know when the desired tint is obtained, though it is desirable to avoid as much as possible taking the articles out of the liquid.

When the operation is completed, the workman perfectly washes the articles so gilded with clean water, they may then be submitted to the usual process of coloring.

If the articles be cast figures of animals, or otherwise of considerable weight, compared with the articles above mentioned, the time required to perform the process will be greater.

In case it is desired to produce what is called a dead appearance, it may be performed by several processes: the one usually employed is to dead the articles in the process of cleaning, as practised by brass founders and other trades; it is produced by an acid, prepared for that purpose, sold by the makers under the term "deadening aquafortis," which is well understood.

It may also be produced by a weak solution of nitrate of mercury, applied to the articles previous to the gilding process, as is practised in the process of gilding with mercury, previous to spreading the amalgam, but generally a much weaker solution; or the articles having been gilded may be dipped in a solution of nitrate of mercury, and submitted to heat to expel the same, as is practised in the usual process of gilding.

Cold gilding.—Sixty grains of fine gold and 12 of rose copper are to be dissolved in two ounces of aqua regia. When the solution is completed, it is to be dropped on clean linen rags, of such bulk as to absorb all the liquid. They are then dried, and burned into ashes. These ashes contain the gold in powder.

When a piece is to be gilded, after subjecting it to the preliminary operations of rusting or annealing and brightening, it is rubbed with a moistened cork, dipped in the above powder, till the surface seems to be sufficiently gilded. Large works are thereafter burnished with pieces of hematite, and small ones with steel burnishers, along with soap water.

In gilding small articles, as buttons, with amalgam, a portion of this is taken equivalent to the work to be done, and some nitrate of mercury solution is added to it in a wooden trough: the whole articles are now put in, and well worked about with a hard brush, till their surfaces are equally coated. They are then washed, dried, and put altogether into an iron frying-pan, and heated till the mercury begins to fly off, when they are turned out into a cask, in which they are tossed and well stirred about with a painter's brush. The operation must be repeated several times for a strong gilding. The surfaces are finally brightened by brushing them along with small beer or all grounds.

For the processes of gilding by electro-chemical means, see **ELECTROTYPE**.

GYMP, or **GYMP**, a silk, woollen, or cotton twist, with often a metal wire, but sometimes a coarse thread running through it; it is much used in coat-making.

GIN, or *Geneva*, from *Genève* (Juniper), is an ardent spirit manufactured in London, and other places, in great quantities, and flavoured generally with juniper berries. It is also made in Holland, and hence called *Holland gin* in this country. To distinguish it from British gin. The materials employed in the distilleries of Schiedam, are two parts of unmalted rye from Riga, weighing about 54 lbs. per bushel, and one part of malted barley, weighing about 37 lbs. per bushel. The mash tun, which serves also as the fermenting tun, has a capacity of nearly 700 gallons, being about 5 feet in diameter at the mouth, rather narrower at the bottom, and 4½ feet deep: the stirring apparatus is an oblong rectangular iron grid made fast to the end of a wooden pole. About a barrel, = 36 gallons of water, at a temperature of from 102° to 105° (the former heat being best for the most highly dried rye), are put into the mash tun for every 1½ cwt. of meal, after which the malt is introduced and stirred, and lastly the rye is added. Powerful agitation is given to the magma till it becomes quite uniform; a process which a vigorous workman piques himself upon executing in the course of a few minutes. The mouth of the tun is immediately covered over with canvas, and further secured by a close wooden lid, to confine the heat, it is left in this state for two hours. The contents being then stirred up once more, the transparent spent wash of a preceding mashing is first added, and next as much cold water as will reduce the temperature of the whole to about 85° F. The best Flanders yeast, which had been brought, for the sake of carriage, in a doughy consistence by pressure, is now introduced to the amount of one pound for every 100 gallons of the mashed materials.

The gravity of the fresh wash is usually from 33 to 36 lbs. per Denis' hydrometer; and the fermentation is carried on from 24 to 60 hours, at the end of which time the attenuation is from 7 to 8 lbs., that is, the specific gravity of the supernatant wash is from 1.007 to 1.004.

The distillers are induced, by the scarcity of beer-barm in Holland, to skim off a quantity of the yeast from the fermenting tun, and to sell it to the bakers, whereby they obtain materially the production of spirit, though they probably improve the quality, by preventing its impregnation with yeasty particles; an unpleasant result which seldom fails to take place in the whisky distilleries of the United Kingdom.

On the third day after the fermenting tun is set, the wash containing the grains is transferred to the still, and converted into low wines. To every 100 gallons of the liquor, two pounds of juniper berries, from 3 to 5 years old, being added, along with about one quarter of a pound of salt, the whole are put into the low wine still, and the fire is raised spirit is drawn off by a gentle and well-regulated heat, till the magna becomes exhausted; the first and the last products being mixed together; whereby a spirit, 2 to 3 per cent. above our hydrometer proof, is obtained, possessing the peculiar fine aroma of gin. The quantity of spirit varies from 15 to 21 gallons per quarter of grain; this large product being partly due to the employment of the spent wash of the preceding fermentation; an addition which contributes at the same time to improve the flavour.

London gin is, as we have stated, a corn spirit, which is, however, rendered sweet and cordial-like, by the use of several injurious substances. Plymouth gin, as manufactured by Coates and Co. of Plymouth, is a far purer spirit. The rectifiers employ a pure grain spirit, and flavour with the wash of the whisky distilleries. Mr. Brande has given the following table of the quantities of alcohol (sp. gr. at 60° F., 0.825) contained in different ardent spirits.

Proportion of Alcohol in ardent Spirits.

	In 100 parts.
Brandy	55.39 by measure.
Rum	53.68 "
Gin	51.80 "
Whisky, Scotch	54.32 "
Do. Irish	53.20 "

When wash is distilled, the fluid that comes over is called *unglings*, or *low wines*. It is concentrated or doubled by a second distillation, and becomes *raw corn spirit*; this is sold to the rectifier at 11 or 25 per cent. over proof.

GINGER BEER. Boil 65 gallons of river water, 1½ cwt. of the best loaf sugar, and 5 lbs. of the best raw ginger, bruised, half an hour; then add the whites of 10 eggs, beaten to a froth with 2 ounces of dissolved isinglass. Stir it well in, and boil 20 minutes longer, skimming it the whole time. Then add the thin rinds of 50 lemons, boiling them 10 minutes more. Cut 25 lbs. of good Malaga raisins in half, take away the stones and stalks, and put them, with the juice of the lemon, strained, into the bogshead. Strain the hot liquor into a cooler, and when it has stood two hours and is settled, draw it off the lees, clear, and put it into the cask; filter the thick and fill up with it. Leave the bung out, and when at the proper temperature, stir 3 quarts of thick fresh ale yeast well into it; put on the bung lightly, and let it ferment 6 or 7 days, filling up with liquor as it ferments over. When the fermentation has ceased, pour in 6 quarts of French brandy, and 8 ounces of the best isinglass, dissolved in a gallon of the wine; then secure the bung effectually, and paste paper over it, &c. Keep it 2 years in a cool cellar, then bottle it, using the best corks, and sealing them; and when it is 4 years old commence using it.

There can be no doubt but that the above receipt by Dr. Ure forms an excellent ginger beer, but it is a totally different thing from the ginger beer of the shops. The following is a good and useful form for its manufacture:—

Barbadoes ginger root	12 ounces.
Tartaric acid	3 ounces.
White sugar	8 pounds.
Gum arabic	8 ounces.
Essence of lemon	2 drachms.
Water	9 gallons.

The ginger root, bruised, is to be boiled for an hour, then the liquor being strained, the tartaric acid and sugar added, boiled and the same removed. The gum arabic dissolved in a separate portion of water, added with the essence of lemons. When the whole has cooled to about 100° Fabr., some fresh yeast is to be added, and the beer carefully fermented. Then bottle for use.

Ginger beer powders are thus prepared:—

White sugar	-	-	-	-	-	-	5 ounces.
Tartaric acid	-	-	-	-	-	-	1½ ounce.
Carbonate of soda	-	-	-	-	-	-	1½ ounce.
Powdered Jamaica ginger	-	-	-	-	-	-	2 drachms.
Essence of Lemon	-	-	-	-	-	-	10 drops.

All the materials are to be carefully dried, and mixed while yet warm, in a warm mortar, and immediately bottled.

If the acid and the carbonate of soda are kept separate, these precautions are not necessary.

WINNING is the name of the operation by which the filaments of cotton are separated from the seeds. See **COTTON MANUFACTURE**.

GIRASOL. The name given by the French to fire opal. See **OPAL**.

GLAIRE. The white of egg. This consists according to Gmelin of albumen, 12.0, mucin, 2.7, salts, 0.3, water, 85.0. Glaire or albumen (*crathumen*) is distinguished from the albumen of the serum of the blood (*seralbumen*), by its being coagulated by ether. Glaire is used by bookbinders in finishing the backs of books, and for a few other purposes in the arts. See **ALBUMEN**.

GLANCE COAL, a name given to anthracite, of which there are two varieties, the *glaze* and the *conchoidal*. See **ANTHRACITE** and **COAL**.

GLASS (*Verre*, Fr.; *Glas*, Germ.) is a transparent solid formed by the fusion of siliceous and alkaline matter. It was known to the Phœnicians, and constituted for a long time an exclusive manufacture of that people, in consequence of its ingredients, natron, sand, and fuel, abounding upon their coasts. It is certain that the ancient Egyptians were acquainted with glass, for, although we find no mention of it in the writings of Moses, we discover glass ornaments in tombs which are as old as the days of Moses. According to Pliny and Strabo, the glass works of Sidon and Alexandria were famous in their times, and produced beautiful articles, which were cut, engraved, gilt, and stained of the most brilliant colours, in imitation of precious stones. The Romans employed glass for various purposes; and have left specimens in Herculaneum of window-glass, which must have been blown by methods analogous to the modern. The Phœnician processes seem to have been learned by the Crusaders, and transferred to Venice in the 13th century, where they were long held secret, and formed a lucrative commercial monopoly. Soon after the middle of the seventeenth century Colbert enriched France with the blown mirror glass manufacture.

Chance may have had a share in the invention of this curious fabrication, but there were circumstances in the most ancient arts likely to lead to it; such as the fusing and vitrifying heats required for the formation of pottery, and for the extraction of metals from their ores. Pliny ascribes the origin of glass to the following accident. A merchant ship laden with natron being driven upon the coast at the mouth of the river Belus, in tempestuous weather, the crew were compelled to cook their victuals ashore, and having placed lamps of the natron upon the sand, as supports to the kettles, found to their surprise masses of transparent stone among the cinders. The sand of this small stream of Galilee, which runs from the foot of Mount Carmel, was in consequence supposed to possess a peculiar virtue for making glass, and continued for ages to be sought after and exported to distant countries for this purpose. There exists good evidence that the manufacture of glass, and of vitreous glazes is much older than the time ascribed by Pliny.

Agricola, the oldest author who has written technically upon glass, describes furnaces and processes closely resembling those employed at the present day. Neri, Knobel, Henckel, Pott, Achard, and some other chemists, have since then composed treatises upon the subject; but Neri, Bose, Antic, Lowsel, and Alut, in the *Encyclopédie Méthodique*, are the best of the older authorities.

The Venetians were the first in modern times who attained in any degree of excellence in the art of working glass, but the French became eventually so zealous of rivalling them, particularly in the construction of mirrors, that a decree was issued by the court of France, declaring not only that the manufacture of glass should not derogate from the dignity of a nobleman, but that nobles alone should be masters of glass-works. Within the last 30 or 40 years, Great Britain has made rapid advances in this important art, and at the present day her pre-eminence in some departments hardly admits of dispute.

The window-glass manufacture was first begun in England in 1557, in Crutched Friars, London; and fine articles of flint glass were soon afterwards made in the Savoy House, Strand. In 1673 the art received a great improvement from Sir Robert Mansell, by the use of coal fuel instead of wood. The first sheets of blown glass for looking-glasses and coach windows were made in 1673 at Lambeth, by Venetian artisans employed under the patronage of the Duke of Buckingham.

The casting of mirror-plates was commenced in France about the year 1683, by Abraham Thevenot; an invention which gave rise soon afterwards to the establishment of the celebrated works of St. Gobain, which continued for nearly a century the sole place where this highly-prized object of luxury was well made. In cheapness, if not in excellence, the French mirror-plate has been for some time rivalled by the English.

The analysis of modern chemists, which will be detailed in the course of this article, and the light thrown upon the manufacture of glass in general by the accurate means now possessed of purifying its several ingredients, would have brought the art long since to the highest state of perfection in this country, but for the long continued vexatious interference and obstructions of our excise laws now happily at an end.

The researches of Berzelius having removed all doubts concerning the acid character of silica, the general composition of glass presents now no difficulty of conception. This substance consists of one or more salts, which are silicates with bases of potash, soda, lime, oxide of iron, alumina, or oxide of lead; in any of which compounds we can substitute one of these bases for another, provided that one alkaline base be left. Silica in its turn may be replaced by the boracic acid, without causing the glass to lose its principal characters.

Under the title glass are therefore comprehended various substances fusible at a high temperature, solid at ordinary temperatures, brilliant, generally more or less transparent, and always brittle. The following chemical distribution of glasses has been proposed:—

1. Soluble glass; a simple silicate of potash or soda; or of both these alkalies.
2. Crown glass; silicate of potash and lime.
3. Bottle glass; silicate of soda, lime, alumina, and iron.
4. Common window glass; silicate of soda and lime; sometimes also of potash.
5. Plate glass; silica, soda or potash, lime, and alumina.
6. Ordinary crystal glass; silicate of potash and lead.
7. Flint glass; silicate of potash and lead; richer in lead than the preceding.
8. Strass; silicate of potash and lead; still richer in lead.
9. Enamel; silicate and stannate or antimoniate of potash or soda, and lead.

The following analyses of these varieties of glass will place the composition more completely before the reader:—

	Silicio Acid.	Potash or Soda.	Lime.	Oxide of Lead.	Alumina.	Water.
1. Soluble glass - -	62	26	0	0	0	12
2. Crown glass - -	68	22	12	0	8	0
3. Bottle glass - -	54	5	20	6 or. iron	0	0
4. Window glass - -	69	11 soda	13	0	7	0
5. Plate glass - -	72	17 soda	6	2 or. iron	2	0
6. Crystal - -	61	6	0	33	0	0
7. Flint glass - -	45	12	0	43	0	0
8. Strass - -	39	8	0	53	1	0
9. Enamel - -	31	8	0	50	10 or. tin	0

Bohemian glass has not been named among the varieties. It has been generally grouped with the English glass as containing no lead, but it has some special peculiarities, as the following analyses by Peligot will show:—

	Silica.	Potash.	Lime.	Alumina.	Soda.
Bohemian glass - -	76.0	15.0	8.0	1.0	0
Do. opal glass - -	80.9	17.6	7	8	0
Do. mirror glass - -	67.7	21.0	9.9	1.4	0
Do. hard glass (as analysed by Mr. Rowney)	73.0	11.5	10.5	2.0	5

In the following table is also given the analyses of a certain number of Bohemian glasses, which will indicate their composition with precision, and show how uncertain their composition is.

	(1.)	(2.)	(3.)	(4.)	(5.)	(6.)	(7.)	(8.)
Silica - - -	71.6	71.7	69.4	62.8	75.9	74.55	70.	57.
Potassa - - -	11.0	12.7	11.8	22.1	-	5.3	20.	25.
Soda - - -	-	2.3	-	-	17.5	12.05	-	-
Lime - - -	10.	10.3	9.2	12.5	3.8	5.6	4.	12.5
Magnesia - - -	2.3	-	-	-	-	-	-	-
Alumina - - -	2.2	0.4	9.6	2.6	2.9	3.5	5.	5.
Oxide of Iron - -	3.9	0.3	-	-	-	-	0.6	1.3
Oxide of Manganese -	0.3	0.2	-	-	-	-	0.4	0.4
	101.2	96.1	100.	100.	100.	100.5	100.	99.2

(1.) Bohemian glass from Neufeld (M. Grus).

(2.) A fine table glass from Neuwelt (M. Berthier); it is exceedingly beautiful, and is prepared, according to M. Perdonnet, with a mixture of 100 quartz, 50 caustic lime, 75 carbonate of potassa, and a very small quantity of nitre, arsenious acid, and oxide of manganese.

(3.) Old Bohemian glass (M. Dumas).

(4.) Crown glass of German manufacture (M. Dumas).

(5.) Glass for mirrors (M. Dumas).

(6.) Another glass for mirrors (M. Dumas).

(7.) White table glass, from Silberberg near Grätz.

(8.) Mirror glass from New-Harkenthal, for the manufacture of cast mirrors.

Pelliot gives the analysis of Venetian aventuring as follows:—

Silica - - -	67.7	Oxide of Tin - - -	2.3
Potash - - -	5.5	Oxide of Lead - - -	1.1
Lime - - -	8.9	Metall. Copper - - -	3.0
Soda - - -	7.1	Oxide of Iron - - -	3.5

See AVENTURINE.

The following analyses of different varieties of continental glass are instructive:—

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.
Silica - - -	71.7	69.2	62.8	60.4	53.55	42.5
Potash - - -	12.7	15.4	22.1	8.2	5.43	11.7
Soda - - -	2.3	3.0	-	S. pot.	-	-
Lime - - -	10.3	7.6	1.5	20.7	20.21	0.5
Alumina - - -	0.4	1.2	-	10.4	6.01	1.6
Magnesia - - -	-	2.0	2.6	0.6	-	-
Oxide of iron - -	0.3	0.3		3.8	5.74	-
— manganese - -	0.2	-	-	-	-	45.5
— lead - - -	-	-	-	0.9	-	-
Baryta - - -	-	-	-	-	-	-

No. 1. is a very beautiful white wine glass of Neuwelt in Bohemia.

No. 2. Glass tubes, much more fusible than common wine glasses.

No. 3. Crown glass of Bohemia.

No. 4. Flask glass of St. Etienne, for which some heavy spar is used.

No. 5. Glass of Sevres.

No. 6. Guinand's flint glass.

Ancient glass has the following composition; the analyses are by Richard Phillips:—

	Silica.	Alumina.	Oxide of Iron.	Manganese.	Lime.	Magnesia.	Soda.
Roman glass - - -	70.54	1.61	0.53	0.45	8.00	trace	14.86
13th. Fluted glass -	71.93	1.76	3.45	0.32	7.20	0.21	18.20
13th. Lachrymatory -	71.45	2.15	1.02	.17	6.14	trace	18.08

Thus we see that the ancient glasses were all soda glasses.

The glasses which contain several bases are liable to suffer different changes when

they are melted or cooled slowly. The silica is divided among these bases, forming new compounds in definite proportions, which by crystallising separate from each other, so that the general mixture of the ingredients which constitute the glass is destroyed. It becomes then very hard, fibrous, opaque, much less fusible, a better conductor of electricity and of heat; forming what Reaumur styled *devitrified glass*; and what is called after him Reaumur's porcelain.

This altered glass can always be produced in a more or less perfect state, by melting the glass and allowing it to cool very slowly; or merely by heating it to the softening pitch, and keeping it at that heat for some time. The process succeeds best with the most complex vitreous compounds, such as bottle glass; next with ordinary window glass; and lastly with glass of potash and lead.

This property ought to be kept constantly in view in manufacturing glass. It shows why in making bottles we should fashion them as quickly as possible with the aid of a mould, and reheat them as seldom as may be absolutely necessary. If glass is often heated and cooled, it loses its ductility, becomes refractory, and exhibits a multitude of stony granulations throughout its substance. When coarse glass is worked at the enameller's lamp, it is apt to change its nature in the same way, if the workman be not quick and expert at his business.

Fusibility, Cooking, Annealing, Devitrification. — All glass is more or less fusible; when it is softened by the action of heat, it may be worked with the greatest ease, and may be drawn out into threads as fine as those of the silkworm. Glass, when it is submitted to rapid cooling, becomes very fragile, and presents several very remarkable phenomena, among which as an example Prince Rupert's drops may be instanced. Glass supports variations of temperatures better in proportion as it has been more slowly cooled; thus, when it has been slightly annealed, or out at all, its fragility may be considerably diminished by annealing it in water, or better, in boiling oil.

Action of Atmospheric and Chemical Agents. — The harder and more infusible a glass is, the less it is alterable by the action of atmospheric and chemical agents, with the exception of hydrofluoric acid. Glass which is too alkaline attracts gradually the moisture of the air, and loses its lustre and polish. Many glasses are perceptibly attacked by a prolonged boiling with water, and a *fortiori* by acid and alkaline solutions; thus, the bottle glass is frequently attacked by the tartar which is found in the wine. According to Guyton-Morveau, all glass which is attacked by prolonged boiling with concentrated solutions of alum, common salt, sulphuric acid, or potassa, is of bad quality.

From these facts we perceive the importance of making a careful choice of the glass intended to be worked in considerable masses, such as the large object glasses of telescopes; as their annealing requires a very slow process of refrigeration, which is apt to cause devitrified specks and clouds. For such purposes, therefore, no other species of glass is well adapted except that with bases of potash and lead; or that with bases of potash and lime. These two form the best flint glass and crown glass; and they should be exclusively employed for the construction of the object glasses of astronomical telescopes.

Glass, it will be apparent from the analyses given, may be defined in technical phraseology, to be a transparent homogeneous compound formed by the fusion of silica with oxides of the alkaline, earthy, or common metals. It is usually colourless, and then resembles rock crystal, but is occasionally stained by accident or design with coloured metallic oxides. At common temperatures it is hard and brittle, in thick pieces; in thin plates or threads, flexible and elastic; sonorous when struck; fracture conchoidal, and of that peculiar lustre called vitreous; at a red heat, becoming soft, ductile and plastic. Other bodies are capable of entering into vitreous fusion, as phosphoric acid, boracic acid, arsenic acid, as also certain metallic oxides, as of lead and antimony, and several chlorides; some of which are denominated glasses.

Silica, formerly styled the earth of flints, which constitutes the basis of all commercial glass, is infusible by itself in the strongest fire of our furnaces; but its vitreous fusion is easily effected by a competent addition of potash or soda, either alone or mixed with lime or litharge. The silica, which may be regarded as belonging to the class of acids, combines at the heat of fusion with these bases, into saline compounds; and hence glass may be viewed as a silicate of certain oxides, in which the acid and the bases exist in equivalent proportions. Were these proportions, or the quantities of the bases which silica requires for its saturation at the melting point, exactly ascertained, we might readily determine beforehand the best proportions of materials for the glass manufacture. But as this is far from being the case, and as it is, moreover, not improbable that the capacity of saturation of the silica varies with the temperature, and that the properties of glass also vary with the bases, we must in the present state of our knowledge, regulate the

proportions rather by practice than by theory, though the latter may throw an indirect light upon the subject. For example, a good colourless glass has been found by analysis to consist of 72 parts of silica, 13 parts of potash, and 10 parts of lime, in 95 parts. If we reduce these numbers to the equivalent ratios, we shall have the following results, taking the atomic weights as given by Berzelius:—

1 atom potash =	390	14.67	
1 lime	856	8.84	
3 silica	1722	42.75	} : 1.49
2 silica	1155	28.70	
	<hr/>	<hr/>	
	3823	95.00	

This glass would therefore have been properly better compounded with the just atomic proportions, to which it nearly approaches, viz. 71.49 silica, 14.67 potash, and 8.84 lime, instead of those given above as its actual constituents.

The proportions in which silica unites with the alkaline and other oxides are modified by the temperature as above stated; the lower the heat, the less silica will enter into the glass, and the more of the base will in general be required. If a glass which contains an excess of alkali be exposed to a much higher temperature than that of its formation, a portion of the base will be set free to act upon the materials of the earthen pot, or to be dissipated in fumes, until such a silicate remains as to constitute a permanent glass corresponding to that temperature. Hence the same mixture of variable materials will yield very different results, according to the heats in which it is fused and worked in the glasshouse; and therefore the composition should always be referrible to "the going" of the furnace. When a species of glass, which at a high temperature formed a transparent combination with a considerable quantity of lime, is kept for some time in fusion at a lower temperature, a portion of the lime unites with the silica into another combination of a semi-vitreous or even of a stony aspect, so as to spoil the transparency of the glass altogether. There is probably a supersilicate, and a sub-silicate formed in such cases; the latter being much the more fusible of the two compounds. The Reaumur's porcelain already mentioned, is an example of this species of vitreous change in which new affinities are exercised at a lower temperature. An excess of silica, caused by the volatilisation of alkaline matter with too strong firing, will bring on similar appearances.

The specific gravity of glass varies from 2.3 to 3.6. That of least specific gravity consists of merely silica and potash fused together; that with lime is somewhat denser, and with oxide of lead denser still. Plate glass made from silica, soda, and lime, has a specific gravity which varies from 2.5 to 2.6; crystal or flint glass containing lead from 3.0 to 3.6.

The density of several glasses *without lead* is as follows:—

Old Bohemian glass (Dumas)	-	-	-	-	2.766
Bohemian bottle glass	-	-	-	-	2.782
do. window glass	-	-	-	-	2.642
Fine glass, called Bohemian crystal	-	-	-	-	2.692
Mirror glass of Cherbourg (Dumas)	-	-	-	-	2.509
do. St. Gobain	-	-	-	-	2.463
do. Newhaus, 1812 (Scholz)	-	-	-	-	2.551
do. do. 1830	-	-	-	-	2.673

The power of glass to resist the action of water, alkalies, acids, air, and light, is in general the greater the higher the temperature employed in its manufacture, the smaller the proportion of its fluxes, and the more exact the equivalent ratios of its constituents. When glass contains too much alkali, it is partially soluble in water. Most crystal glass is affected by having water boiled in it for a considerable time; but crown glass is being poorer in alkali, and containing no lead, resists that action much longer, and is therefore better adapted to chemical operations. In general also potash glass is more apt to become damp than soda glass, agreeably to the respective hygrometric properties of these two alkalies, and also to the smaller proportion of soda than of potash requisite to form glass.

Air and light operate upon glass probably by their oxidising property. Bluish or greenish coloured glasses become by exposure colourless, in consequence undoubtedly of the peroxidation of the iron, to whose protoxide they owed their tint; other glasses become purple red from the peroxidation of the manganese. The glasses which contain lead, suffer another kind of change in the air, if sulphuretted hydrogen be present; the oxide of lead is converted into a sulphuret, with the effect of rendering the surface of the glass opaque and iridescent. The more lead is in the glass, the quicker does this iridescence supervene. If boiling concentrated sulphuric acid in a glass

vessel, or upon glass, we can ascertain its power of resisting ordinary menstrua. Good glass will remain smooth and transparent; bad glass will become rough and dim. The conditions of decomposition as it occurs in glass of great age, have not been satisfactorily explained. The glass of the Roman tombs decomposes from the surface, exhibiting in a remarkable manner, film after film, of a pearly and beautifully iridescent character, falling off one after the other. The same kind of change is seen on the windows of our ancient churches.

The brittleness of unannealed glass by change of temperature is sometimes very great. This defect may be corrected by slowly heating the vessel in salt-water or oil to the highest pitch consistent with the nature of these liquids, and letting it cool very slowly. Within the limits of that range of heat, it will, in consequence of this treatment, bear alternations of temperature without cracking.

It has been said that glass made from silica and alkalis alone, will not resist the action of water, but that the addition of a little lime is necessary for this effect. In general 100 parts of quartz-sand require 33 parts of dry carbonate of soda for their vitrification, and 45 parts of dry carbonate of potash. But to make unchangeable alkaline glass especially with potash, a smaller quantity of this than the above should be used with a very violent heat. A small proportion of lime increases the density, hardness, and lustre of glass; and it aids in decomposing the alkaline sulphates and muriates always present in the pent-lash of commerce. From 7 to 20 parts of dry slaked lime have been added for 100 of silica, with advantage. It is said, in some German glass manufactories, where the alkaline matter is soda; for potash does not assimilate well with the calcareous earth.

In many glass works on the continent, sulphate of soda is the form under which alkaline matter is introduced into glass. This salt requires the addition of 8 per cent. of charcoal to decompose and dissipate its acid; a result which takes place at a high heat, without the addition of any lime. 84 pounds of quartz-sand, 44 pounds of dry glauber salt, and 3 pounds of charcoal, properly mixed and fused, afford a limpid, dense, and workable glass; with the addition of 17 pounds of lime, these materials fuse more readily into a plastic mass. If less carbon be added, the fusion becomes more tedious.

If a proper addition of galena (the native sulphuret of lead) to glauber salt and quartz sand, without charcoal, it is said a tolerably good crystal glass may be formed. The sulphuric acid of the salt is probably converted by the reaction of the sulphuret of lead into sulphurous acid gas, which is disengaged.

One atom of sulphuret of lead = 1495.67, is requisite to decompose 3 atoms of sulphate of soda = 2676. It is stated, on good authority, that a good colourless glass may be obtained by using glauber salt without charcoal, as by the following formula.

Quartz sand - - -	100 pounds	Lime - - -	20 pounds
Calcined glauber salt - 20 "		Cullet of soda glass - 12 "	

The melting heat must be continued for 26½ hours. A small quantity of the sand is reserved to be thrown in towards the conclusion of the process, in order to facilitate the expansion of air bubbles. The above mixture will bear to be bleached by the addition of manganese and arsenic. The decomposition of the salt is in this case effected by the lime, with which the sulphuric acid first combines, which is then converted into sulphurous acid, and dissipated. Glass made in this way was found by analysis to consist of 72 parts of silica, 12 lime, and 96 soda, without any trace of gypsum or sulphuric acid.

Glauber salt is partially volatilised by the heat of the furnace, and sets upon the arch of the oven and the tops of the pots. This is best prevented by introducing at first into the pots the whole of the salt mixed with the charcoal, the lime, and one-fourth part of the sand; fusing this mixture at a moderate heat, and adding gradually afterwards the remainder of the sand, increasing the temperature at the same time. If we put in the whole ingredients together, as is done with potash glass, the sand and lime soon fall to the bottom, while the salt rises to the surface, and the combination becomes difficult and unequal.

Sulphate of potash acts in the same way as sulphate of soda.

Muriate of soda also, according to Kiru, may be used as a glass flux with advantage. The most suitable proportions are 4 parts of potash, 2 of common salt, and 3 of lime, agreeably to the following compositions.

	1.	2.
Quartz sand - - -	60.0	67.1
Calcined carbonate of potash -	17.8	19.1
Common salt - - -	8.9	9.3
Lime - - -	13.3	14.5

For No. 1, the melting heat must be 10 hours, which turns out a very pure, solid, good glass; for No. 2, 23 hours of the furnace are required. Instead of the potash, glauber salt may be substituted; the proportions being then 19·1 glauber salt, 9·3 muriate of soda, 14·3 lime, 57·1 sand, and 1·3 charcoal.

The oxide of lead is an essential constituent of the denser glasses, and may be regarded as replacing the lime, so as to form with the quartz sand a silicate of lead. It assimilates best with purified pearl ash, on account of the freedom of this alkali from iron, which is present in most sodas.

Its atomic constitution may be represented as follows:—

				Calculated	Analysed
Silicic acid	-	-	5 atoms =	2877·0	59·19
Oxide of lead	-	-	1	= 1394·5	28·20
Potash	-	-	1	= 590·0	5·00
Oxides of iron and manganese	-	-	-	-	1·40
				4861·5	97·40

The above analysis by Berthier relates to a specimen of the best English crystal glass, perfectly colourless and free from air-bubbles. This kind of glass may, however, take several different proportions of potash and silica to the oxide of lead.

The composition of mirror-plate, as made on the Continent, is as follows:—

White quartz sand	-	-	-	-	300 pounds
Dry carbonate of soda	-	-	-	-	100
Lime slaked in the air	-	-	-	-	45
Cullet, or old glass	-	-	-	-	300

The manganese should not exceed one half per cent. of the weight of soda.

Optical glass requires to be made with very peculiar care. It is of two different kinds; namely, *crown glass* and *flint glass*. The latter contains a considerable proportion of lead, in order to give it an increased dispersive power upon the rays of light, in proportion to its mean refractive power.

Optical crown glass should be perfectly limpid, and have so little colour, that a pretty thick piece of it may give no appreciable tinge to the rays of light. It should be exempt from striae or veins as well as air-bubbles, and have not the slightest degree of milkiness. It should, moreover, preserve these qualities when worked in considerable quantities. Potash is preferable to soda for making optical crown glass, because the latter alkali is apt to make a glass which devitrifies and becomes opalescent, by long exposure to heat in the annealing process. A simple potash silicate would be free from this defect, but it would be too attractive of moisture, and apt to decompose eventually by the humidity of the atmosphere. It should, therefore, contain a small quantity of lime, and as little potash as suffices for making a perfect glass at a pretty high temperature. It is probably owing to the high heats used in the English crown glass works, and the moderate quantity of alkali (soda) which is employed, that our crown glass has been found to answer so well for optical purposes.

The following recipe for crown glass is excellent. —

5 atoms of silica (27)	-	-	-	-	50
1 carbonate of soda	-	-	-	-	34
5 silica	-	-	-	-	80
1 carbonate of lime	-	-	-	-	30
1 atom of carbonate of baryta	-	-	-	-	98
5 atoms of silica	-	-	-	-	80

Silicates of lime and baryta *per se*, or even combined, are very refractory; but they vitrify well along with a third silicate, such as that of soda or potash.

The following are additional recipes for making different kinds of glass.

1. *Bottle glass*. — 11 pounds of dry glauber salts; 12 pounds of soap salts; a half bushel of waste soap ashes; 56 pounds of sand; 22 pounds of glass skimmings; 1 cwt. of green broken glass; 25 pounds of basalt. This mixture affords a dark green glass.

2. Yellow or white sand, 100 parts; kelp, 30 to 40; lixiviated wood ashes, from 160 to 170 parts; fresh wood ashes, 30 to 40 parts; potter's clay, 50 to 100 parts; cullet or broken glass, 100. If basalt be used, the proportion of kelp may be diminished.

In two bottle-glass houses in the neighbourhood of Valenciennes, an unknown in-

gradient, sold by a Belgian, was employed, which he called *spar*. This was discovered by chemical analysis to be sulphate of baryta. The glass-makers observed that the bottles which contained some of this substance were denser, more homogeneous, more fusible, and worked more kindly, than those formed of the common materials. When one prime equivalent of the silicate of baryta = 123, is mixed with three primes of the silicate of soda = (3×77.6) 232.8, and exposed in a proper furnace, vitrification readily ensues, and the glass may be worked a little under a cherry-red heat, with as much ease as a glass of lead, and has nearly the same lustre.

3. *Green window glass, or broad glass*.—11 pounds of dry glauber salt; 10 pounds of soap salts; half a bushel of lixivated soap waste; 50 pounds of sand; 22 pounds of glass pot skimmings; 1 cwt. of broken green glass.

4. *Crown glass*.—300 parts of fine sand; 200 of good soda ash; 33 of lime; from 50 to 100 of broken glass; 60 of white sand; 30 of purified potash; 15 of saltpetre (1 of borax); $\frac{1}{2}$ of arsenious acid.

5. *Nearly white table glass*.—20 pounds of potashes; 11 pounds of dry glauber salts; 16 of soap salt; 55 of sand; 140 of cullet of the same kind. Another.—100 of sand; 235 of kelp; 60 of wood ashes; $\frac{1}{2}$ of manganese; 100 of broken glass.

6. *White table glass*.—40 pounds of potashes; 11 of chalk; 76 of sand; $\frac{1}{2}$ of manganese; 95 of white cullet.

Another.—50 of purified potashes; 100 of sand; 20 of chalk; and 2 of saltpetre.

Bohemian table or plate glass is made with 63 parts of quartz; 26 of purified potashes; 11 of sifted slaked lime, and some cullet.

7. *Crystal glass*.—60 parts of purified potashes; 120 of sand; 24 of chalk; 2 of saltpetre; 2 of arsenious acid; $\frac{1}{16}$ of manganese.

Another.—70 of purified pearl ashes; 120 of white sand; 10 of saltpetre; $\frac{1}{2}$ of arsenious acid; $\frac{1}{2}$ of manganese.

A third.—67 of sand; 23 of purified pearl ashes; 10 of sifted slaked lime; $\frac{1}{2}$ of manganese; (5 to 8 of red lead).

A fourth.—120 of white sand; 50 of red lead; 40 of purified pearl ashes; 20 of saltpetre; $\frac{1}{2}$ of manganese.

A fifth.—120 of white sand; 40 of pearl ashes purified; 35 of red lead; 13 of saltpetre; $\frac{1}{16}$ of manganese.

A sixth.—30 of the finest sand; 20 of red lead; 8 of pearl ashes purified; 2 of saltpetre; a little arsenious acid and manganese.

A seventh.—100 of sand; 45 of red lead; 35 of purified pearl ashes; $\frac{1}{2}$ of manganese; $\frac{1}{2}$ of arsenious acid.

8. *Plate glass*.—Very white sand, 300 parts; dry purified soda, 100 parts; carbonate of lime, 43 parts; manganese, 1; cullet, 300.

Another.—Finest sand, 720; purified soda, 450; quicklime, 80 parts; saltpetre, 25 parts; cullet, 425.

A little borax has also been prescribed; much of it communicates an exfoliating property to glass.

PRACTICAL DETAILS OF THE MANUFACTURE OF GLASS.

There are five different species of glass, each requiring a peculiar mode of fabrication, and peculiar materials:—1. The coarsest and simplest form of this manufacture is *bottle glass*. 2. Next to it in cheapness of material may be ranked *broad or spread window glass*. An improved article of this kind is now made near Birmingham, under the name of British or German plate. 3. Crown glass comes next, or window glass, formed in large circular plates or discs. This glass is peculiar to Great Britain. 4. Flint glass, crystal glass, or glass of lead. 5. Plate or fine mirror glass.

THE POTS.—The materials of every kind of glass are vitrified in pots made of a pure refractory clay; the best kind of which is a species of shale or slate clay dug out of the coal-formation near Stourbridge. It contains hardly any lime or iron, and consists of silica and alumina in nearly equal proportions. The masses are carefully picked, brushed, and ground under edge iron wheels of considerable weight, and sifted through sieves having 20 meshes in the square inch. This powder is moistened with water (not hot), and kneaded by the feet or a loam-mill into a uniform smooth paste. A large body of this dough should be made up at a time, and laid by in a damp cellar to ripen. Previously to working it into shapes, it should be mixed with about a fourth of its weight of cement of old pots, ground to powder. This mixture is sufficiently plastic, and being less contractile by heat, forms more solid and durable vessels. Glass-house pots have the figure of a truncated cone, with the narrow end undermost; those for bottle and window-glass being open at top, about 30 inches diameter at bottom, 40 inches at the mouth, and 40 inches deep; but the flint glass pots are covered in at top with a dome-cap, having a mouth at the side, by which the

materials are introduced, and the glass is attracted. Bottle and crown-house pots are from 3 to 4 inches thick; those for flat-houses are an inch thinner, and of proportionally smaller capacity. See CLAY.

The well-mixed and kneaded dough is first worked upon a board into a cake for the bottom; over this the sides are raised, by laying on its edges rolls of clay above each other with much manual labour, and careful condensation. The clay is made into lumps, is equalized, and stamped much in the same way as for making pottery. The pots thus fashioned must be dried very prudently, first in the atmospheric temperature, and finally in a stove flue, which usually borrows its heat directly from the glass-house. Before setting the pots in the furnace, they are annealed during 4 or 5 days, at a red heat in a small reverberatory vault, made on purpose. When completely annealed, they are transferred with the utmost expedition into their seat in the fire, by means of powerful tongs supported on the axle of an iron-wheel carriage frame, and terminating in a long lever for raising them and swinging them round. The pot-setting is a desperate service, and when unskilfully conducted without due mechanical aids, is the forlorn hope of the glass-founder.

The glass-houses are usually built in the form of a cone, from 60 to 100 feet high, and from 50 to 80 feet in diameter at the base. The furnace is constructed in the centre of the area, above an arched or grouted gallery which extends across the whole space, and terminates without the walls, in large folding doors. This cavern must be sufficiently high to allow labourers to wheel out the cinders in their barrows. The middle of the vaulted top is left open in the building, and is covered over with the grate-bars of the furnace.

1. *Hot glass.*—The bottle-house and its furnace resemble nearly *fig. 595*. The furnace is usually an oblong square chamber, built of large fire-bricks, and arched over with fire-stone, a siliceous grit of excellent quality extracted from the coal measures of Newcastle. The furnace stands in the middle of the area and has its measures of Newcastle. The furnace stands in the middle of the area and has its base divided into three compartments. The central space is occupied by the grate-bars, and on either side is the platform or fire-brick *seige* (seat), raised about 12 inches above the level of the ribs upon which the pots rest. Each *seige* is about 3 feet broad.

In the sides of the furnace semi-circular holes of about a foot diameter are left, opposite to, and a little above the top of, each pot, called working holes, by which the workmen shovel in the materials, and take out the plastic glass. At each angle of the furnace there is likewise a hole of about the same size, which communicates with the calcining furnace of a cylindrical form, dome-shaped at top. The flame that escapes from the founding or pot-furnace is thus economically brought to reverberate on the raw materials of the bottle glass, so as to dissipate their carbonaceous or volatile impurities, and convert them into a frit. A bottle-house has generally eight other furnaces or fire arches: of which six are used for annealing the bottles after they are blown, and two for annealing the pots, before setting them in the furnace.

Generally, for common bottles, the common river sand and soap-binders' waste are used. About 3 parts of waste, consisting of the insoluble residuum of kelp or red wash lime, and a little saline substance, are employed for 1 part of sand. This waste is first of all calcined in two of the fire arches or reverberatories reserved for that purpose, called the coarse arches, where it is kept at a red heat, with occasional stirring, from 24 to 30 hours, being the period of a journey, or *jourée*, in which the materials could be melted and worked into bottles. The roasted soap-waste is then withdrawn under of the name of ashes, from its arch, coarsely ground, and mixed with its proper proportion of sand. This mixture is now put into the fine arch, and calcined during the working journey, which extends to 10 or 12 hours. Whenever the pots are worked out, that frit is immediately transferred into them in its ignited state, and the founding process proceeds with such despatch that this first charge of materials is completely melted down in 6 hours, so that the pots might admit to be filled up again with the second charge of frit, which is founded in 4 hours more. The heat is briskly continued, and in the course of from 12 to 18 hours, according to the size of the pots, the quality of the fuel, and the draught of the furnace, the vitrification is complete. Before blowing the bottles, however, the glass must be left to settle, and to cool down to the blowing consistency, by shutting the cone doors and feeding holes, so as to exclude the air from the fire-grate and the bottom of the hearth. The glass or metal becomes more dense, and by its subsidence throws up the foreign lighter earthy and saline matters in the form of a scum on the surface, which is removed with skimming irons. The furnace is now charged with coal, to enable it to afford a working heat for 4 or 5 hours, at the end of which time more fuel is cautiously added to preserve adequate heat for finishing the journey.

It is hardly possible to convey in words alone a correct idea of the manipulations necessary to the formation of a wine bottle. Six people are employed at this task;

one, called a gatherer, dips the end of an iron tube, about five feet long, previously made red hot, in the pot of melted *molil*, turns the rod round so as to surround it with a little, lifts it out to cool a little, and then dips and turns it round again; and so in succession till a ball is formed on its end sufficient to make the required bottle. He then hands it to the blower, who rolls the plastic lump of glass on a smooth stone or cast-iron plate, till he brings it to the very end of the tube; he next introduces the pear-shaped ball into an open brass or cast-iron mould, shuts this together by pressing a pedal with his foot, and holding his tube vertically, blows through it, so as to expand the cooling glass into the form of the mould. Whenever he takes his foot from the pedal lever, the mould spontaneously opens out into two halves, and falls asunder by its bottom hinge. He then lifts the bottle up at the end of the rod, and transfers it to the finisher, who, touching the glass-tube at the end of the pipe with a cold iron, cracks off the bottle smoothly at its mouth-ring. The finished bottles are immediately piled up in the hot annealing arch, where they are afterwards allowed to cool slowly for 24 hours at least.

2. *Blow or spread window glass*.—This kind of glass is called *inferior window glass* in this country, because coarse in texture, of a wavy wrinkled surface, and very cheap; but on the continent *spread window glass*, being made with more care, is much better than ours, though still far inferior in transparency and polish to crown glass, which has, therefore, nearly superseded its use among us. Hut Messrs Chance and Co., of Birmingham, make *British sheet glass* upon the best principles, and turn out an article quite equal, if not superior, to anything of the kind made either in France or Belgium. Their materials are those used in the crown-glass manufacture. The vitrifying mixture is fused for 24 or 30 hours in a reverberatory arch, with considerable stirring and paddling with long handled shovels and rakes; and the frit is then transferred by shovels, while red hot, to the melting pots to be founded. When the glass is rightly vitrified, settled, and brought to a working heat, it is lifted out by iron tubes, blown into pears, which, being elongated into cylinders, are cracked up along one side parallel to the axis, by touching them with a cold iron dipped in water, and are then opened out into sheets. The glass cylinders are spread on a bed of smooth stone Paris-plaster, or laid on the bottom of a reverberatory arch; the cylinder being placed on its side horizontally, with the cracked line uppermost, gradually opens out, and flattens on the hearth. At one time, thick plates were thus prepared for subsequent polishing into mirrors; but the glass was never of very good quality; and this mode of making mirror-plate has accordingly been generally abandoned.

The spreading furnace or oven is that in which cylinders are expanded into tables or plates. It ought to be maintained at a brisk red heat, to facilitate the softening of the glass. The oven is placed in immediate connection with the annealing arch, so that the tables may be readily and safely transferred from the former to the latter. Sometimes the cylinders are spread in a large muffle furnace, in order to protect them from being tarnished by sulphureous and carbonaceous fumes.

Fig. 890 represents a ground plan of both the spreading and annealing furnace; fig. 891 is an oblong profile in the direction of the dotted line *x x*, fig. 890.

a is the fire-place; *b b*, the canals or flues through which the flame rises into both furnaces; *c*, the spreading furnace, upon whose sole is the spreading slab; *d*, is the cooling and annealing oven; *e e*, iron bars which extend obliquely across the annealing arch, and serve for resting the glass tables against during the cooling. *f f*, the channel along which the previously cracked cylinders are slid, so as to be gradually warmed; *g*, the opening in the spreading furnace, for enabling the workmen to regulate the process; *h*, a door in the annealing arch, for introducing the tools requisite for raising up and removing the tables.

The series of transformations in sheet glass, already described, is represented in fig. 892, at *a, b, c, d, e, f, g, h*.

Figs. 893 and 894 represent a Bohemian furnace in which excellent white window glass is founded. Fig. 893 is a longitudinal section of the glass and annealing furnace. Fig. 894 is the ground plan. *a* is the ash pit vaulted under the sole of the furnace.

the fire-place itself is divided into three compartments; with a middle slab at *d*, which is hollowed in the centre, for collecting any spilt glass, and two hearth tiles or slabs *b b*. *c c* are the draught or air holes; *e e* are arches upon which the bearing slabs *f f* partly rest. In the middle between these arches, the flame strikes upwards upon the pots *g g*, placed as closely together as possible for economy of room. *A* is the breast wall of the furnace; *a*, *fig* 894, the opening through which the pots are introduced; *u* is tricked up as soon as they are set. *A h* is the base of the cone or dome of the furnace; *l l*, the working apertures, which are made larger or smaller according to the size of the glass articles to be made. *m* is the flue which leads to the annealing stove *n*, with an arched door. Exterior to this there is usually a drying kiln, not shown in the figure; and there are adjoining stoves, called arches, for drying and annealing the new pots before they are set.

The cooling or annealing arch, or leer, is often built independent of the glass-house furnace, is then heated by a separate fire-place, and constructed like a very long reverberatory furnace.

The leer pans, or trays of sheet iron, are laid upon its bottom in an oblong series, and hooked to each other.

3. *Crown-glass*.—The crown-glass house with its furnace is represented in *fig* 895, where the *blowing* operation is shown on the one side of the figure, and the *flashing* on the other. The furnace is usually constructed to receive 4 or 6 pots, of such dimensions as to make about a ton of glass each at a time. There are, however, several subsidiary furnaces to a crown-house: 1, a reverberatory furnace or *culcar*, for calcining or frittng the materials; 2, a blowing furnace, for blowing the pear-shaped balls made at the pot-holes, into large globes, 3, a flashing furnace, and bottoming hole for communicating a softening heat, in expanding the globe into a circular plate; 4, the annealing arch for the finished tables; 5, the reverberatory oven for annealing the pots prior to their being set upon the foundling sieve.

The materials of crown glass used to be, fine sand, by measure 3 parts, or by weight 10; ground kelp, by measure 11 parts, or by weight 16½; but instead of kelp, soda ash is now generally employed. From 6 to 8 cwt. of sand, lime, and soda-ash, mixed together in wooden boxes with a shovel, are thrown on the sole of a large reverberatory. Here the mixture is well worked together with iron paddles, flat shovels, and rakes with long handles; the area of this furnace being about 6 feet square, and the height 2 feet. The heat soon brings the materials to a pasty consistence, when they must be diligently turned over, to favour the dissipation of the carbon, sulphur, and other volatile matters of the kelp or soda ash, and to incorporate the fixed ingredients uniformly with the sand. Towards the end of 3 hours, the fire is considerably raised, and when the fourth hour has expired, the frittng operation is finished. The mass is now shovelled or raked out into shallow cast-iron square cases, smoothed down, and divided before it hardens by cooling, into square lumps, by cross sections with the spade. These frit-bricks are afterwards piled up

895

in a large apartment for use; and have been supposed to improve with age, by the effluence of their saline constituents into carbonate of soda on their surface.

The founding-pots are filled up with these blocks of frit, and the furnace is powerfully urged by opening all the subterranean passages to its grate, and closing all the doors and windows of the glass-house itself. After 8 or 10 hours the vitrification has made such progress, and the blocks first introduced are so far melted down, that another charge of frit can be thrown in, and thus the pot is full with frit all the proper quantity is used. In about 16 hours the vitrification of the frit has taken place, and a considerable quantity, amounting often to the ewt. of liquid saline matter floats over the glass. This salt is carefully skimmed off into iron pots with long ladles. It is called Sandiver, or Glass-gall, and consists usually of muriste of soda with a little sulphate. The pot is now ready for receiving the *typping of cullet*, which is broken pieces of window glass, to the amount of 3 or 4 ewt. This is shovelled in at short intervals; and as its pressure forces up the residuary saline matter, this is removed; for were it allowed to remain, the body of the glass would be materially deteriorated.

The heat is still continued for several hours till the glass is perfect, and the extrusion of gas called the *haul*, which accompanies the fusion of crown glass, has nearly terminated, when the fire is abated, by shutting up the lower vault doors and every avenue to the grate, in order that the glass may settle fine. At the end of about 40 hours altogether, the fire being slightly raised by adding some coals, and opening the doors, the glass is carefully skimmed, and the working of the pots commences.

Before describing it, however, we may state that the marginal figure, 896, shows the base of the crown-house cone, with the four open pots in two ranges on opposite sides of the furnace, sitting on their raised sieges, at each side of the grate. At one side of the base the door of the vault is shown, and its course is marked by the dotted line.

The crown-glass furnace, figs. 827, 828, is an oblong square, built in the centre of a brick cone, large enough to contain within it two or three pots at each side of the

front elevation of a six-pot furnace. 1, 2, 3, *fig.* 897, are the working holes for the purposes of ventilation, of putting in the materials, and of taking out the metal to be wrought. 4, 5, 6, 7, are pipe holes for warming the pipes before beginning to work with them. 8, 9, 10, are soot holes for mending the pots and steges. 11 is a bar of iron for binding the furnace, and keeping it from swelling.

The arch is of an elliptic form; though a barrel arch, that is, an arch shaped like the half of a barrel cut lengthwise through the centre, is sometimes used. But this soon gives way when used in the manufacture of crown glass, although it does very well in the clay-furnace used for bottle houses.

The best stone for building furnaces is fire-stone; it may be obtained in the neighbourhood of Newcastle from the coal-measures generally, and some of the sandstones of the eastern counties are found to answer the purpose admirably. The great danger in building furnaces is, lest the cement at the top should give way with the excessive heat, and by dropping into the pots, spoil the metal. The top should therefore be built with stones only, as loose as they can hold together after the centres are removed, and without any cement whatever. The stones expand and come quite close together when annealing; an operation which takes from eight to fourteen days at most. There is thus less risk of any thing dropping from the roof of the furnace.

The inside of the square of the furnace is built either of Stourbridge fire-clay annealed, or of fire-stone, to the thickness of sixteen inches. The outside is built of common brick, about nine inches in thickness.

The furnace is thrown over an ash-pit, or cove as it is called, which admits the atmospheric air, and promotes the combustion of the furnace. This cove is built of stone until it comes beneath the grate room, when it is formed of fire-brick. The abutments are useful for binding and keeping the furnace together, and are built of masonry. The furnaces are stoutly clasped with iron all round, to keep them tight. In four-pot furnaces this is unnecessary, provided there be four good abutments.

Fig. 899 is an elevation of the flashing furnace. The outside is built of common brick, the inside of fire-brick, and the mouth or nose of Stourbridge fire-clay.

Fig. 900 is the annealing kiln. It is built of common brick, except round the grate room, where fire-brick is used.

Few tools are needed for blowing and flashing crown-glass. The requisite ball of plastic glass is gathered, in successive layers as for bottles, on the end of an iron tube, and rolled into a pear-shape, on a cast-iron plate; the workman taking care that the air blown into its cavity is surrounded with an equal body of glass, and if he perceives any side to be thicker than another, he corrects the inequality by rolling it on the sloping iron table called *marver* (*marbre*). He now bends the bulb in the fire, and rolls it so as to form the glass upon the end of the tube, and by a dexterous swing or two he lengthens it, as shown in *i.*, *fig.* 901. To extend the neck of that pear, he next rolls it over a smooth iron rod, turned round in a horizontal direction, into the shape *K*, *fig.* 901. By further expansion at the blowing furnace, he now brings it to the shape *L*, represented in *fig.* 901.

This spheroid having become cool and somewhat stiff, is next carried to the bottoming bulb (like *fig.* 899), to be exposed to the action of flame. A slight wall erected before one half of this hole, screens the workman from the heat, but leaves room for the globe to pass between it and the posterior wall. The blowing-pipe is made to rest a little way from the neck of the globe, on a hook fixed in the front wall; and this may be made easily to revolve on its axis, and by giving centrifugal force to the globe, while the bottom of it, or part opposite to the pipe, is softened by the heat, it soon assumes the form exhibited in *K*, *fig.* 901.

In this state the flattened globe is removed from the fire, and its rod being rested on the *casher bar* covered with coal cinders, another workman now applies the end of

a solid iron rod tipped with melted glass, called a *pont*, to the nipple or prominence in the middle; and thus attaches it to the centre of the globe, while the first workman cracks off the globe by touching its tubular neck with an iron chisel dipped in cold water. The workman having thereby taken possession of the globe by its bottom or knobbed pole attached to his puntty rod, he now carries it to another circular opening, where he exposes it to the action of moderate flame with regular rotation, and thus slowly heats the thick projecting remains of the former neck, and opens it slightly out, as shown at x, in fig. 201. He next hands it to the *flasher*, who, resting the iron rod in a hook placed near the side of the orifice A, fig. 229, wheels it rapidly round opposite to a powerful flame, till it assumes first the figure o, and finally that of a flat circular table.

The flasher then walks off with the table, keeping up a slight rotation as he moves along, and when it is sufficiently cool, he turns down his rod into a vertical position, and lays the table flat on a dry block of fire-brick, or bed of sand, when an assistant nips it off from the *pont* with a pair of long iron shears, or cracks it off with a touch of cold iron. The loose table or plate is lastly lifted up horizontally on a double pronged iron fork, introduced into the annealing arch, fig. 200, and raised on edge; an assistant with a long-kneed fork preventing it from falling too rapidly backwards. In this arch a great many tables of glass are piled up in iron frames, and slowly cooled from a heat of about 600° to 100° F., which takes about 24 hours; when they are removed. A circular plate or table of about 3 feet diameter weighs on an average 9 pounds.

4. *Flint glass*.—This kind of glass is so called because originally made with calcined flints, as the siliceous ingredient. The materials at present employed in this country for the finest flint glass are, first, sand, calcined, sifted, and washed; second, an oxide of lead, either red lead or litharge; and third, pearl-ash. Sand for flint glass manufacture is obtained from the Isle of Wight, Aylesbury, the New Forest, and some other localities in this country. A very beautiful sand is brought from America, and some has been sent home from Australia. The pearl ash of commerce must however be purified by digesting it in a very little hot water, which dissolves the carbonate of potash, and leaves the foreign salts, chiefly sulphate of potash, muriate of potash, and muriate of soda. The solution of the carbonate being allowed to cool and become clear in lead pans, is then run off into a shallow iron boiler, and evaporated to dryness. Nitre is generally added as a fourth ingredient of the body of the glass; and it serves to correct any imperfections which might arise from accidental combustible particles, or from the lead being not duly oxidised. The above four substances constitute the main articles; to which we may add arsenic and manganese, introduced in very small quantities, to purify the colour and clear up the transparency of the glass. The black oxide of manganese, when used in such quantity only as to peroxidise the iron of the sand, simply removes the green tinge caused by the protoxide of iron; but if more manganese be added than accomplishes that purpose, it will give a purple tinge to the glass. The arsenic is supposed to counteract the injury arising from excess of manganese, but is itself very apt on the other

hand to communicate some degree of opalescence, or at least to impair the lustre of the glass.

The raw materials of flint glass, are always mixed with about a third or a fourth of their weight of broken glass of like quality; this mixture is thrown into the pot with a shovel; and more is added when ever the preceding portions by melting subsides; the object being to obtain a pot full of glass, to facilitate the skimming off the impurities and sand-iver. The mouth of the pot is now shut, by applying clay-lute round the stopper, with the exception of a small orifice below, for the escape of the liquid saline matter. Flint glass requires about 48 hours for its complete vitrification, though the materials are more fluid than

than of crown glass; in consequence of the contents of the pot being partially screened by its cover from the action of the fire, as also from the lower intensity of the heat.

Fig. 902 represents a flint glass house for 6 pots, with the arch or leer on one side for annealing the crystal ware. In fig. 903, the base of the cone is seen, and the glass pots are *situ* on their platform ranged round the central fire grate. The dotted line denotes the contour of the furnace, fig. 902.

Whenever the glass appears fine, and is freed from its air bubbles, which it usually is in about 36 hours, the heat is suffered to fall a little by closing the bottom valves, &c., that the pot may settle; but prior to working the metal, the heat is somewhat raised again.

It would be useless to describe the manual operations of fashioning the various articles of the flint-glass manufacture, because they are indefinitely varied to suit the conveniences and caprices of human society.

Every different flint-house has a peculiar proportion of glass materials. The following have been offered as good practical mixtures:—

1. Fine white sand	-	-	-	-	-	-	300 parts.
Red lead or litharge	-	-	-	-	-	-	200
Refined pearl ashes	-	-	-	-	-	-	80
Nitre	-	-	-	-	-	-	20
Arsenic and manganese, a minute quantity.							
2. Fine sand	-	-	-	-	-	-	50.5
Litharge	-	-	-	-	-	-	27.2
Refined pearl ashes (carbonate of potash, with 5 per cent. of water)	-	-	-	-	-	-	17.5
Nitre	-	-	-	-	-	-	4.8

1000

To these quantities from 30 to 50 parts of broken glass or cullet are added, with about a two-thousandth part of manganese, and a three-thousandth part of arsenic. Hot manganese varies so extremely in its purity, and contains often so much oxide of iron, that nothing can be predicated as to its quantity previously to trial.

M. Payen, an eminent manufacturing chemist in France, says that the composition of "crystal" (the name given in France to their finest flint glass) does not deviate much from the following proportions:—

	Wood fire.	Coal fire.
Siliceous sand	-	3
Minium	-	2½
Carbonate of potash	-	1½

The flint-glass leer for annealing glass, is an arched gallery or large flue, about 36 feet long, 3 feet high, 4 wide; having its floor raised above 2 feet above the ground of the glass-house. The hot air and smoke of a fire-place at one end pass along this gallery, and are discharged by a chimney 8 or 10 feet short of the other end. On the floor of the vault, large iron trays are laid and hooked to each other in a series, which are drawn from the fire end towards the other by a chain, wound about a cylinder by a winch handle projecting through the side. The flint-glass articles are placed in their hot state into the tray next the fire, which is moved onwards to a cooler station whenever it is filled, and an empty tray is set in its place. Thus, in the course of about 20 hours, the glass advances to the cool end thoroughly annealed.

Besides colourless transparent glass, which forms the most important part of this manufacture, various coloured glasses are made to suit the taste of the public. The opaline crystal may be prepared by adding to the above composition (No. 2) phosphate of lime, or well burnt bone-ash in fine powder, washed, and dried. The article must be as uniform in thickness as possible, and speedily worked into shape, with a moderate heat. Oxide of tin, *putty-powder*, was formerly used for making opalescent glass, but the lustre of the body was always impaired by its means.

Crystal vessels are made of which the inner surface is colourless, and all the external facets coloured. Such works are easily executed. The end of the blowing-rod must be dipped first in the pot containing colourless glass, to form a bulb of a certain size, which being cooled a little is then dipped for an instant into the pot of coloured glass. The two layers are associated without intermixture; and when the article is finished in its form, it is white within and coloured without. Fluted lines somewhat deeply cut, pass through the coloured coat, and enter the colourless one; so that when they cross, their ends alone are coloured.

For some time past, likewise, various crystal articles have been exhibited in the

market with coloured enamel figures on their surface, or with white incrustations of a silvery lustre in their interior. The former are prepared by placing the enamel object in the brass mould, at the place where it is sought to be attached. The bulb of glass being put into the mould, and blown while very hot, the small plate of enamel gets cemented to the surface. For making the white argentine incrustations, small figures are prepared with an impalpable powder of dry porcelain paste, cemented into a solid by means of a little gypsum plaster. When these pieces are thoroughly dried, they are laid on the glass while it is red hot, and a large patch of very liquid glass is placed above it, so as to encase it and form one body with the whole. In this way the incrustation is completely enclosed; and the polished surface of the crystal which scarcely touches it, gives a brilliant aspect, pleasing to the eye.

OPTICAL GLASS.—An uniform flint-glass, free from striae, or *wreath*, is much in demand for the optician. It would appear that such an article was much more commonly made by the English manufacturers many years ago, than at present; and that in improving the brilliancy of crystal glass they have injured its fitness for constructing optical lenses, which depends, not so much on its whiteness and lustre, as on its homogeneous character. Even a potful of pretty uniform glass, when it stands some time liquid, becomes eventually unequal by the subsidence of the denser portions; so that striae and gelatinous appearances begin to manifest themselves, and the glass becomes of little value. Glass allowed to cool slowly to mass in the pot is particularly full of *wreath*, and if quickly refrigerated, that is in two or three hours, it is apt to split into a multitude of minute splinters, of which no use can be made. For optical purposes, the glass must be taken out in its liquid state, being gathered on the end of the iron rod from the central portion of a recently skimmed pot, after the upper layers have been worked off in general articles.

M. Guinand, of Brenets near Neuchâtel, a workman in the watch and clock trade, appears to have discovered processes that furnished almost certainly pieces of flint glass capable of forming good lenses of remarkable dimensions, even of 11 inches diameter, of adequate density and transparency, and nearly free from striae. Guinand's plan consisted mainly in thoroughly mixing the melted "metal" with an iron rod, Guinand joined M. Fraunhofer, of Munich, and one of the largest of the lenses produced by them, the diameter of which is 9 inches, is now in the observatory at Dorpat.

Guinand was long in communication with the Astronomical Society of London; and he sent over some discs of flint-glass, of which Messrs. Dollond and Herschel made a favourable report. A commission was formed, consisting of Herschel, Dollond, Faraday, and Roget, but owing to the annoying interferences of the excise officers, notwithstanding the Government had made some special exceptions in favour of these scientific experiments, the results were not practically of that high value which might have been expected. Many of the observations however were of great value. Amongst other discoveries might be named the remarkable heavy glass, the *Silico-borate of lead*, with which the discovery of the "so-called" magnetisation of a ray of light was made. M. Guinand died, and one of his sons worked with M. Montempy, while the widow and another son set up works in Switzerland. From their manufactory some examples of lenses were sent to the Great Exhibition of 1851. M. Montempy was in 1848 prevailed upon to accept the invitation of Messrs. Chance Brothers and Co. to unite with them in attempts they were then making to improve the quality of glass. They succeeded in producing discs of extraordinary dimensions in flint of 29 inches diameter, weighting two cwt., and of crown glass up to 20 inches. Messrs. Chance, at the recommendation of the jury, were induced to submit their disc of flint-glass to the operation of grinding, finishing, and other processes necessary in order to ascertain the uniformity of its density throughout, and its superior quality was fully established.

M. Maës of Clichy, near Paris, proposes to manufacture optical glass, with the addition of barytes, magnesia, and oxide of zinc, in combination with boracic acid. The glass manufactured by M. Maës is exceedingly beautiful, but the boracic acid renders it very expensive. M. Cauchoix, the eminent French optician, says, that out of ten object glasses, 4 inches in diameter, made with M. Guinand's flint-glass, eight or nine turned out very good, while out of an equal number of object glasses made of the flint-glass of the English and French manufactories, only one, or two at most, were found serviceable.

An achromatic object glass for telescopes and microscopes consists of at least two lenses; the one made with glass of lead, or flint glass, and the other with crown glass; the former possessing a power of dispersing the coloured rays relatively to its mean refractive power much greater than the latter; upon which principle, the achromatism of the image is produced, by re-uniting the different coloured rays into one focus. Three plans have been prescribed for obtaining homogeneous pieces of optical glass. 1, to lift a mass of it in large ladles, and let it cool in them; 2, to pour it out from the pots into moulds; 3, to allow it to cool in the pots, and afterwards to cut it off in

horizontal strata. The last method seldom affords pieces of uniform density, unless peculiar precautions have been adopted to settle the flint glass in uniform strata; because its materials are of such unequal density, the oxide of lead having a specific gravity of 8, and silica of 2.5, that they are apt to stand at irregular heights in the pots.

One main cause of these inequalities lies in the construction of the furnace, whereby the bottom of the pot is usually much less heated than the upper part. In a plate glass furnace the temperature of the top of the pot has been found to be 180° Wedgew., while that of the bottom was only 110°, constituting a difference of no less than 2610° F. The necessary consequence is that the denser particles which subside to the bottom during the fusion of the materials, and after the first extrication of the gases, must remain there, not being duly agitated by the expansive force of caloric, acting from below upwards.

The following suggestions, deduced from a consideration of principle, may probably lead to some improvements, if judiciously applied. The great object is to counteract the tendency of the glass of lead to distribute itself into strata of different densities; which may be effected either by mechanical agitation or by applying the greatest heat to the bottom of the pot. But however homogeneous the glass may be thereby made, its subsequent separation into strata of different densities must be prevented by rapid cooling and solidification. As the deeper the pots, the greater is the chance of unequal specific gravity in their contents, it would be advisable to make them wider and shallower than those in use for making ordinary glass. The intermixture may be effected either by lifting the glass out of one pot into another in the furnace, and back again, with copper ladles, or by stirring it up with a rouser, then allowing it to settle for a short time, till it becomes clear and free from air bubbles. The pot may now be removed from the furnace, in order to solidify its contents in their homogeneous state; after which the glass may be broken in pieces, and be perfected by subjecting it to a second fusion; or what is easier and quicker, we may form suitable discs of glass without breaking down the potful, by lifting it out in flat copper ladles with iron shanks, and transferring the lumps after a little while into the annealing lehr. — *Ure*.

To render a potful of glass homogeneous by agitation, is a most difficult task, as an iron rod would discolour it, and a copper rod would be apt to melt. An iron rod sheathed in laminated platinum would answer well, but for its expense. A stoneware tube supported within by a rod of iron, might also be employed for the purpose in careful hands; the stirring being repeated several times, till at last the glass is suffered to stiffen a little by decrease of temperature. It must be then allowed to settle and cool, after which the pot, being of small dimensions, may be drawn out of the fire.

2. The second method of producing the desired uniformity of mixture, consists in applying a greater heat to the bottom than to the upper part of the melting pot. *Fig. 901* represents in section a furnace contrived to effect this object. It is cylindrical, and of a diameter no greater than to allow the flames to play round the pot, containing from three to four cwt. of vitreous materials. *A* is the pot, resting upon the arched grid *b a*, built of fire-bricks, whose apertures are wide enough to let the flames rise freely, and strike the bottom and sides of the vessel. From *1½* to 2 feet under that arch, the fuel grate *c d* is placed. *a c* are the two working openings for introducing the materials and inspecting the progress of the fusion; they must be closed with fire-tiles and luted with fire-clay at the beginning of the process. At the back of the furnace, opposite the mouth of the fire-place, there is a door-way, which is bricked up, except upon occasion of putting in and taking out the pot. The draught is regulated by means of a slide-plate, upon the mouth of the ash-pit *f*. The pot being heated to the proper pitch, some purified pearl ash, mixed with fully twice its weight of colourless quartz sand, is to be thrown into it, and after the complete fusion of this mixture, the remaining part of the sand, along with the oxide of lead (fine litharge), is to be strewn upon the surface. These siccious particles in their descent serve to extricate the air from the mass. Whenever the whole is fused, the heat must be strongly urged to insure a complete uniformity of combination by the internal motion of the particles. As soon as the glass has been found by making test phials to be perfectly fine, the fire must be withdrawn, the two working holes must be opened, as well as the mouths of

the fire-place and ash pit to admit free ingress to cooling currents of air, so as to congeal the liquid mass as quickly as possible; a condition essential to the uniformity of the glass. It may be worth while to stir it a little with the pottery rod at the commencement of the cooling process. The solidified glass may be afterwards detached by a hammer in conchoidal discs, which after chipping off their edges, are to be placed in proper porcelain or stone-ware dishes, and exposed to a softening heat, in order to give them a lenticular shape. Great care must be taken that the heat thus applied by the muffle furnace be very equable, for otherwise wreathes might be very readily reproduced in the discs. A small oven upon the plan of a baker's, is best fitted for this purpose, which being heated to dull redness, and then extinguished, is ready to soften and afterwards anneal the conchoidal pieces.

Gilman's dense optical flint glass, of specific gravity 3.616, consists, by analysis, of oxide of lead, 43.05; silica, 44.3; and potash, 11.75; but requires for its formation the following ingredients:—100 pounds of ground quartz; 100 pounds of fine red lead; 35 pounds of purified potash; and from 2 to 4 pounds of saltpetre. As this species of glass is injured by an excess of potash, it should be compounded with rather a defect of it, and melted by a proportionally higher or longer heat. A good optical glass has been made in Germany with 7 parts of pure red lead, 3 parts of finely ground quartz, and 2 parts of calcined borax.

5. *Plate glass*.—This, like English crown-glass, has a soda flux, whereas flint-glass requires potash, and is never of good quality when made with soda. We shall distribute our account of this manufacture under two heads.

1. The different furnaces and principal machines, without whose knowledge it would be impossible to understand the several processes of a plate-glass factory.

2. The materials which enter into the composition of this kind of glass, and the series of operations which they undergo; devoting our chief attention to the changes and improvements which long experience, enlightened by modern chemistry, has introduced into the great manufactory of Saint-Gobain in France, under the direction of M. Tassart. It may however be remarked that the English plate-glass manufacture derives peculiar advantages from the excellence of its grinding and polishing machinery.

The following description given by Dr. Ure refers almost entirely to the manufacture of plate glass in France. It is retained in nearly its original form, and is, in nearly all respects, equally applicable to the manufacture of the best plate glass in this country.

The clay for making the bricks and pots should be free from lime and iron, and very refractory. It is mixed with the powder of old pots passed through a silk sieve. If the clay be very plastic it will bear its own weight of the powder, but if shorter in quality, it will take only three-fifths. But before mingling it with the cement of old pots, it must be dried, bruised, then picked, ground, and finally elutriated by agitation with water, decantation through a hair sieve, and subsidence. The clay fluid after passing the sieve is called *slip* (*caulie*).

The furnace is built of dry bricks, cemented with slip, and has at each of its four angles a peculiar annealing arch, which communicates with the furnace interiorly, and thence derives sufficient heat to effect in part, if not wholly, the annealing of the pots, which are always deposited there a long time before they are used. Three of these arches, exclusively appropriated to this purpose, are called *pot-arches*. The fourth is called the *arch of the materials*, because it serves for drying them before they are founded. Each arch has, moreover, a principal opening called the throat, another called *bonnard*, by the French workmen, through which fire may be kindled in the arch itself, when it was thought to be necessary for the annealing of the pots; a practice now abandoned. The duration of a furnace is commonly a year, or at most 14 months; that of the arches is 30 years or upwards, as they are not exposed to so strong a heat.

In the manufacture of plate-glass two sorts of crucibles are employed, called the pots and the basins (*cuvettes*). The first serve for containing the materials to be founded, and for keeping them a long time in the melted state. The *cuvettes* receive the melted glass after it is refined, and decant it out on the table to be rolled into a plate. Three pots hold liquid glass for six small basins, or for three large ones, the latter being employed for making mirrors of great dimensions, that is, 100 inches long and upwards. Furnaces have been lately constructed with 6 pots, and 12 *cuvettes*, 8 of which are small, and 4 large; and *cuvettes* of three sizes are made, called *small*, *middling*, and *large*. The small are perfect cubes, the middling and the large ones are oblong parallelepipeds. Towards the middle of their height, a notch or groove, two or three inches broad, and an inch deep, is left, called the girdle of the *cuvette*, by which part they are grasped with the tongs, or rather are clamped in the iron frame. This frame goes round the four sides of the small *cuvettes*, and may be placed indifferently upon

all their sides; in the other cuvettes, the girille extends only over the two large sides, because they cannot be turned up. See *fig. 803*, p. 360.

The pot is an inverted truncated cone, like a crown glass pot. It is about 30 inches high, and from 30 to 32 inches wide, including its thickness. There is only a few inches of difference between the diameter of the top and that of the bottom. The bottom is three inches thick, and the body tapers gradually thinner till it is an inch at the mouth of the pot.

The large building or factory, of which the melting furnace occupies the middle space, is called the *halle* in French. At Ravenhead in Lancashire it is called the foundry, and is of magnificent dimensions, its length is 829 feet, and its breadth 195. The famous *halle* of St. Gobain is 174 feet by 120. Along the two side walls of the *halle*, which are solidly constructed of hewn stone, there are openings like those of common ovens. These ovens, destined for the annealing of the newly cast plates, bear the name of *carquasse*. Their soles are raised two feet and a half above the level of the ground, in order to bring them into the same horizontal plane with the casting tables. Their length, amounting sometimes to 30 feet, and their breadth to 20, are required in order to accommodate 6, 8, or even 10 plates of glass alongside of each other. The front aperture is called the throat, and the back door the little throat (*garulotte*). The carquasse is heated by means of a fire-place of a square form called a *tasar*, which extends along its side.

The founding or melting furnace is a square brick building laid on solid foundations, being from 8 to 10 feet in each of its fronts, and rising inside into a vault or crown about 10 feet high. At each angle of this square, a small oven or arch is constructed, likewise vaulted within, and communicating with the melting furnace by square flues, called *fontettes*, through which it receives a powerful heat, though much inferior to that round the pots. The arches are so distributed as that two of the exterior sides of the furnace stand wholly free, while the two other sides, on which the arches encroach, offer a free space of only 3 feet. In this interjacent space, two principal openings of the furnace, of equal size in each side, are left in the building. These are called tunnels. They are destined for the introduction of the pots and the fuel.

On looking through the tunnels into the inside of the furnace, we perceive to the right hand and the left, along the two free sides, two low platforms or sieges, at least 30 inches in height and breadth. See *figs. 896, 898*.

These sieges (*seats*) being intended to support the pots and the cuvettes filled with heavy materials, are terminated by a slope, which ensures the solidity of the fire-clay mound. The slopes of the two sieges extend towards the middle of the furnace so near as to leave a space of only from 6 to 10 inches between them for the hearth. The end of this is perforated with a hole sufficiently large to give passage to the liquid glass of a broken pot, while the rest is preserved by lading it from the mouth into the adjoining cuvette.

In the two large parallel sides of the furnace, other apertures are left, much smaller than the tunnels, which are called *overrears* (peep holes). The lower ones, or the *overrears en bas*, called *cuvette* openings, because, being allotted to the admission of these vessels, they are exactly on a level with the surface of the sieges, and with the floor of the *halle*. Plates of cast iron form the thresholds of these openings, and facilitate the ingress and egress of the cuvettes. The apertures are arched at top, with hewn stones like the tunnels, and are 18 inches wide when the cuvettes are 16 inches broad.

The upper and smaller apertures, or the higher *overrears*, called the *lading* holes, because they serve for transvassing the liquid glass, are three in number, and are placed 31 or 32 inches above the surface of the sieges. As the pots are only 30 inches high, it becomes easy to work through these openings either in the pots or the cuvettes. The pots stand opposite to the two pillars which separate the openings, so that a space is left between them for one or more cuvettes according to the size of the latter. It is obvious that if the tunnels and *overrears* were left open, the furnace would not draw or take the requisite founding heat. Hence the openings are shut by means of fire tiles. These are put in their places, and removed by means of two holes left in them in correspondence with the two prongs of a large iron fork supported by an axle and two iron wheels, and terminated by two handles which the workmen lay hold of when they wish to move the tile.

The closing of the tunnel is more complex. When it is shut or ready for the firing, the aperture appears built up with bricks and mortar from the top of the arch to the middle of the tunnel. The remainder of the door-way is closed, — 1. on the two sides down to the bottom, by a small upright wall, likewise of bricks, and 3 inches broad, called walls of the *glaze*; 2. by an assemblage of pieces called pieces of the *glaze*, because the whole of the closure of the tunnel bears the name of *glaze*. The upper hole, 4 inches square, is called the *tasar*, through which bullets of wood are tossed into the

fire. Fuel is also introduced into the posterior openings. The fire is always kept up on the hearth of the tunnel, which is on this account, 4 inches higher than the furnace-hearth, in order that the glass which may accidentally fall down it, and which does not flow off by the bottom hole, may not impede the combustion. Should a body of glass, however, at any time obstruct the grate, it must be removed with rakes by opening the tunnel and dismounting the fire-tile stoppers of the *plage*.

Formerly wood fuel alone was employed for heating the melting-furnaces of the mirror-plate manufactory of Saint-Gobain; but within these few years, the director of the works makes use with nearly equal advantage of pit-coal. In the same establishment, two melting-furnaces may be seen, one of which is fired with wood, and the other with coals, without any difference being perceptible in the quality of the glass furnished by either. It is not true, as has been stated, that the introduction of pit-coal has made it necessary to work with covered pots in order to avoid the decomposition of the materials, or that more alkali was required to compensate for the diminished heat in the covered pots. They are not now covered when pit-coal is used, and the same success is obtained as heretofore by leaving the materials two or three hours longer in the pots and the cavettes. The construction of the furnaces in which coal is burned is the same as that with wood, with slight modifications. Instead of the close-topped hearth of the wood furnace, there is an iron grate in the coal-hearth through which the air enters, and the waste ashes descend.

When billets of wood were used as fuel, they were well dried beforehand, by being placed a few days on a frame work of wood called the wheel, placed two feet above the furnace and its arches, and supported on four pillars at some distance from the angles of the building.

The progress of chemistry, the discovery of a good process for the manufacture of soda from sea salt, which furnishes a pure alkali of uniform power, and the certain methods of ascertaining its purity, have rendered this department of glass-making far more certain than formerly. At Saint-Gobain no alkali is employed except artificial crystals of soda, prepared at the manufactory of Chauny, subsidiary to that establishment. The first crop of soda crystals is reserved for the plate-glass manufacture, the other crystals and the mother-water salts are sold to the makers of inferior glass.

If glass contains much lead it has a yellow tint. If manganese is present it changes by the action of light to a pale rose. Iron imparts a dull greenish tint; therefore the proportions of all these materials should be adjusted with great care.

At the mirror-plate works of Ravenhead, near St. Helen's in Lancashire, soda crystals, from the decomposition of the sulphate of soda by chalk and coal, have been also tried, but without equal success as at Saint-Gobain; the failure being unquestionably due to the impurity of the alkali. Hence, in the English establishment, the soda is obtained by treating sea-salt with pearl-ash, whence carbonate of soda and muriate of potash result. The latter salt is crystallised out of the mingled solution, by evaporation at a moderate heat, for the carbonate of soda does not readily crystallise till the temperature of the solution fall below 60° Fahr. When the muriate of potash is thus removed, the alkaline carbonate is evaporated to dryness.

Long experience at Saint-Gobain has proved that one part of dry carbonate of soda is adequate to vitrify perfectly three parts of fine siliceous sand, as that of the mound of Ammont near Scalis, of Alum Bay in the Isle of Wight, or of Lynn in Norfolk. It is also known that the degree of heat has a great influence upon the vitrification, and that increase of temperature will compensate for a certain deficiency of alkali; for it is certain that a very strong fire always dissipates a good deal of the soda, and yet the glass is not less beautiful. The most perfect mirror-plate has constantly afforded to M. Vanquelin, in analysis, a portion of soda inferior to what had been employed in its formation. Hence, it has become the practice to add, for every 100 parts of cullet or broken plate that is mixed with the glass composition, one part of alkali, to make up for the loss that the old glass must have experienced.

To the above mentioned proportions of sand and alkali, independently of the cullet which may be used, dry slaked lime carefully sifted is to be added to the amount of one seventh of the sand; or the proportion will be, sand, 7 cwt.; quicklime, 1 cwt.; dry carbonate of soda, 2 cwt. and 37 lbs.; besides cullet. The lime improves the quality of the glass; rendering it less brittle and less liable to change. The preceding quantities of materials, suitably blended, have been uniformly found to afford most advantageous results. The practice formerly was to dry that mixture, as soon as it was made, in the arch for the materials, but it has been ascertained that this step may be dispensed with, and the small portion of humidity present is dissipated almost instantly after they are thrown into the furnace. The coat of glaze previously applied to the inside of the pot, prevents the moisture from doing them any harm. For this reason, when the demand for glass at Saint-Gobain is very great, the materials are neither

fritted nor even dried, but shovelled directly into the pot; this is called *foundling raw*. Six workmen are employed in shovelling in the materials either fritted or otherwise, for the sake of expedition, and to prevent the furnace getting cooled. One-third of the mixture is introduced at first; whenever this is melted, the second third is thrown in, and then the last. These three stages are called the first, second, and third fusion or *foundling*.

According to the ancient practice, the foundling and refining were both executed in the pots, and it was not till the glass was refined, that it was laded into the *cuvettes*, where it remained only 3 hours, the time necessary for the disengagement of the air bubbles introduced by the transvason, and for giving the metal the proper consistence for casting. At present, the period requisite for foundling and refining is equally divided between the pots and the *cuvettes*. The materials are left 16 hours in the pots, and as many in the *cuvettes*; so that in 32 hours, the glass is ready to be cast. During the last two or three hours, the fireman or *tiseur* comes to add fuel; all the openings are shut, and the glass is allowed to assume the requisite fluidity; an operation called *stopping the glass*, or *performing the ceremony*.

The transfer of the glass into the *cuvettes*, is called *lading* (*tréjetage*). Before this is done, the *cuvettes* are cleared out, that is, the glass remaining on their bottom is removed, and the ashes of the firing. They are lifted red hot out of the furnace by the method presently to be described, and placed on an iron plate, near a tub filled with water. The workmen, by means of iron paddles 6 feet long, flattened at one end and hammered to an edge, scoop out the fluid glass expeditiously, and throw it into water; the *cuvettes* are now returned to the furnace, and a few minutes afterwards the lading begins.

In this operation, ladles of wrought iron are employed, furnished with long handles, which are plunged into the pots through the upper openings or lading holes, and immediately transfer their charge of glass into the buckets. Each workman dips his ladle only three times, and empties its contents into the *cuvette*. By these three immersions (whence the term *tréjeter* is derived), the large iron spoon is heated so much that when plunged into a tub full of water, it makes a noise like the roaring of a lion, which may be heard to a very great distance.

The foundling, refining, and *ceremony* being finished, they next try whether the glass be ready for casting. With this view, the end of a rod is dipped into the bucket, which is called *drawing the glass*; the portion taken up, being allowed to run off, naturally assumes a pear-shape, from the appearance of which they can judge if the consistence be proper, and if any air bubbles remain. If all be right, the *cuvettes* are taken out of the furnace, and conveyed to the part of the *halle* where their contents are to be poured out. This process requires peculiar instruments and manipulations.

Casting. — While the glass is refining, that is, coming to its highest point of perfection, preparation is made for the most important process, the casting of the plate, whose success crowns all the preliminary labours and cares. The oven or *carquasse* destined to receive and anneal the plate, is now heated by its small fire or *tiseur* to such a pitch that its sole may have the same temperature as that of the plates, being nearly red-hot at the moment of their being introduced. An unequal degree of heat in the *carquasse* would cause breakage of the glass. The casting table is then rolled towards the front door or throat, by means of levers, and its surface is brought exactly to the level of the sole of the oven.

The table *r. fig. 903*, is a mass of bronze, or now preferably cast-iron, about 10 feet long, 3 feet broad, and from 6 to 7 inches thick, supported by a frame of carpentry, which rests on three cast-iron wheels. At the end of the table opposite to that next to the front of the oven, is a very strong frame of timber-work, called the puppet or standard, upon which the bronze roller which spreads the glass is laid, before and after the casting. This is 5 feet long by 1 foot in diameter; it is thick in the metal but hollow in the axis. The same roller can serve only for two plates at one casting, when another is put in its place, and the first is laid aside to cool; for otherwise the hot roller would, at a third casting, make the plate expand unequally, and cause it to crack. When the rollers are not in action, they are laid aside in strong wooden trestles, like those employed by sawyers. On the two sides of the table in the line of its length, are two parallel bars of bronze, *l. l.* destined to support the roller during its passage from end to end; the thickness of these bars determines that of the plate. The table being thus arranged, a crane is had recourse to for lifting the curvette, and keeping it suspended, till it be emptied upon the table. This raising and suspension are effected by means of an iron gib, furnished with pullers, held horizontally, and which turns with them.

The tongs, *r. fig. 905*, are made of four iron bars, bent into a square frame in their middle, for embracing the bucket. Four chains proceeding from the corners of the

frame *v*, are united at their other ends into a ring which fits into the hook of the crane. Things being thus arranged, all the workmen of the foundry co-operate in the manipu-

lations of the casting. Two of them fetch, and place quickly in front of one of the lower openings, the small *cuvette*-carriage, which bears a forked bar of iron, having two prongs corresponding to the two holes left in the fire-tile door. This fork, mounted on the axle of two cast-iron wheels, extends at its other end into two branches terminated by handles, by which the workmen move the fork, lift out the tile stopper, and set it down against the outer wall of the furnace.

The instant these men retire, two others push forward into the opening the extremity of the *tongs*-carriage, so as to seize the bucket by the girdle or rather to clamp it. At the same time, a third workman is busy with an iron plate or long chisel, detaching the bucket from its seat, to which it often adheres by some spilt glass; whenever it is free, he withdraws it from the furnace. Two powerful branches of iron united by a bolt, like two scissor blades, which open, come together, and join by a quadrant near the other end, form the *tongs*-carriage, which is mounted upon two wheels like a truck.

The same description will apply almost wholly to the iron-plate carriage, on which the bucket is laid the moment it is taken out of the furnace; the only difference in its construction is, that on the bent iron bars which form the tail or lower steps of this carriage (in place of the *tongs*) is permanently fastened an iron plate, on which the bucket is placed and carried for the casting.

Whenever the *cuvette* is set upon its carriage, it must be rapidly wheeled to its station near the crane. The *tongs* *t* above described are now applied to the girdle, and are then hooked upon the crane by the suspension chains. In this position the bucket is skimmed by means of a copper tool called a *sabre*, because it has nearly the shape of that weapon. Every portion of the matter removed by the *sabre* is thrown into a copper ladle (*poche de gamin*), which is emptied from time to time into a cistern of water. After being skimmed, the bucket is lifted up, and brushed very clean on its sides and bottom; then by the double handles of the suspension-tongs it is swung round to the table, where it is seized by the workmen appointed to turn it over; the roller having been previously laid on its ruler bars, near the end of the table which is in contact with the annealing oven. The *cuvette*-men begin to pour out towards the right extremity *n* of the roller, and terminate when it has arrived at the left extremity *n*. While preparing to do so, and at the instant of casting, two men place within the ruler-bar on each side, that is, between the bar and the liquid glass, two iron instruments called *hands*, *m m*, *m m*, which prevent the glass from spreading beyond the rulers, whilst another draws along the table the wiping bar *c c*, wrapped in linen, to remove dust, or any small objects which may interpose between the table and the liquid glass.

Whenever the melted glass is poured out, two men spread it over the table, guiding the roller slowly and steadily along, beyond the limits of the glass, and then run it smartly into the wooden standard prepared for its reception, in place of the trestles *v v*.

The empty bucket, while still red-hot, is hung again upon the crane, set on its plate-iron carriage, freed from its *tongs*, and replaced in the furnace, to be speedily cleared out anew, and charged with fresh fluid from the pots. If, while the roller glides along, the two workmen who stand by with picking tools perceive *tears* in the matter in advance of the roller, and can dextrously snatch them out, they are suitably rewarded, according to the spot where the blemish lay, whether in the centre, where it would have proved most detrimental, or near the edge. These tears proceed usually from

small portions of semi-vitrified matter which fall from the vault of the furnace, and from their density occupy the bottom of the *curette*.

While the plate is still red-hot and ductile, about 2 inches of its end opposite to the *carquaise* door is turned up with a tool; this portion is called the *head of the mirror*; against the outside of this head, the shovel, in the shape of a rake without teeth, is applied, with which the plate is eventually pushed into the oven, while two other workmen press upon the upper part of the head with a wooden pole, eight feet long, to preserve the plate to its horizontal position, and prevent its being warped. The plate is now left for a few moments near the throat of the *carquaise*, to give it solidity; after which it is pushed further in by means of a very long iron tool, whose extremity is forked like the letter *y*, and hence bears that name; and is thereby arranged in the most suitable spot for allowing other plates to be introduced.

However numerous the manipulations executed from the moment of withdrawing the *curette* from the furnace, till the cast-plate is pushed into the annealing oven, they are all performed in less than five minutes.

When all the plates of the same casting have been placed in the *carquaise*, it is sealed up; that is to say, all its orifices are closed with sheets of iron, surrounded and made tight with plastic loam. With this precaution, the cooling goes on slowly and equably in every part, for no cooling current can have access to the interior of the oven.

After they are perfectly cooled, the plates are carefully withdrawn one after another, keeping them all the while in a horizontal position, till they are entirely out of the *carquaise*. As soon as each plate is taken out, one set of workmen lower quickly and steadily the edge which they hold, while another set raise the opposite edge, till the glass be placed upright on two cushions stuffed with straw, and covered with canvas. In this vertical position they pass through, beneath the lower edge of the plate, three girths or straps, each four feet long, thickened with leather in their middle, and ending in wooden handles; so that one embraces the middle of the plate, and the other two the ends. The workmen, six in number, now seize the handles of the straps, lift up the glass closely to their bodies, and convey it with a regular step to the warehouse. Here the head of the plate is first cut off with a diamond square, and then the whole is attentively examined, in reference to its defects and imperfections, to determine the sections which must be made of it, and the eventual size of the pieces. The parings and small cuttings detached are set aside, in order to be ground and mixed with the raw materials of another glass-pot.

The apartment in which the roughing-down and smoothing of the plates is performed, is furnished with a considerable number of stone tables, truly hewn and placed apart like billiard tables, in a horizontal position, about 2 feet above the ground. They are rectangular, and of different sizes proportional to the dimensions of the plates, which they ought always to exceed a little. These tables are supported either on stone pillars or wooden frames, and are surrounded with a wooden board whose upper edge stands somewhat below their level, and leaves in the space between it and the stone all round an interval of 3 or 4 inches, of which we shall presently see the use.

A cast plate, unless formed on a table quite new, has always one of its faces, the one next the table, rougher than the other; and with this facing the roughing-down begins. With this view, the smoother face is cemented on the stone table with Paris-plaster. But often instead of one plate, several are cemented alongside of each other, those of the same thickness being carefully selected. They then take one or more crude plates of about one-third or one-fourth the surface of the plate fixed to the table, and fix it on them with liquid gypsum to the large base of a quadrangular truncated pyramid of stone, of a weight proportioned to its extent, or about a pound to the square inch. This pyramidal muller, if small sized, bears at each of its angles of the upper face a peg or ball, which the grinders lay hold of in working it; but when of greater dimension, there is adapted to it horizontally a wheel of slight construction, 6 or 10 feet in diameter, whose circumference is made of wood rounded so as to be seized with the hand. The upper plate is now rubbed over the lower ones, with moistened sand applied between.

This operation is however performed by machinery. The under plate being fixed or imbedded in stucco, on a solid table, the upper one likewise imbedded by the same cement in a cast-iron frame, has a motion of circumrotation given to it, closely resembling that communicated by the human hand and arm, moist sand being supplied between them. While an eccentric mechanism imparts this double rotatory movement to the upper plate round its own centre, and of that centre round a point in the lower plate, this plate placed on a movable platform changes its position by a slow horizontal motion, both in the direction of its length and its breadth. By this ingenious contrivance, which pervades the whole of the grinding and polishing machinery, a remarkable regularity of friction and truth of surface is produced. When the plates are sufficiently worked on one face, they are reversed in the frames, and worked together

on the other. The Paris plaster is usually coloured red, in order to show any defects in the glass.

The smoothing of the plates is effected on the same principles by the use of moist emery washed to successive degrees of fineness, for the successive stages of the operation; and the polishing process is performed by rubbers of hot-felt and a thin paste of coleothar and water. The coleothar, called also crocus, is red oxide of iron prepared by the ignition of copperas, with grinding and elutriation.

The last part, or the polishing process, is performed by hand. This is managed by females, who slide one plate over another, while a little moistened *patty* of tin finely levigated is thrown between.

Large mirror-plates are now the indispensable ornaments of every large and sumptuous apartment; they diffuse lustre and gaiety round them, by reflecting the rays of light in a thousand lines, and by multiplying indefinitely the images of objects placed between opposite parallel planes. For the process of silvering, see MIRRORS.

Bohemian glass. — M. Peligot states that the hard glass of Bohemia is composed of 100 parts of silica, 12 parts of quicklime, and only 28 parts of carbonate of potash. These proportions give a glass quite unmanageable in ordinary furnaces; but the addition of a comparatively small quantity of boracic acid is capable of determining fusion, and the result is a glass having all the requisite transparency at a high temperature, and possessing at the same time a great brilliancy and hardness.

The Bohemian glass is, within certain limits, perfectly elastic, and very sonorous; when well made, it is sufficiently hard to strike fire with steel, and is scratched with difficulty. The lead glasses, on the other hand, have but little hardness, and less in proportion as they contain more oxide of lead; besides which they rapidly lose their brilliancy by use.

The silica which is employed in Bohemia in the manufacture of glass, is obtained by calcining crystalline quartz, and afterwards pounding it while dry. When the quartz has been heated to a cherry-red, it is withdrawn from the fire, and thrown immediately into cold water.

Almost all the Bohemian glass is a potash glass, because soda and its salts give to glass a sensible yellowish tint. The limonaceous which is used is as white as Carrara marble. The clay employed for the crucibles is very white, and consists of silica, 43½; alumina, 40½; and water, 17½.

The manufacture of glass in Bohemia is of very high antiquity, and the same peculiarities have always belonged to the true Bohemian manufacture.

In our modern times the Bohemian glass has been more especially celebrated for the beautiful varieties of colours which are produced. See GLASS, COLOURED.

Venetian glass. — From an early date the city of Venice has been celebrated for its glass; the *reticulated glass*, the *crackle glass*, and the glass paper weights, or *milk-flores*, are all due to the Venetians.

The manufacture of *glass beads* at Murano, near Venice, has been carried on for an indefinite period, and Africa and Asia have been supplied from their glass-houses. The process is most ingeniously simple. Tubes of glass of every colour, are drawn out to great lengths in a gallery adjoining the glass-house pots, in the same way as the more moderate lengths of the thermometer and barometer tubes are drawn in our glass-houses. These tubes are chopped into very small pieces of nearly uniform length on the up-right edge of a fixed chisel. These elementary cylinders being then put in a heap into a mixture of fine sand and wood ashes, are stirred about with an iron spatula till their cavities get filled. This curious mixture is now transferred to an iron pan suspended over a moderate fire, and continually stirred about as before, whereby the cylindrical bits assume a smooth rounded form; so that when removed from the fire and cleared out in the bore, they constitute beads, which are packed in casks, and exported in prodigious quantities to almost every country. See GLASS, ARTIFICIAL.

The manufacture of reticulated glass for which Venice was equally celebrated, was long lost; it was at length revived by Pohl, and the crackle glass was in like manner reproduced by Mr. Apsey Pallatt in 1831.

The reticulated glass is produced by a kind of network consisting of small bubbles of air inclosed within the mass, and ranged in regular series crossing and interlacing each other. To produce this ornamental appearance, hollow glass cones or conical tubes are kept prepared, containing already this network arrangement of air bubbles. These tubes are made by arranging a number of small glass rods round a centre, so as to form a cylinder, and fixing them in this position by melted glass. The cylinder is then heated until the single rods stick together, when they are drawn out on the pipe to a long cone, and spirally twisted at the same time, the one half to the right and the other to the left, when one of these hollow cones is inserted into the other, and the two are heated until they fuse together, wherever the little rods cross each other a bubble of air will be inclosed, and this occurring in a very regular

runner, the reticulated appearance is produced. The Venetians were also celebrated for their "filigree." This glass has of late years been reintroduced in France and in this country. The process of manufacture has been thus described by Mr. Apaley Pollatt, in his *Curiosities of Glass Manufacture*:—

"Before ornaments or vessels can be blown, small filigree canes, with white or variously coloured enamels must be drawn. These are first 'whittied' off to the required lengths, and then put into a cylindrical mould with suitable internal recesses, and both cane and mould are then submitted to a moderate heat. The selection of the colour of the canes depends upon the taste of the manufacturer. Two to four white enamel canes are chiefly used, alternately, with about half the number of coloured. The blower then prepares a solid ball of transparent flint glass, which being deposited in contact with the various canes, at a welding heat, occasions them to adhere. This solid ball is then taken from the mould, is reheated, and 'marcered' till the adhering projecting ornamental canes are rubbed into one uniform mass; the ball is next covered with a gathering of white glass, which must then be drawn to any size and length that may be required. Should a spiral cane be preferred, the 'puerella' holds the apex in a fixed position, while the ornamental mass, still adhering to the glass maker's iron, is revolved during the process, till the requisite twist is given. Where vases are formed of alternately coloured and enamelled filigree canes, the above process is repeated, and the usual mode of blowing is followed."

The Venetian ball is a collection of waste pieces of filigree glass conglomerated together without regular design: this is packed into a pocket of transparent glass, which is adhesively collapsed upon the interior mass by sucking up, producing outward pressure of the atmosphere.

Millefiori, or star work of the Venetians, is similar to the last, only, the lozenges of glass are more regularly placed.

The *Vetro di Trino* of the Venetians is similar to the filigree in many respects; but by closing an outer on the latter case, each containing filigree canes, a bubble of air is introduced between each crossing of the canes.

The celebrated frosted glass of the Venetians was reintroduced by Mr. Apaley Pollatt in 1851, who thus describes the process of manufacture:—"Frosted glass, like *Vetro di Trino*, is one of the few specimens of Venetian work not previously made by the Egyptians and the Romans; and not since executed by the Bohemian or French glass makers. The process of making it, until recently practised at the Falcon Glass Works, was considered a lost art. Frosted glass has irregularly varied marble-like projecting dislocations in its intervening fissures. Suddenly plunging hot glass into cold water, produces crystalline convex fractures, with a polished exterior, like Derbyshire spar; but the concave intervening figures are caused, first by chilling, and then reheating at the furnace, and simultaneously expanding the reheated ball of glass by blowing; thus separating the crystals from each other, and leaving open figures between, which is done preparatory to forming vases or ornaments. Although frosted glass appears covered with fractures, it is perfectly *incorrupt*."

GLASS, COLOURED. Most of the metallic oxides impart a colour to glass, and some non-metallic, and even some substances derived from the organic kingdom have the power of imparting permanent colours to the vitreous combinations of flint and potash. There is much in this subject which still requires examination. M. Montemp, at the meeting of the British Association at Birmingham, brought forward some very extraordinary facts in connection with the colouring powers of different bodies. Of his communication the following is an abstract.

In the first place it was shown, that all the colours of the prismatic spectrum might be given to glass by the use of the oxide of iron in varying proportions, and by the agency of different degrees of heat; the conclusion of the author being, that all the colours are produced in their natural disposition in proportion as you increase the temperature. Similar phenomena were observed with the oxide of manganese. Manganese is employed to give a pink or purple tint to glass, and also to neutralise the slight green given by iron and carbon to glass in its manufacture. If the glass coloured by manganese remains too long in the melting-pot or the annealing-kiln, the purple tint turns first to a light brownish red, then to yellow, and afterwards to green. White glass, in which a small proportion of manganese has been used, is liable to become light yellow by exposure to luminous power. This oxide is also, in certain window glass, disposed to turn pink or purple under the action of the sun's rays. M. Montemp has found that similar changes take place in the annealing oven. He has determined, by experiments made by him on polygonal lenses for M. Fresnel, that light is the agent producing the change mentioned; and the author expresses a doubt whether any change in the oxidation of the metal will explain the photogenic effect. A series of chromatic changes of a similar character were observed with the oxides of copper, the colours being in like manner regulated by the heat to which

the glass was exposed. It was found that silver, although with less intensity, exhibited the same phenomena; and gold, although usually employed for the purpose of imparting varieties of red, was found by varying degrees of heating at a high temperature, and recasting several times, to give a great many tints, varying from blue to pink, red, opaque yellow, and green. Charcoal in excess in a mixture of silica-alkaline glass gives a yellow colour, which is not so bright as the yellow from silver; and this yellow colour may be turned to a dark red by a second fire. The author is disposed to refer these chromatic changes to some modifications of the composing particles rather than to any chemical changes in the materials employed.

It is not possible in the present essay to enter into the minute details of this beautiful branch of glass manufacture. In the following statement the materials ordinarily employed to colour glass alone are named.

YELLOW. Charcoal or soot is used for producing the commoner varieties of yellow glass.

The glass of *antimony*, which is obtained by roasting sulphide of antimony until antimonious acid is formed, and melting it with about 3 per cent. of undecomposed sulphide of the same metal.

The *antimoniate of potash*, 2 preparation similar to James's powder, is stated to answer the same purpose. Bohemian glass is coloured yellow with glass of antimony, minium, and oxide of iron.

Silver imparts a very beautiful yellow colour to glass; but it requires some caution in its mode of application. It is believed, that the presence of alumina is necessary to the production of colour, since a fine yellow cannot be produced unless alumina be present. A mixture of powdered clay and chloride of silver is prepared, and spread upon the surface of the glass; the glass is then reheated and the silver penetrates to a certain depth into the glass, before the latter softens. The coating is then scraped off and the fine yellow colour appears. If the silver yellow glass is held over the flame of burning wood, a peculiar opalescence is produced upon the surface, probably by the oxidation of the silver.

Uranium produces the beautiful canary yellow, which is found in many articles of an ornamental kind. This glass possesses the very peculiar property of giving a green colour when it is looked at, although perfectly and purely yellow when looked through. This has been attributed to the presence of iron in the commercial oxide of uranium employed; but the purer the uranium is, the more beautifully will this phenomenon be brought out. It depends upon a very remarkable physical peculiarity belonging to uranium and some other bodies. See **FLORESCENCE**.

RED. A common brownish red colour is produced in glass by oxide of iron, added as ochre, or in the state of pure peroxide. Muller found ancient red glass to contain silicic acid, alkalies, lime, magnesia, alumina, protoxide of iron, and suboxide of copper.

Copper is more generally employed in colouring glass red. The use of this metal for this purpose dates from very high antiquity, and all through the middle ages it was employed to produce the reds which we see in the fine old windows left by our ancestors for our admiration. The ancient *Hematine* was a copper red glass. Suboxide of copper is used, either in the state of commercial copper scale, or it is prepared by heating copper turnings to redness. If, during the fusion of the glass in the pot, the sub-oxide unites with an additional quantity of oxygen, green and not red is the result. This is avoided by combining some reducing agent with the melted substance. Glass thus coloured does not exhibit its red colour on leaving the crucible; it is nearly colourless, or with a tinge of green even when cold; but if it is then heated a second time it assumes the red colour. H. Rose supposes that a colourless neutral or acid silicate of the sub-oxide of copper is formed at a high temperature, and that the subsequent softening of the glass at a lower temperature causes the decomposition of this compound and a separation of a portion of the sub-oxide. We believe that no such chemical change takes place, and that the alteration is due merely to a change in the molecular arrangement of the particles. The sub-oxide of copper possesses an intense colouring power, so great indeed that glass coloured with even a very small quantity is almost impermeable to light; hence it is usual merely to *flask* colourless glass with this coloured glass, that is, to spread a very thin film of it over the colourless surface. A process for colouring glass red after its manufacture with sulphide of copper has been introduced by Hordford.

Gold can according to circumstances be made to impart a ruby, carmine, or pink tint to glass. The purple of Cassius, was employed; but Dr. Fnm first showed that a mere solution of gold without the presence of tin, as in the sal; named, is capable of producing rose and carmine coloured glass.

Similar changes to those already described with copper occur with the salts of gold. Perhaps the glass is colourless in the pot, and it then remains colourless when cold; but when reheated, the glass quickly assumes a light red colour, which rapidly

spreads from the heated point over the whole glass, and increases in intensity until it becomes nearly a black red. This coloured glass can be again rendered colourless by fusion and slow cooling; its colour is again produced by a repetition of the heating process. If, however, it is suddenly cooled it cannot again be made to resume its ruby colour. This is also an example confirmatory in the highest degree of the view, that no chemical change takes place; but that all the phenomena are due to alterations in molecular structure. The practice of *flashing* colourless glass with the ruby glass from gold is commonly adopted. The beautiful examples of the Bohemian glass manufacture, in which we have a mixture of rich ruby and the purest crystal, are produced in this way. A globe of hot colourless glass is taken from the pot, and a cake of ruby glass prepared with a composition called *schmebze*, is warmed and brought into contact with the melted globe; this ruby glass rapidly diffuses itself over the surface, and the required article is blown or moulded with a coating of glass, coloured ruby by gold, of any required thickness.

Schmebze is prepared with 500 parts of silica, 500 of minium, 100 of nitre, and the same quantity of potash. A very small portion of a solution of gold in *aqua regia* is intimately mixed with 500 parts of *schmebze*, 43 parts of prismatic borax, 3 or 4 of oxide of tin, and a similar quantity of oxide of antimony. This mixture is heated for twelve hours in an open crucible placed in a flat furnace, and then cooled slowly in an annealing oven. A *Bohemian ruby*, especially so called, is prepared by melting together fulminating gold rubbed in with oil of turpentine, quartz powdered, and fritted minium, sulphide of antimony, peroxide of manganese, and potash. Blume has given an analysis of a Venetian ruby glass, in which $\frac{1}{4}$ of a grain of gold is combined with about 150 of the ordinary ingredients of glass, with some tin and iron.

Manganese is sometimes employed to give a fine amethystine colour to glass; care is however required to prevent the reduction of the peroxide of manganese in the process.

GREEN. Green colours may be obtained by a variety of metallic oxides. *Protoside of iron* imparts a dull green; an emerald green colour is given by *oxide of copper*. Either copper scales or verdigris dried and powdered are employed, the colour being much finer with a lead glass, than with one containing no lead. Translucent or *dull glass* is converted into a deep blue or turquoise colour by oxide of copper and not into a green. An emerald green is also produced by the *oxide of chromium*. Two kinds of Bohemian green glass, known respectively as the ancient and modern emerald greens, are prepared from mixtures of the oxides of nickel and of uranium.

BLUE. The only fine blue is produced by *cobalt*. The manufacture of *smalt* or *saffre* is so important that it will be treated of in a separate article. See **SMALT** and **COBALT**.

BROWN. Peroxide of manganese with saffre yields a fine garnet-like brown.

PINK or FLESH COLOUR. Oxide of iron and alumina, obtained by heating a mixture of alum and green vitriol.

ORANGE. Peroxide of iron with chloride of silver.

JASPER. A Bohemian glass, generally black, but of fine lustre, prepared by adding forge scales, charcoal, and bone ashes to the ordinary materials for glass.

Amongst the different varieties of glass, artificial gems may be enumerated. For a description of their manufacture, see **GEMS, ARTIFICIAL**.

GLASS, its physical conditions and chemical constitution.—So far as may be inferred, from the analysis of ordinary commercial samples of window-glass, this substance has not only a very variable composition, but, worse than this, it is out of all keeping with anything like definite proportion. That it should be full of striae, and, therefore, refract the rays of light unequally, as it does, so as to produce the most hideous appearances of distortion, is a mere natural consequence of its mechanical composition, which might, and must one day be corrected; but that whole nations should have come to view this defect as an unavoidable peculiarity, is precisely one of those surprising facts which demonstrate the influence of habit over the powers of the mind, and show how easily human reason can reconcile itself to the most gross inconsistencies. If window-glass had one uniform atomic composition, the tendency to form these striae would nowhere exist in excess; and, therefore, their production would diminish as the skill of the workmen increased; but, with the present variable compound, the glass stretches unequally in different parts, by an equal application of force, and, in spite of human skill, presents a result alternately thick or thin, as accident determines. That these striae have not the same composition as the parts surrounding them is very obvious, from the circumstance that, if striated glass be cut to an uniform thickness, and polished on both sides, the optical defects remain but little changed, and occasionally they are found to be increased. Again it is known, that the more complex the composition of any glass may be, the greater the liability to this striated structure,—of which flint glass offers an opposite illustration; for here, in

addition to the ordinary components of glass, the silicate of lead is superadded. Now the specific gravity of silicate of lead is very high compared with that of silicate of soda, potash, or lime; hence, unless employed in the exact quantity to form a chemical combination with the other silicates, a mere mechanical mixture is produced of very different densities throughout; and the product, under the action of light, displays, permanently, that peculiar fugitive appearance seen when syrup and water, or alcohol and water, are mixed together; that is to say, a series of curved lines are formed by the unequal refraction of the two fluids, which entirely disappear, so soon as perfect admixture has taken place, but which remain in the case of flint-glass, from the utter impossibility of effecting the necessary union between its various parts. Although, however, this cannot be done mechanically, yet, in a chemical way, nature performs such operations with ease and unerring fidelity. The French chemist, Berthier, long ago proved that many neutral salts combine together by fusion in atomic proportions, and form new and definite compounds. Thus, carbonate of potash and carbonate of soda when mixed, atom for atom, unite and produce a compound more easy of fusion than the most fusible of the two:—similarly, either of these carbonates will act with carbonate of baryta or strontia, and again, fluor-spar and sulphate of lime, two remarkably infusible substances, when mixed, melt readily, at a low red heat into a fluid as mobile and transparent as water. It is useless to multiply examples of this kind, for thousands exist; and the alkaline and earthy silicates form no exception to this almost universal rule. A mixture of silicate of potash and silicate of soda will, if in atomic ratios, fuse much more readily than either of them alone. But now, let us imagine an attempt to fuse these two bodies together, in any other proportion than that in which they are naturally disposed to combine;—any that the silicate of soda is in excess; then the silicate of potash would unite with exactly sufficient of the silicate of soda to produce the extremely fusible compound above spoken of; whilst the less easily fusible silicate of soda, added in excess, would form a kind of network throughout the mass. It may be said, that a higher heat would overcome this difficulty, by thoroughly liquefying the silicate of soda; and this is really the plan now used with that view; but, independent of the fact that the mixed silicate of potash and soda would also undergo a corresponding liquefaction, and, therefore, favour the separation of the silicate of soda; yet, as the ideal union is impossible, from the very conditions of the experiment, even the most perfect mechanical mixture, under the greatest advantages of fluidity, would never generate a homogeneous body. The strim might, indeed, be diminished in size; but this would imply a corresponding increase in their number; and, if carried very far, complete opacity would result from such an endeavour to subvert the laws of nature. The power of the workmen to remedy this defect is therefore limited to the capability of modifying its more salient features; he can neither remove nor destroy it. What we have here illustrated by the simplest of all assumptions, gathers and accumulates into a formidable evil when several silicates are fused together, having considerable differences of specific weight. Thus, in the case of flint-glass before alluded to, there are generally three, and sometimes five, of these silicates fused together, into, probably, one of the most antagonistic compounds that could be conceived, refracting and dispersing the ray of light in fifty directions, and demonstrating the unfriendly nature of its coerced union, by flying in pieces from the most trivial applications of heat or violence. Yet in flint-glass we are not surpassed, nor indeed equalled, by any other nation; and so thoroughly has this beautiful substance become associated with our industrial reputation, that the British name, flint glass, has been adopted into several continental languages. Nevertheless, it cannot be doubted that a wide field of improvement is open in this quarter, and that some more solid foundation is needed by our manufacturers in this line, than the prestige of a name, or the force of capital.

In France, as in England, the ingredients are mixed with some care, and introduced into a crucible, heated by a powerful furnace. These ingredients are sand or silica, carbonate of soda, and carbonate of lime, with perhaps a little ground felspar in some cases. The carbonate of soda is first attacked by the silica, and its carbonic acid driven off, whilst the remaining silica and carbonate of lime become imbedded in the vitrifying mass. As the heat increases, a more perfect fusion takes place; and then the carbonic acid of the carbonate of lime makes its way through the fused materials by which they are mechanically mingled together during the effervescence, which is technically termed the "boil;" and, provided no after separation ensues from the process of "settling," the whole crucible or "pot" of glass will have a uniform composition. But, as we have seen, this depends altogether upon the relative proportion of the materials towards each other, for an excess of either one or either of the masses will destroy the homogeneous character of the whole, and introduce a plexus of struts. Now the plate-glass of St. Gobain is almost exactly an atomic compound, and consists of one atom of the trisilicate of soda and one atom of the trisilicate of lime, with a

small percentage of alumina. The union is therefore complete; and when it is remembered that the celebrated French chemist, Gay-Lussac, was regularly employed as an adviser to this company, and that his son, M. Jules Lussac, retains that appointment to this day, it is not very surprising that our manufacturers are defeated in the article of plate-glass. Science must ever take the lead of prejudice and custom.

The examination of English plate glass fully corroborates the general result deduced from the action of light. There is no approach to an atomic arrangement. The principal constituent is trisilicate of soda, but variable quantities of lime, alumina, and even magnesia, exist in it. Potash is sometimes present, and oxide of iron is invariably so; but in not one single instance, out of 17 samples examined with great care, could so much as a surmise of the doctrine of combining proportions be gathered from the result of the analyses. Similarly fruitless was a research instituted upon tint-glass, both British and foreign. Of 35 samples analysed, no satisfactory evidence could be adduced to favour the opinion that science had been a helpmate to industry, or was at all concerned in this branch of manufacture. There are, however, some points of vast interest associated with the practical working out of this matter. Potash is known to give a more brilliant and harder glass than soda, and alumina seems to tend in the same direction. The Bohemian glass, so celebrated throughout Europe, is a glass of this description, and contains silicate of alumina, silicate of lime, and silicate of potash, but not in chemical proportions. This glass is therefore striated, but it seems to permit of a more perfect decoration by metallic oxides than can be developed in glass of lime and soda. This very probably depends upon the alumina contained in it. From some singular oversight, the use of carbonate of baryta has not yet found its way into the composition of glass, though we can scarcely conceive a more hopeful material. This substance may be had in large quantity in the North of England, of great purity, and at a merely nominal cost as compared with its value for such a purpose as glass-making. That it would fuse readily with a due amount of soda, and give "a boil" as well as chalk, there can be no doubt; whilst its great density will certainly improve the refractive power of the resulting product, and thus rival the brilliancy of lead or flint-glass, without imparting that softness and liability to receive scratches which are so objectionable in the latter variety. One difficulty may perhaps result in the want of information concerning the quantity to be employed. But this is easily adjusted; for it has been demonstrated that, during vitrification, the silicic acid unites to bases in the proportion of three atoms to one; consequently three atoms, or 138 parts, will always require one atom of each base. Therefore, this weight of good dry sand may be set against 84 of dry carbonate of soda, 70 of carbonate of potash, 50 of pure marble or chalk, 99 of carbonate of baryta, and 112 of oxide of lead or litharge. Suppose, then, that the object is to employ carbonate of baryta for the first time, here 6 atoms or 276 parts of sand, 1 atom or 84 parts of dry carbonate of soda, and 1 atom or 99 parts of carbonate of baryta, may be mixed and fused together with every prospect of obtaining a good result; or 9 atoms of silica, 1 of carbonate of potash, 1 of carbonate of soda, and 1 of carbonate of baryta, might be tried without fear of failure. Again, in the case of flint-glass, 112 of litharge, 84 of soda, and 276 of sand, would probably succeed, or an additional atom of fragments of potash might be used. For many years past, M. Dumas, now, perhaps, the first chemist in France, has been in the habit of demonstrating to his pupils that glass of all kinds, when properly made, must necessarily be an atomic compound; and yet we scarcely expect to find a single British glassmaker who will admit that his art is susceptible of such decisive and beautiful simplification.

To assist as far as we can in the attainment of this end, we shall proceed to describe a simple means for the analysis of glass, which will enable any person, possessed of even very trifling chemical skill, to determine the composition of any given sample of glass in a comparatively short time. From the nature of the material, it becomes necessary to divide the analysis into two distinct portions; one of which has for its object the estimation of its alkaline ingredients, the other that of the earthy, metallic, and siliceous matters. Having heated a sufficient quantity of the sample in question to dull redness, it must be suddenly thrown, whilst still hot, into a basin containing cold water. In this way it becomes cracked and flaked in all directions, so as to favour its reduction into powder. When dry it must, therefore, be carefully ground in an agate or steel mortar, until it has the appearance of fine flour. Nor is it a matter of indifference whether this takes place in contact with water or not; for glass in this extreme state of comminution, readily gives up a part of its alkali to water; and hence, if ground in the presence of that fluid, the resulting analysis would prove incorrect. But we will suppose that a quantity of finely powdered glass has been obtained as above indicated, and the amount of its alkali is desired; then weigh out 100 grains of the glass, and carefully mix with it 200 grains of pure flint spar in a similarly powdered condition. Place the mixture in a platinum or leaden vessel, and

pour over it 500 grains of strong sulphuric acid, — stirring the whole well together with a silver spoon, but taking care not to remove any portion of the materials. Next, apply a heat of about 212° Fahr.; and as the process draws to a conclusion, this may be raised as high as 300° . When all evolution of gaseous fumes has ceased, water may be poured on the residuary mass to the extent of four or five ounces, and the mixture thrown on a filter. After the clear fluid has passed through, a little more water must be added to the filter, so as to wash out the whole of the soluble matter; these washings being joined to the original clear fluid, which consists of sulphate of soda or potash, or both, with a quantity of sulphate of lime, and perhaps also of magnesia and alumina. To this an excess of carbonate of ammonia must now be added, to admit of the separation of the earthy salts being effected by filtration. The clear solution is next boiled down to dryness, and the residue is heated red-hot for a minute or two. This residue is the soda or potash, or both, formerly contained in 100 grains of the glass, but now united to sulphuric acid. Having ascertained its weight, the relative proportions of potash and soda may be found by testing its content of sulphuric acid with a barytic solution, and calculating the result by the well-known Archimedean equation; or by dissolving the mixed salt in a small quantity of water, and, after adding an excess of tartaric acid, leaving the whole for a few hours covered up in a cool place. Almost the whole of the potash will separate in this way as bitartrate of potash. The quantity of alkali may be determined from the atomic constitution of the alkaline salts. Thus, supposing the dry residue altogether composed of sulphate of soda, then as 72 grains of it indicate 32 of pure soda, the result may be obtained by the rule of proportion. The amount of alkali being known, another portion of the powdered glass must be employed for ascertaining the remainder of the ingredients. That is to say, 100 grains of the sample must be mixed with 200 grains of pure potash, and the whole fused together in a silver crucible, at a red heat, until perfect liquefaction ensues, when the crucible and its contents may be withdrawn from the fire, and, as soon as cool enough, boiled in half a pint of pure water, so as thoroughly to dissolve the fused mass from the crucible. An excess of nitric acid being poured into the solution, the mixture is then evaporated to dryness, by which means the silicic acid is rendered insoluble; consequently, on the application of water, this remains, and may be dried and weighed, whilst the lime, alumina, and lead of the glass may be separated from the soluble portion by the addition, first, of sulphuretted hydrogen, which separates the lead, then of ammonia, which throws down the alumina, and, next, by pouring in carbonate of ammonia, which precipitates the lime as a carbonate. Thus, therefore, the alkaline matters are found by one process, and the silica, earthy, and metallic constituents by another, both of which may be conducted at the same time. It has been recommended to employ carbonate of baryta in the analysis of glass; but the high temperature required with this substance dissipates a portion of the alkaline components, and thus leads to serious errors. Even mere fusion in a glass furnace expels soda from glass, and renders it more and more infusible; but this expulsion is much favoured by the presence of baryta. The above method of analysing glass is, therefore to be preferred to the baryta plan, by individuals not habitually engaged in manipulative chemistry. — *Urr.*

GLASS for horticultural purposes. — An impression taken up loosely in the first instance from some experiments on the action of the chemical rays of light, when made to permeate coloured glass, has led the public frequently to conceive that glasses which admitted freely the chemical rays were the most adapted to accelerate the growth of plants. No more mistaken view was ever entertained. At different periods in the life of a plant different influences are necessary; at one time the chemical force is required, at another the luminous power, and at another the calorific agent. The solar rays, as we receive them direct from the sun, have those forces exactly adjusted to produce the best possible conditions; but under some of the artificial conditions in which we place plants, it is important to know the conditions of the solar rays best suited to produce a given effect. This we must briefly attempt to explain: —

1. Seeds germinating absorb oxygen, and convert their starch into sugar; this is a purely chemical process, and demands the full power of the chemical rays (*actinism*).
2. Wood forming, from the decomposition of carbonic acid, is a function of the vital power of the plant, excited by light (*luminous force*).
3. Flowering and fruiting manifest compound actions, and appear to demand the combined power of heat (*colorific power*) and of the chemical rays.

Such are the three chief conditions in the phenomena of vegetable growth. Now *a*, a glass stained blue with cobalt admits the permeation of the chemical rays with great freedom, obstructing both light and heat; *b*, a glass stained yellow with silver, will powerfully obstruct the chemical rays, and allow the luminous rays to pass freely; *c*, deep copper or gold red glasses admit the maximum heat rays to pass freely, and in general allow of the permeation of a small quantity of the chemical rays.

When seed is placed in the soil to germinate, a blue glass placed above the soil will greatly accelerate the process, the first leaves will appear above the soil, in many instances, days before they are seen when the seed is under the ordinary conditions in the soil; but if a plant is allowed to grow under these circumstances, scarcely any wood is produced, but long succulent stalks are formed, with imperfect leaves.

After germination has taken place, if the plant is brought under the influence of the rays permeating yellow glass (light separated to a considerable extent from the chemical power), wood is formed abundantly, and very healthy plants with dark leaves are produced. For the production of perfect flowers and fruit, the red glass named is the most effective. Plants growing in conservatories which have been glazed with the colourless German sheet glass, frequently suffer from scorching. To avoid this if possible, the editor of this volume was consulted on the glass which should be employed in glazing the great palm house at Kew, the problem being to avoid the necessity of blinds, and to secure the plants from the injurious action of the scorching rays. By a long series of experiments it was determined that glass stained green with a little of the oxide of copper, and from which there was an entire absence of the oxide of manganese, entirely effected this end. The great palm house in the Royal Botanic Gardens at Kew was glazed with glass made on this principle, by the Messrs. Chance Brothers and Co. of Birmingham, and it has now been tested by the sunshine of twelve summers (1850); and the plants, as every one may observe, grow most luxuriantly, and are entirely free from any indications of scorching on their leaves.

GLASS CUTTING AND GRINDING, for common and optical purposes. By this mechanical process the surface of glass may be modified into almost any ornamental or useful form.

1. *The grinding of crystal ware.* This kind of glass is best adapted to receive polished facets, both on account of its relative softness, and its higher refractive power, which gives lustre to its surface. The cutting shop should be a spacious long apartment, furnished with numerous skylights, having the grinding and polishing lathes arranged right under them, which are set in motion by a steam-engine or water-wheel at one end of the building. A shaft is fixed as usual in gall ways along the ceiling; and from the pulleys of the shaft, bands descend to turn the different lathes, by passing round the driving pulleys near their ends.

The turning lathe is of the simplest construction. Fig. 906, b, is an iron spindle with two well-turned prolongations, running in the iron puppets *a a*, between two concave bushes of tin or type metal, which may be pressed more or less together by the thumb-screws shown in the figure.

These two puppets are made fast to the wooden support *u*, which is attached by a strong screw and bolt to the longitudinal beam of the workshop *A*. *x* is the fast and loose pulley for putting the lathe in and out of gear with the driving shaft. The projecting end of the spindle is furnished with a hollow head-plate, into which the rod *c* is pushed tight. This rod carries the cutting or grinding disc plate. For heavy work, this rod is fixed into the head by a screw. When a conical fit is preferred, the cone is covered with lead to increase the friction.

Upon projecting rods or spindles of that kind the different discs for cutting the glass are made fast. Some of these are made of fine sandstone or polishing slate, from 8 to 10 inches in diameter, and from $\frac{1}{2}$ to $\frac{3}{4}$ inch thick. They must be carefully turned and polished at the lathe, not only upon their rounded but upon their flat face, in order to grind and polish in their turn the flat and carved surfaces of glass vessels. Other discs of the same diameter, but only $\frac{1}{4}$ of an inch thick, are made of cast tin truly turned, and serve for polishing the vessels previously ground; a third set consists of sheet iron from $\frac{1}{2}$ to $\frac{3}{4}$ an inch thick, and 12 inches in diameter, and are destined to cut grooves in glass by the aid of sand and water. Small discs of well-hammered copper from $\frac{1}{2}$ to 3 inches in diameter, whose circumference is sometimes flat, and sometimes concave or convex, serve to make all sorts of delineations upon glass by means of emery and oil. Lastly, there are rods of copper or brass furnished with small hemispheres from $\frac{1}{16}$ to $\frac{1}{4}$ of an inch in diameter, to excavate round hollows in glass. Wooden discs are also employed for polishing, made of white wood cut across the grain, or also of cork.

The cutting of deep indentations, and of grooves, is usually performed by the iron

disc, with sand and water, which are allowed constantly to trickle down from a wooden hopper placed right over it, and furnished with a wooden stopple or plug at the apex, to regulate by its greater or less looseness the flow of the grinding materials. The

907

same effect may be produced by using buckets as shown in fig 907. The sand which is contained in the bucket *v*, above the lathe, has a spigot and faucet inserted near its bottom, and is supplied with a stream of water from the stopcock in the vessel *o*, which, together, running down the inclined board, are conducted to the periphery of the disc as shown in the figure, to whose lowest point the glass vessel is applied with pressure by the hand. The sand and water are afterwards collected in the tub *n*. Finer markings which are to remain without lustre, are made with the small copper discs emery, and oil. The polishing is effected by the edge of the tin disc, which is from time to time moistened with putty (white oxide of tin) and water. The wooden disc is also employed for this purpose with putty, colcothar, or washed tripoli. For fine delineations, the glass is first traced over with some coloured varnish, to guide the hand of the cutter.

In grinding and faceting crystal glass, the deep grooves are first cut, for example, the cross lines, with the iron disc and rounded edge, by means of sand and water. That disc is one sixth of an inch thick and 12 inches in diameter. With another iron disc about half an inch thick, and more or less in diameter, according to the curvature

of the surface, the grooves may be widened. These roughly cut parts must be next smoothed down with the sandstone disc and water, and then polished with the wooden disc about half an inch thick, to whose edge the workman applies, from time to time, a bag of fine linen containing some ground pumice moistened with water. When the cork or wooden disc edged with bat felt is used for polishing, putty or colcothar is applied to it. The above several processes in a large manufactory, are usually committed to several workmen on the principle of the division of labour, so that each may become expert in his department.

2. *The grinding of optical glasses.* — The glasses intended for optical purposes being optically ground, are called lenses; and are used either as simple magnifiers and spectacles, or for telescopes and microscopes. The curvature is always a portion of a sphere, and either convex or concave. This form insures the convergence or divergence of the rays of light that pass through them, as the polishing does the brightness of the image.

The grinding of the lenses is performed in brass moulds, either concave or convex, formed to the same curvature as that desired in the lenses; and may be worked either by hand or by machinery. A gauge is first cut out of brass or copper plate to suit the curvature of the lens, the circular arc being traced by a pair of compasses. In this way both a convex and concave circular gauge are obtained. To these gauges the brass moulds are turned. Sometimes, also, lead moulds are used. After the two moulds are made, they are ground face to face with fine emery.

The piece of glass is now roughed into a circular form by a pair of pincers, leaving it a little larger than the finished lens ought to be, and then smoothed round upon the stone disc, or in an old mould with emery and water, and is next made fast to a holdfast. This consists of a round brass plate having a screw in its back; and is somewhat smaller in diameter than the lens, and two thirds as thick. This is turned concave upon the lathe, and then attached to the piece of glass by drops of pitch applied to several points of its surface, taking care, while the pitch is warm, that the centre of the glass coincides with the centre of the brass plate. This serves not merely as a holdfast, by enabling a person to seize its edge with the fingers, but it prevents the glass from bending by the necessary pressure in grinding.

The glass must now be ground with coarse emery upon its appropriate mould, whether convex or concave, the emery being all the time kept moist with water. To prevent the heat of the hand from affecting the glass, a rod for holding the brass plate is screwed to its back. For every six turns of circular motion, it must receive two or three rubs across the diameter in different directions, and so on alternately. The middle point of the glass must never pass beyond the edge of the mould; nor should strong pressure be at any time applied. Whenever the glass has assumed the shape of the mould, and touches it in every point, the coarse emery must be washed away, finer be substituted in its place, and the grinding be continued as before, till all the scratches disappear, and a uniform dead surface be produced. A commencement of polishing is now to be given with pumice-stone powder. During all this time the convex mould should be occasionally worked in the concave, in order that both may preserve their correspondence of shape between them. After the one surface has

been thus finished, the glass must be turned over, and treated in the same way upon the other side.

Both surfaces are now to be polished. With this view equal parts of pitch and resin must be melted together, and strained through a cloth to separate all impurities. The concave mould is next to be heated, and covered with that mixture in a fluid state to the thickness uniformly of one quarter of an inch. The cold convex mould is now to be pressed down into the yielding pitch, its surface being quite clean and dry, in order to give the pitch the exact form of the ground lens; and both are to be plunged into cold water till they be chilled. This pitch impression is now the mould upon which the glass is to be polished, according to the methods above described, with finely washed colcothar and water, till the surface become perfectly clear and brilliant. To prevent the pitch from changing its figure by the friction, cross lines must be cut in it about $\frac{1}{4}$ an inch asunder, and $\frac{1}{12}$ th of an inch broad and deep. These grooves remove all the superfluous parts of the polishing powder, and tend to preserve the polishing surface of the pitch clean and unaltered. No additional colcothar after the first is required in this part of the process, but only a drop of water from time to time. The pitch gets warm as the polishing advances, and renders the friction more laborious from the adhesion between the surfaces. No interruption must now be suffered in the work, nor must either water or colcothar be added; but should the pitch become too adhesive, it must be merely breathed upon, till the polish be complete. The nearer the lens is brought to a true and fine surface in the first grinding, the better and more easy does the polishing become. It should never be submitted to this process with any scratches perceptible in it, even when examined by a magnifier.

As to small lenses and spectacle eyes, several are ground and polished together. The pieces of glass are affixed by means of a resinous cement to the mould, close to each other, and are then all treated as if they formed but one large lens. Plane glasses are ground upon a surface of pitch rendered plane by the pressure of a piece of plate glass upon it in its softened state.

Lenses are also ground and polished by means of machinery, into the details of which the limits of this work will not allow us to enter. See LENSES.

GLASS PAPER and CLOTH. Paper or cloth being covered with glue, sand, varying in its degree of fineness, is dusted over it, and of course adheres. These are used for polishing, or removing the rough surfaces of woods or metals.

GLAUBER'S SALTS (the *Sal catharticus Glauberi*, or *Sal mirabile Glauberi*). Sulphate of soda was discovered by Glauber in 1658. Its composition is:—

Soda - - - - -	19.74
Sulphuric acid - - - - -	24.78
Water - - - - -	56.00
	100.00

GLAZES. See POTTERY.

GLAZIER, is the workman who cuts plates or panes of glass with the diamond, and fastens them by means of putty in frames or window casements. See DIAMOND, for an explanation of its glass cutting property.

GLAZING The process of giving a hard polished surface to bodies. Paper is glazed by the use of resins, gelatine, &c. See PAPER. Pottery is glazed by the use of certain fusible materials. See POTTERY and PORCELAIN. Some metals are said to be "glazed" when, by means of polishing wheels, the highest finish is put upon their surfaces.

GLOVE MANUFACTURE. In February, 1822, Mr. James Winter of Stoke-under-Hamilton, in the county of Somerset, obtained a patent for an improvement upon a former patent machine of his for sewing and pointing leather gloves. Fig. 904, represents a pedestal, upon which the instrument called the jaws is to be placed. Fig. 909 shows the jaws, which instead of opening and closing by a circular movement upon a joint, as described in the former specification, are now made to open and shut by a parallel horizontal movement, effected by a slide and screw; *a a* is the fixed jaw, made of one piece, on the under side of which is a tenon, to be inserted into the top of the pedestal. By means of this tenon the jaws may be readily removed, and another similar pair of jaws placed in their stead, which affords the advantage of expediting the operation by enabling one person to prepare the work whilst another is sewing; *b b* is the movable jaw, made of one piece. The two jaws being placed together in the manner shown at fig. 910, the movable jaw traverses backwards and forwards upon two guide-bars, *c*, which are made to pass through holes exactly fitted to them, in the lower parts of the jaws. At the upper parts of the jaws are what are called the indexes, *d d*, which are pressed tightly together by a spring shown at fig. 911, and intended to be introduced between the perpendicular ribs of the jaws at *e*. At *f* is a thumb-screw, passing through the ribs for the purpose of

tightening the jaws, and holding the leather fast between the indexes while being sewn, this screw, however, will seldom, if ever, be necessary if the spring is sufficiently strong, *g* is an eye or ring fixed to the movable jaw, through which the end of a lever, *h* in *fig. 908*, passes, this lever is connected by a spring to a treadle *i*, at the base of the pedestal, and by the pressure of the right foot upon this treadle, the movable jaw is withdrawn; so that the person employed in sewing may shift the leather, and place another part of the glove between the jaws. The pieces called indexes are connected to the upper part of the jaws, by a screw passing through elongated holes which render them capable of adjustment.

The patentee states, that in addition to the index described in his former patent, which is applicable to what is called round seam sewing only, and which permits the leather to expand but in one direction, when the needle is passed through it, namely, upwards, he now makes two indexes of different construction, one of which he calls the *receding index*, and the other the *longitudinally grooved index*. *Fig. 911* represents an end view, and *fig. 912*, a top view of the *receding index*, which is particularly adapted for what are called "draw sewing, and prick-seam sewing." This index, instead of biting to the top, is so rounded off in the middle from the bottom of the cross grooves, as to permit the needles, by being passed backwards and

forwards, to carry the silk thread on each side of the leather without passing over it. *Fig. 913* represents an end view of the *longitudinally grooved index*, partly open, to show the section of the grooves more distinctly; and *fig. 914* represents an inside view of one side of the same index, in which the longitudinal groove is shown, passing from *k* to *l*. This index is more particularly adapted to round-seam sewing, and permits the leather to expand in every direction when the needle is passed through it, by which the leather is less strained, and the sewing consequently rendered much stronger.

GLOVE SEWING. The following simple and ingenious apparatus, invented by an Englishman, has been employed extensively in Paris. The instrument is shown in profile ready for action in *fig. 915*. It resembles an iron vice, having the upper portion of each jaw made of brass, and tipped with a kind of comb of the same metal. The teeth of this comb, only one-twelfth of an inch long, are perfectly regular and equal. Change combs are provided for different styles of work. The vice *A A* is made fast to the edge of the bench or table *n*, of the proper height, by a thumb screw *c*, armed with a cramp which lays hold of the wood. Of the two jaws composing the machine, the one *v* is made fast to the foot *A*, but the other *x* is movable

upon the solid base of the machine, by means of a hinge at the point *r*. At *t t* is shown how the upper brass portion is adjusted to the lower part made of iron, the two being secured to each other by two stout screws. The comb, seen separately in *fig. 917*, is made fast to the upper end of each jaw, by the three screws *a, a, a*. *Fig. 918*, is a front view of the jaw mounted with its comb, to illustrate its construction.

The lever *x* corresponds by the stout iron wire *z*, with a pedal pressed by the

needle-woman's foot, whenever she wishes to separate the two jaws, in order to insert between them the parallel edges of leather to be sewed. The instant she lifts her foot, the two jaws join by the force of the spring *a*, which pushes the movable jaw *b* against the stationary one *c*. The spring is made fast to the frame of the vice by the screw *d*.

After putting the double edge to be sewed in its place, the woman passes her needle successively through all the teeth of the comb, and is sure of making a regular seam in every direction, provided she is careful to make the needle graze along the bottom of the notches. As soon as this piece is sewed, she presses down the pedal with her toes, whereby the jaws start asunder, allowing her to introduce a new seam; and so in quick succession.

The comb may have any desired shape, straight or curved; and the teeth may be larger or smaller, according to the kind of work to be done. With this view, the combs might be changed as occasion requires; but it is more economical to have sets of vices ready mounted with combs of every requisite size and form.

GLUCINA (*Glucina*, Fr.; *Beryllide*, Germ.) is one of the primitive earths, originally discovered by Vauquelin in 1797 in the emerald of Limoges; he called it glucina from the sweet taste possessed by its salts. Its existence in several other minerals has since been proved, viz., in cymophane or chrysoberyl, phenacite, euclase, gadolinite, leucoclane, &c. Its properties have been comparatively little studied, owing to the tedious and expensive processes required for its preparation. From the circumstance that this earth may probably be employed in the production of gems by artificial methods, it is thought important to describe its peculiarities fully.

GLUCINUM, the metal of Glucina has been obtained by M. H. Debray (*Ann. et Phys.* xlv. 5), by the following process. Into a wide glass tube are introduced two vessels, one containing chloride of glucinum, and the other sodium, deprived of the greatest part of the adhering naphtha by compression between two sheets of blotting paper. The glass tube is placed in a combustion furnace. It is then traversed by a current of hydrogen, passing from the chloride of glucinum to the sodium. The sodium is not placed in the tube until all the air has been expelled by the hydrogen. The tube is then heated just where the sodium is placed, which by this means is deprived of the last particles of naphtha, and fused. The chloride of glucinum is then heated. The vapour of chloride driven forwards by the hydrogen arrives over the fused sodium. It then swells up, and the heat generated by chemical action is sufficient to raise the contents of the vessel to redness, which often breaks the vessel if made of porcelain. The operation is ended when the chloride of glucinum sublimes beyond the sodium vessel. When the tube is cool the vessel is withdrawn, and in the place of the sodium a large quantity of a blackish substance is found, composed of common salt and the metal glucinum in brilliant shingles, and sometimes even in globules. This mass is quickly detached and fused in a small crucible, with the addition of some dried common salt, which acts as a flux, and facilitates the union of the globules of metal.

It is a white metal, whose density is 2.1. It may be forged and rolled into sheets like gold. Its melting point is inferior to that of silver. It may be melted in the outer blowpipe flame, without exhibiting the phenomenon of ignition presented by some mild iron under the same circumstances. It cannot be set on fire in an atmosphere of pure oxygen, but in both cases is covered with a film of oxide, which seems to protect it from further action. It is not acted on by sulphur, but readily combines with chlorine and iodine by the aid of heat.

Silicium unites readily with it, forming a hard, brittle substance, capable of taking a high polish. This substance is always formed when glucinum is prepared in porcelain vessels, the silica being reduced by this metal. After several fusions in such vessels, glucinum may contain as much as 20 per cent. of silicium. Glucinum does not decompose water at the temperature of ebullition, nor even at a white heat.

Sulphuric and hydrochloric acids dissolve it easily, either concentrated or diluted, with the evolution of hydrogen.

Nitric acid, even when concentrated, has, at ordinary temperatures, no action upon it, and dissolves it but slowly when boiling.

Glucinum, though not acted on by ammonia, dissolves readily in caustic potash.

The metal which Wohler obtained, by igniting chloride of glucinum with potassium in a platinum crucible, differs considerably from that just described; the metal thus obtained being a grey powder, very refractory in the furnace, but combines with oxygen, chlorine, and sulphur much more energetically than the metal described by Debray. The differences arise probably partly from the different state of aggregation, and partly from the contamination of Wohler's metal with platinum and potassium.

Berzelius effected the solution of the beryl by fusing the finely-powdered beryl with three times its weight of carbonate of potash in a platinum crucible, and

then treating the fused mass with hydrochloric acid; but the swelling up of the mixture of carbonate of potash and beryl at the moment of fusion, prevents large quantities being made at a time. To obviate this, Debray uses lime. The following is the process given by him.

The pulverised emerald is mixed with half its weight of quick-lime in powder; the mixture is then fused in an earthen crucible placed in a wind-furnace; the temperature at which the fusion takes place is much lower than that required for the assay of iron. The glass thus obtained is powdered and moistened with water acidulated with nitric acid, so as to obtain a thick paste, to which is added concentrated nitric acid, taking care to stir the mass, which is converted, in the cold, but better by heat, into an homogeneous jelly; this is evaporated to drive off the excess of acid, then heated so as to decompose the nitrates of alumina, glucina, and iron. It is advisable to raise the temperature at the end of the operation so as to decompose a small portion of the nitrate of lime. The result of this calcination is composed of insoluble silica, alumina, glucina, and sesquioxide of iron, insoluble in water, finally nitrate of lime, and a little free lime. It is boiled with water containing some chloride of ammonium.

The nitrate of lime is rapidly removed by the water, and the lime decomposing the chloride of ammonium is also at length dissolved, with liberation of ammonia. This disengagement of ammonia ceases as soon as all the lime is dissolved, and as it is the surest guarantee of the non solution of the alumina and glucina, the calcination of the nitrates should be repeated, unless ammonia is liberated under the circumstances just mentioned. The residue of silica, alumina, glucina, and iron is well washed until all the lime is removed, which is known by oxalate of ammonia causing no cloudiness in the washings. The separation of the silica and the earths is easily effected, mere boiling with nitric acid dissolving the alumina, glucina, and iron, and leaving the silica undissolved. The solution of the nitrates of alumina, glucina and iron, is then poured into a solution of carbonate of ammonia, to which a little ammonia has been added. The precipitation of the earths takes place without liberation of carbonic acid, and the glucina at length redissolves in the carbonate of ammonia. The solution of the glucina may be considered complete after seven or eight days' digestion. As the carbonate of ammoniac may dissolve a little iron, it is better to add to the solution a few drops of sulphide of ammonium, which precipitates it completely. The solution is then filtered and boiled to drive off the carbonate of ammonia, when the glucina is precipitated in the state of carbonate.

The carbonate of glucina is a dense white powder, easily washed; it is collected on a filter and dried.

From the carbonate any of the other compounds of glucina may be easily prepared; simple calcination converts it into glucina. A process for the separation of alumina and glucina has been proposed by M. Berthier; it consists in suspending the well washed earths in water, and passing a current of sulphurous acid through them. Their solution is complete. The liquid is then boiled to expel the excess of sulphurous acid, when a dense sub-sulphite of alumina is precipitated, leaving the glucina in solution. Debray found that sometimes in this process the glucina was entirely precipitated with the alumina.

Glucina thus obtained possesses the following properties.

It is a light white powder, without smell or taste. Infusible, but volatilises just as zinc and magnesia. Heat does not harden glucina as it does alumina, but renders it nevertheless insoluble in acids. Boiling concentrated sulphuric acid dissolves it easily, but the action of nitric acid is very feeble when the glucina has been strongly heated. Caustic potash dissolves it readily; and glucina is even capable of expelling the carbonic acid from carbonate of potash; it is again precipitated from its solution in potash by boiling when diluted to a certain extent.

Eichenen has obtained it in hexagonal prisms by submitting a solution of glucina, in fused boracic acid, to a powerful and long-continued heat. It may likewise be obtained in microscopic crystals by a more easy process, which consists in decomposing the sulphate of glucina at a high temperature, in the presence of sulphate of potash; also by calcining the double carbonate of glucina and ammonia. The crystals are separated from the sulphate of potash by washing.

The hydrate of glucina is obtained by precipitating a salt of that base by ammonia. The presence of ammoniac salts does not hinder the precipitation. When recently prepared it greatly resembles the hydrate of alumina; only it absorbs, by drying in the air, a notable quantity of carbonic acid.

The hydrate of glucina easily loses its water by heat, and becomes then insoluble in carbonate of ammonia, the hydrate when pure being very soluble in it; but its solution is hindered by the presence of alumina, in which case, it is only complete after several hours' digestion. It is also soluble in sulphurous acid and bisulphate of ammonia.

Glucina precipitated from some of its solutions by ammonia, is redissolved by pro-

longed ebullition, but this is observed more especially when precipitated from the oxalate or acetate of glucina.

Chloride of glucinum, is prepared by the same process as the chloride of aluminium, merely substituting glucina for alumina, and at first sight very much resembles it; it is, however, much less volatile than chloride of aluminium, being about as volatile as chloride of zinc. It differs also from chloride of aluminium inasmuch as it is not capable of forming definite compounds with some protochlorides; chloride of aluminium uniting with certain protochlorides forming a series of compounds, fusible at a low temperature, volatile at a red heat without decomposition; and the composition of which is represented by the formula $AlPCl + NCl$. The crystals of chloride of aluminium may be called chlorinated spinelles, and are easily obtained, it being only necessary, in order to form the sodium compound of the group, to mix the chloride of aluminium with half its weight of common salt, and distil, one distillation producing it pure, the formula of it being $AlPCl + NaCl$. Chloride of glucinum is very soluble in water; it may, however, be obtained in crystals, by allowing its solution to evaporate over sulphuric acid under a bell jar. The presence of a little free hydrochloric acid favours the crystallisation. Thus obtained, this salt is a hydrate, and according to Awdejew its formula is $GlCl + 4HO$. The hydrated chloride of glucinum is decomposed by heat into hydrochloric acid and glucina.

Iodide of glucinum.—This compound presents all the characters of the chloride, only being a little less volatile. The affinity of iodine for glucinum, is not very strong, oxygen decomposing the iodide at the heat of a spirit lamp, liberating iodine and forming glucina.

Glucinum is also capable of combining with fluorine; the double fluoride of glucinum and potassium being formed by pouring a solution of fluoride of potassium into a salt of glucina. It is but little soluble in the cold, and is deposited in the form of brilliant scales.

Sulphate of glucina.—This salt is white, has an acid and slightly sweet taste. It is unalterable in the air at ordinary temperatures but effloresces in dry and warm air. By heat, it first fuses, in its water of crystallisation, then at a red heat is decomposed into sulphurous acid, oxygen, and glucina.

Water at $57^{\circ} F.$ ($14^{\circ} C$) dissolves about its own weight of this salt; its solubility is increased by heat, and boiling water dissolves an indefinite quantity. The presence of free sulphuric acid or alcohol lessens its solubility.

It loses a portion of its acid in many cases with facility; for instance, we obtain an uncrystallisable tribasic sulphate of glucina, by dissolving carbonate of glucina in a concentrated solution of the sulphate; carbonate of glucina is added until carbonic acid ceases to be liberated at each addition; the liquid filtered and evaporated gives a gummy residue. The very dilute solution of this salt lets fall some glucina, and is changed into a dibasic sulphate, also uncrystallisable.

Sulphate of glucina dissolves zinc with disengagement of hydrogen, forming a dibasic sulphate of glucina and sulphate of zinc. Sulphate of alumina, under the same circumstances, dissolves zinc with liberation of hydrogen, and forms a sulphate of zinc and an insoluble subsulphate of alumina. Taking advantage of this difference, Debray proposed a method (*Ann. Chym. et Phys.* xlv. 26), for the separation of alumina and glucina, but which does not answer for analytical purposes, as chemically pure zinc is only acted on with great difficulty by these sulphates. Sulphate of glucina is formed by dissolving the carbonate in dilute sulphuric acid, the evaporated liquid depositing it on cooling. It is essential to keep the liquid distinctly acid; it assists the crystallisation, and besides, if we were to dissolve the carbonate in it until the liberation of carbonic acid ceased, we should obtain a basic uncrystallisable salt. According to Awdejew the formula of this salt is

Double sulphate of glucina and potash.—This salt was discovered by Awdejew; he obtained it while endeavouring to produce the double sulphate of glucina and potash corresponding to common alum (which, had he succeeded, would have been one of the best proofs of the analogy existing between alumina and glucina).

It is obtained in crystalline crusts, by evaporating a solution containing 15 parts of sulphate of glucina to 14 parts of sulphate of potash. The concentration is stopped as soon as the liquid becomes turbid; at the end of a few hours this salt is deposited, which is purified by recrystallisation. It is precipitated as a crystalline powder by the addition of sulphuric acid to the concentrated solution. It is but little soluble in the cold, much more so, though slowly, in hot water. By the action of heat it first fuses in its water of crystallisation, then is decomposed entirely into glucina and sulphate of potash, if the heat is strong and long enough applied. Its composition is represented by the formula

Carbonate of glucina.—Glucina is soluble in carbonate of ammonia. When the solution is boiled, carbonate of ammonia is driven off, and a precipitate of carbonate of glucina is formed, the composition of which seems to be

but if we arrest the boiling as soon as the solution becomes turbid, we obtain a solution of a double carbonate of glucina and ammonia, from which, by the addition of alcohol, this salt is deposited in clear crystals. *Double carbonate of glucina and ammonia* is white, very soluble in cold water, but is easily decomposed by hot water, liberating carbonate of ammonia and depositing carbonate of glucina. It is much less soluble in dilute alcohol, and nearly insoluble in absolute alcohol. It is easily decomposed by heat, leaving as a residue pure glucina.

It is also decomposed by exposure to the air after some time. According to Debray the formula of this salt is

There also exists a double carbonate of potash and glucina corresponding to this salt, and is prepared by the same process, merely substituting carbonate of potash for carbonate of ammonia; the carbonate of potash, however, takes longer to dissolve the glucina than carbonate of ammonia.

Oxalic acid dissolves glucina but does not yield any crystallisable compounds, except in combination with other oxalates, as the oxalate of potash or ammonia.

These double salts crystallise well and have the following simple composition:—

These salts are obtained by dissolving carbonate of glucina in binoxalate of ammonia or potash in the cold, until carbonic acid ceases to be given off. They decrepitate by the application of heat. The composition of glucina is still undecided; herself as regarding it as a sesquioxide, and Andrjew and others as a protoxide. The latter view gives greater simplicity in the formula of its compounds, but glucina has no decided analogy in the ordinary class of protoxides, lime and magnesia, &c.—H. K. B.

GLUCOSE. The name given to grape and starch sugar by M. Dumas. See SUGAR.

GLUE. (*Calle forte*, Fr.; *Leim*, *Tischlerleim*, Germ.) is the chemical substance glutine in a dry state. The preparation and preservation of the skin and other animal matters employed in the manufacture of glue, constitute a peculiar branch of industry. Those who exercise it should study to prevent the fermentation of the substances, and to diminish the cost of carriage by depriving them of as much water as can conveniently be done. They may then be put in preparation by macerating them in milk of lime, renewed three or four times in the course of a fortnight or three weeks. This process is performed in large tanks of masonry. They are next taken out with all the adhering lime, and laid in a layer, 2 or 3 inches thick, to drain and dry, upon a sloping pavement, where they are turned over by prongs two or three times a day. The action of the lime dissolves the blood and certain soft parts, attacks the epidermis, and dissolves the gelatinous matter to dissolve more readily. When the cleansed matters are dried, they may be packed in sacks or hogheads, and transported to the glue manufactory at any distance. The principal substances of which glue is made are the parings of ox and other thick hides, which form the strongest article, the refuse of the leather dresser; both afford from 45 to 55 per cent. of glue. The tendons, and many other offals of slaughter-houses, also afford materials, though of an inferior quality, for the purpose. The refuse of tanneries, such as the ears of oxen, calves, sheep, &c., are better articles; but parings of parchment, old gloves, and, in fact, animal skin in every form, uncombined with tannin, may be made into glue.

The manufacturer who receives these materials is generally careful to ensure their purification by subjecting them to a weak lime steep, and rinsing them by exposure in baskets to a stream of water. They are lastly drained upon a sloping surface and well turned over till the quicklime gets mild by absorption of carbonic acid; for, in its caustic state, it would damage the glue at the heat of boiling water. It is not necessary, however, to dry them before they are put into the boiler, because they dissolve faster in their soft and tanned state.

The boiler is made of copper, rather shallow in proportion to its area, with a uniform flat bottom, equally exposed all over to the flame of the fire. Above the true bottom there is a false one of copper or iron, pierced with holes, and standing upon feet 3 or 4 inches high, which serves to sustain the animal matters, and prevent them from being injured by the fire. The copper being filled to two-thirds of its height with soft water, is then heaped up with the bulky animal substances, so high as to mount its brim. But soon after the ebullition begins they sink down, and, in a few hours, get entirely immersed in the liquid. They should be stirred about from time to time,

and well pressed down towards the false bottom, while a steady but gentle boil is maintained.

The solution must be drawn off in successive portions: a method which fractions the products, or subdivides them into articles of various value, gradually decreasing from the first portion drawn off to the last. It has been ascertained by careful experiments that gelatine gets altered over the fire very soon after it is dissolved, if the heat of 212° is maintained, and it ought therefore to be drawn off whenever it is sufficiently fluid and strong for forming a clear gelatinous mass on cooling, capable of being cut into moderately firm slices by the wire. The point is commonly determined by filling half an egg-shell with the liquor, and exposing it to the air to cool. The jelly ought to get very consistent in the course of a few minutes; if not so, the boiling must be persisted in a little longer. When this term is attained, the fire is smothered up, and the contents of the boiler are left to settle for a quarter of an hour. The stop-cock being partially turned, all the thin gelatinous liquor is run off into a deep boiler, immersed in a warm water bath, so that it may continue hot and fluid for several hours. At the end of this time the supernatant clear liquid is to be drawn off into congealing boxes, as will be presently explained.

The grounds, or undissolved matters in the boiler, are to be again supplied with a quantity of boiling water from an adjoining copper, and are to be once more subjected to the action of the fire, till the contents assume the appearance of dissolved jelly, and afford a fresh quantity of strong glue liquor, by the stop-cock. The grounds should be subjected a third time to this operation, after which they may be put into a bag, and squeezed in a press to leave nothing unextracted. The latter solutions are usually too weak to form glue directly, but they may be strengthened by boiling with a portion of fresh skin-parings.

Fig. 913 represents a convenient apparatus for the boiling of skins into glue, in

which there are three coppers upon three different levels; the uppermost being acted upon by the waste heat of the chimney, provides warm water in the most economical way; the second contains the crude materials, with water for dissolving them; and the third receives the solution to be settled. The last vessel is double, with water contained between the outer and inner one; and discharges its contents by a stop-cock into buckets for filling the gelatinising wooden boxes. The last made solution has about one-five-hundredth part of alum in powder usually added to it, with proper agitation, after which it is left to settle for several hours.

The three successive boils furnish three different qualities of glue.

Flanders or Dutch glue, long much esteemed on the Continent, was made in the manner above described, but at two boils, from animal offals well washed and soaked, so as to need less boiling. The liquor being drawn off thinner, was therefore less coloured, and being made into thinner plates was very transparent. The above two boils gave two qualities of glue.

By the English practice, the whole of the animal matter is brought in solution at once, and the liquor being drawn off, hot water is poured on the residuum, and made to boil on it for some time, when the liquor thus obtained is merely used instead of water upon a fresh quantity of glue materials. The first drawn off liquor is kept hot in a settling copper for five hours, and then the clear solution is drawn off into the boxes.

These boxes are made of deal, of a square form, but a little narrower at bottom than at top. When very regular cakes of glue are wished for, cross grooves of the desired square form are cut in the bottom of the box. The liquid glue is poured into the boxes placed very level, through funnels furnished with filter cloths, till it stands at the brim of each. The apartment in which this is done ought to be as cool and dry as possible, to favour the solidification of the glue, and should be floored with stone flags kept very clean, so that if any glue run through the seams, it may be recovered. At the end of 12 or 18 hours, or usually in the morning if the boxes have been filled over-night, the glue is sufficiently firm for the nets, and they are at this time removed to an upper story, mounted with ventilating windows to admit the air from all quarters. Here the boxes are inverted upon a riven table, so that the gelatinous cake thus turned out will not adhere to its surface; usually the moist blade of a long knife is insinuated round the sides of the boxes beforehand, to loosen the glue. The mass is first divided into horizontal layers by a brass wire stretched in a frame, like that of a bow-saw, and guided by rulers which are placed at distances corresponding to the desired thickness of the cake of glue. The lines formed by the guides in the bottom of the box define the superficial area of each cake, where it is to be cut with a moist knife. The gelatinous layers thus formed, must be dextrously lifted, and immediately laid upon nets stretched in wooden frames, till each frame be filled. These frames are set over each other at distances of about three inches, being supported by small wooden pegs, stuck into mortise holes in an upright, fixed round the room, so that the air may have perfectly free access on every side. The cakes must moreover be turned upside down upon the nets twice or thrice every day, which is readily managed, as each frame may be slid out like a drawer, upon the pegs at its two sides.

The drying of the glue is the most precarious part of the manufacture. The least disturbance of the weather may injure the glue during the two or three first days of its exposure; should the temperature of the air rise considerably, the gelatine may turn so soft as to become enshaped, and even to run through the meshes upon the pieces below, or it may get attached to the strings and surround them, so as not to be separable without plunging the net into boiling water. If frost supervene, the water may freeze and form numerous cracks in the cakes. Such pieces must be immediately re-melted and re-formed. A slight fog even produces upon glue newly exposed a serious deterioration; the damp condensed upon its surface occasioning a general mouldiness. A thunderstorm sometimes destroys the regulating power in the whole lamina at once; or causes the glue to *turn* on the nets, in the language of the manufacturer. A wind too dry or too hot may cause it to dry so quickly, as to prevent it from contracting to its proper size without numerous cracks and fissures. In this predicament, the closing of all the flaps of the windows is the only means of abating the mischief. On these accounts it is of importance to select the most temperate season of the year, such as spring and autumn, for the glue manufacture.

After the glue is dried upon the nets it may still preserve too much flexibility, or softness at least, to be saleable; in which case it must be dried in a stove by artificial heat. This aid is peculiarly requisite in a humid climate, like that of Great Britain.

When sufficiently dry it next receives a gloss, by being dipped, cake by cake, in hot water, and then rubbed with a brush, also moistened in hot water; after which the glue is arranged upon a hurdle, and transferred to the stove room, if the weather be not sufficiently hot. One day of proper drought will make it ready for being packed up in casks.

The pale coloured, hard, and solid article, possessing a brilliant fracture, which is made from the parings of ox-bones by the first process, is the best and most cohesive, and is most suitable for joiners, cabinet-makers, painters, &c. But many workmen are influenced by such ignorant prejudices, that they still prefer a dark-coloured article, with somewhat of a fetid odour, indicative of its impurity and bad preparation, the result of bad materials and too long exposure to the boiling heat.

There is a good deal of glue made in France from bones freed from the phosphate of lime by muriatic acid. This is a poor article, possessing little cohesive force. It dissolves almost entirely in cold water, which is the best criterion of its imperfection. Glue should merely soften in cold water, and the more considerably it swells, the better, generally speaking, it is.

Some manufacturers prefer a brass to a copper pan for boiling glue, and insist much on skimming it as it boils; but the apparatus represented renders skimming of little consequence. For use, glue should be broken into small pieces, put along with some water into a vessel, allowed to soak for some hours, and subjected to the heat of a boiling-water bath, but not boiled itself. The surrounding hot water keeps it long in a fit state for joiners, cabinet-makers, &c.

Water containing only one-hundredth part of good glue, forms a tremulous solid. When the solution, however, is heated and cooled several times, it loses the property of gelatinising, even though it be enclosed in a vessel hermetically sealed. Isinglass or fish glue undergoes the same change. Common glue is not soluble in alcohol, but is precipitated in a white, coherent, elastic mass, when its watery solution is treated with that fluid. By transmitting chlorine gas through a warm solution of glue, a combination is very readily effected, and a viscid mass is obtained like that thrown down by alcohol. A little chlorine suffices to precipitate the whole of the glue. Concentrated sulphuric acid makes a glue undergo remarkable changes; during which are produced sugar of gelatine, leucine, an animal matter, &c. Nitric acid, with the aid of heat, converts glue into malic acid, oxalic acid, a fat analogous to suet, and into tanning; so that, in this way, one piece of skin may be made to tan another. When the mixture of glue and nitric acid is much evaporated, a detonation at last takes place. Strong acetic acid renders glue first soft and transparent, and then dissolves it. Though the solution does not gelatinise, it preserves the property of glueing surfaces together when it dries. Liquid glue dissolves a considerable quantity of lime, and also of the phosphate of lime recently precipitated. Accordingly glue is sometimes contaminated with that salt. Tannin both natural and artificial combines with glue; and with such effect, that one part of glue dissolved in 5000 parts of water affords a sensible precipitate with the infusion of nuxgalla. Tannin unites with glue in several proportions, which are to each other as the numbers 1, 1½, and 2; one compound consists of 100 glue and 29 tannin; another of 100 glue and 60 tannin; and a third of 100 glue and 120 tannin. These two substances cannot be afterwards separated from each other by any known chemical process.

Glue may be freed from the foreign animal matters generally present in it, by softening it in cold water, washing it with the same several times till it no longer gives out any colour, then bruising it with the hand, and suspending it in a linen bag beneath the surface of a large quantity of water at 60° F. In this case, the water loaded with the soluble impurities of the glue gradually sinks to the bottom of the vessel, while the pure glue remains in the bag surrounded with water. If this softened glue be heated to 92° without adding water, it will liquefy; and if we heat it to 122°, and filter it, some albuminous and other impurities will remain on the filter, while a colourless solution of glue will pass through.

Experiments have not yet explained how gelatine is formed from skin by ebullition. It is a change somewhat analogous to that of starch into gum and sugar, and takes place without any appreciable disengagement of gas, and even in close vessels. Gelatine, says Berzelius, does not exist in the living body, but several animal tissues, such as skin, cartilages, hartshorn, tendons, the serous membranes, and bones, are susceptible of being converted into it. See GELATINE.

GLUTEN (*Colle Vegetale* and *Gluten*, Fr.; *Kleber*, Germ.) was first extracted by Beccaria from wheat flour, and was long regarded as a proximate principle of plants, till Kihnhoff, Taddel, and Berzelius succeeded in showing that it may be resolved by means of alcohol into three different substances, one of which resembles closely animal albumine, and has been called *Zymone*, or vegetable albumine; another has been called *Gladine*; and a third *Mucine*.

Gluten, when dried in the air or a stove, diminishes greatly in size, becomes hard, brittle, glistening, and of a deep yellow colour. It is insoluble in ether, in fat and essential oils, and nearly so in water. Alcohol and acetic acid cause gluten to swell and make a sort of milky solution. Dilute acids and alkaline lyes dissolve gluten. Its ultimate constituents are not determined, but azote is one of them, and accordingly when moist gluten is left to ferment, it exhales the smell of old cheese.

Some years since, M. E. M. Martin, of Vervins, proposed to extract the starch without injuring the gluten, which then becomes available for alimentary purposes. His process is a mechanical one (resembling that long practised in laboratories for procuring gluten), and consists in washing wheat flour, made into a paste, with water, either by the hand or machinery.

The gluten thus obtained is susceptible of numerous useful applications for alimentary purposes. Mixed with wheat flour, in the proportions of 30 parts of flour, 10 of fresh gluten, and 7 of water, it has been employed to produce a superior sort of macaroni, vermicelli, and other kinds of Italian pastes; and M. M. Viron Frères, of Paris, have made with it a new sort of paste, which they have termed *granulated gluten* (*gluten granulé*).

GLYCERINE is a sweet substance extracted from fatty substances. It may be prepared in the utmost purity by the following process:—If we take equal parts of olive oil and finely-ground bluisharge, put them into a basin with a little water, set this on a sand bath moderately heated, and stir the mixture constantly, with the occasional addition of hot water to replace what is lost by evaporation, we shall obtain, in a short

time, a soap or plaster of lead. If, after having added more water to this, we remove the vessel from the fire, decant the liquor, filter it, pass sulphuretted hydrogen through it to separate the lead, then filter afresh, and concentrate the liquor as much as possible without burning; upon the sand-bath, we obtain glycerine; but what remains must be finally evaporated within the receiver of the air-pump. Glycerine thus prepared is a transparent liquid, without colour or smell, and of a syrupy consistence. It has a very sweet taste. Its specific gravity is 1.27 at the temperature of 60°. When thrown upon burning coals, it takes fire and burns like an oil. Water combines with it in almost all proportions; alcohol dissolves it readily; nitric acid converts it into oxalic acid; and, according to Vogel, sulphuric acid transforms it into sugar, in the same way as it does starch. By yeast it becomes acid by the formation of formic and metacetic acids.

Its constituents are, carbon 40, hydrogen 9, oxygen 51, in 100.

Glycerine is one of the products of the saponification of fat oils. It is produced in large quantities in the soap manufactory in a very impure state, being contaminated with saline and empyreumatic matters, and having a very strong disagreeable odour. In order to obtain glycerine from this source, the residuary liquors are evaporated and treated with alcohol, which dissolves out the glycerine. The alcohol having been separated by evaporation, the glycerine is diluted with water, and boiled with animal charcoal. This process must be repeated several times, or until the result is sufficiently free from smell. It is, however, difficult to obtain pure glycerine from this source, on account of the nature and condition of the ingredients usually employed in making soap, which it is almost impossible to deprive of rancid odour.

The compounds of glycerine with the fatty acids constitute the various kinds of fats and oils, but the base does not appear to have the same composition in all. A certain quantity of water appears to separate, and the equivalent of glycerine to be in some fats but half what it is in others. Thus the glycerine of the palm oil has the formula $C_{11}H_{19}O$, and the glycerine of myristine, or nutmeg butter, $C_{11}H_{19}O$, of which bodies the common glycerine should be the hydrate.

Glycerine is now obtained in great quantities from palm oil, in the process of purification for candles. It is employed with much advantage to preserve soft bodied animals. It is manufactured into soap, is administered internally, and is supposed to possess highly nutritive properties. It has been employed in cases of deafness, and in diseases of the throat. By some it is used to preserve collodion plates in a state of sensitiveness for many days.

GLYPHOGRAPHY. A process introduced some years since to cheapen wood engraving. A metal plate was covered with a thick etching-ground, and an etching made through to the metal in the usual manner. Several coats of ink were then applied by means of a small composition roller. This adheres only to the varnish. When the hollows are deep enough, the plate is placed in connection with a voltaic battery, and copper is deposited in the usual way (see *ELECTRO-METALLURGY*); the result being a plate with the drawing in relief. The process is rarely practised.

GNEISS may be called stratified, or, by those who object to that term, foliated granite, being formed of the same materials as granite, namely, felspar, quartz, and mica.—*Lyell*.

Gneiss might indeed, in its purest and most typical form, be termed schistose granite, consisting, like granite, of felspar, quartz, and mica; but having these minerals arranged in layers or strata, rather than in a confused aggregation of crystals.—*Jukes*.

In whatever state of aggregation the particles of gneiss may have been originally deposited, we know now that it is a hard, tough, crystalline rock, exhibiting curved and twisted lines of stratification, and composed in the main of quartz, felspar, mica, and hornblende. Mineralogically speaking, it differs from the granite rocks with which it is associated chiefly in this, that while the crystals of quartz, felspar, &c., are distinct and entire in granite, in gneiss they are broken, water-worn, and confusedly aggregated. Hence the general belief is, that gneiss or gneissose rocks are but the particles of granite weathered and worn, carried down by streams and rivers, and deposited in the seas of that early period.—*Lyell*.

GOBELIN MANUFACTORY. This establishment, which has been long celebrated for its tapestry, took its name from the brothers Gobelin. One Gobelin, a dyer at Paris, in the time of Francis I., had found out an improvement in the then usual scarlet dye; and as he had remarked that the water of the rivulet *leuvre*, in the suburbs of St. Marcan, was excellent for his art, he erected on it a large dye house, which, out of ridicule, was called *Folie-Gobelins* (*Rebelin*). About this period a Flemish painter, whose name some name Peter Kock, and others Klock, and who had travelled a long time in the East, established, and continued to his death in 1550, a manufactory for dyeing scarlet cloth by an improved process. Through the means of Colbert, minister of Louis XIV., one of the Gobelins learned the process used for

preparing the German scarlet dye from one Gluck, whom some consider to be Gulick (who was said to have learned to dye scarlet from one Kuffelar, a dyer at Leyden), and others as Kloeck; and the Parisian scarlet dye soon rose into so great repute that the populace imagined that Gobel in had acquired the art from the devil. It is known that Louis XIV., by the advice of Colbert, purchased Gobel in's building from his successors in 1667, and transformed it into a palace, to which he gave the name of *Hôtel Royal des Gobelins*, and which he assigned for the use of first-rate artists, particularly painters, jewellers, weavers of tapestry, and others.—*Beckmann*.

The national manufactory is now alone remarkable for its production in textile manufacture of some of the finest works of art: and not only does it excel in the high character of its designs, but also in the brilliancy and permanence of its colours.

GOLD. (Eng. and Germ.; Or, Fr.) This metal is distinguished by its splendid yellow colour; its great density = 19.3 compared to water 1.0; its fusibility at the 32nd degree of Wedgewood's pyrometer; its pre-eminent ductility and malleability, whence it can be beaten into leaves only 1-262,000th of an inch thick; and its insolubility in any acid menstruum, except the mixture of muriatic and nitric acids,—styled by the alchemists *aqua regia*, because gold was deemed by them to be the king of metals,—or in solutions of chlorine.

Gold is found only in the metallic state, sometimes crystallized in the cube, and its derivative forms. It occurs also in threads of various sizes, twisted and interlaced into a chain of minute octahedral crystals; as also in spangles or rounded grains, which when of a certain magnitude are called *pepitas*. The small grains are not fragments broken from a greater mass; but they show by their flattened ovoid shape and their rounded outline that this is their original state. The spec. grav. of native gold varies from 13.3 to 17.7. Humboldt states that the largest *pepita* known was one found in Peru weighing about 12 kilogrammes (26½ lbs. avoird.); but masses have been quoted in the province of Quito which weighed nearly four times as much. Some of the " nuggets " from Australia have greatly exceeded this.

Another ore of gold is the alloy with silver, or argental gold, the *electrum* of Pliny. It seems to be a definite compound, containing in 100 parts, 64 of gold and 36 of silver.

The mineral formations in which this metal occurs are the crystalline primitive rocks, the compact transition rocks, the trachytic and trap rocks, and alluvial grounds. Sir Roderick Murchison says, in his chapter *On the Original Formation of Gold*, in his "Silurian":—"We may first proceed to consider the nature and limits of the rich gold-bearing rocks, and then offer proofs, that the chief auriferous wealth, as derived from them, occurs in superficial detritus. Appealing to the structure of the different mountains, which at former periods have afforded, or still afford, any notable amount of gold, we find in all a general agreement. Whether, referring to past history, we cast our eyes to the countries watered by the sources of the Golden Tagus, to the Phrygia and Thrace of the Greeks and Romans, to the Bohemia of the Middle Ages, to tracts in Britain which were worked in old times, and are now either abandoned, or very slightly productive, or to those chains in America and Australia which, previously unsearched, have in our times, proved so rich, we invariably find the same constants in nature. In all these lands, gold has been imparted abundantly to the ancient rocks only, whose order and succession we have traced, or their associated eruptive rocks. Sometimes, however, it is also shown to be diffused through the body of such rocks, whether of igneous or of aqueous origin. The stratified rocks of the highest antiquity, such as the oldest gneiss and quartz rocks (like those, for example, of Scandinavia and the northern Highlands of Scotland), have very seldom borne gold; but the sedimentary accumulations which followed, or the Silurian, Devonian, and carboniferous (particularly the first of these three) have been the deposits which, in the tracts where they have undergone a metamorphosis or change of structure by the influence of igneous agency, or other causes, have been the chief sources whence gold has been derived."

Gold is usually either disseminated, and as it were impasted in stony masses, or spread out in thin plates or grains on their surface, or, lastly, implanted in their cavities, under the shape of filaments or crystallized twigs. The minerals composing the veins are either quartz, calcspar, or sulphate of barite. The ores that accompany the gold in these veins are chiefly iron pyrites, copper pyrites, galena, blende, and mispickel (arsenical pyrites).

In the ores called auriferous pyrites, this metal occurs generally in an invisible form; but though invisible in the fresh pyrites the gold becomes visible by its decomposition; as the hydrated oxide of iron allows the native gold particles to shine forth on their reddish-brown ground, even when the precious metal may constitute only the five millionth part of its weight, as at Rammelsberg to the Harz. In that state it has been extracted with profit; most frequently by amalgamation with mercury, proving

that the gold was in the native state, and not in that of a sulphuret. The iron pyrites of Wicklow, and of some of our English mines contain gold. After the sulphur of the ore has been separated in the process of manufacturing sulphuric acid, the residuary mass, called "sulphur cake," is roasted with common salt. This is thrown into hot water, the copper which is present, is dissolved as muriate of copper. The silver present has been converted by the roasting process into a chloride; this is dissolved out with a strong brine, from which the silver is precipitated by zinc. The silver cake obtained in this way is sold from prices varying from 6s. to 10s. the ounce the additional sum above 5s. 6d. the ounce for pure silver being given for the gold it contains.

Gold exists among the primitive strata, disseminated in small grains, spangles, and crystals. Brazil affords a remarkable example of this species of gold mine. Beds of granular quartz, or micaceous specular iron, in the Sierra de Cochis, 12 leagues beyond Villa Rica, which form a portion of a mica-slate district, includes a great quantity of native gold in spangles, which in this ferruginous rock replace mica.

The auriferous ores of Hungary and Transylvania, composed of tellurium, silver pyrites or sulphuret of silver, and native gold, lie in masses or powerful veins in a rock of trachyte, or in a decomposed felspar subordinate to it. Such is the locality of the gold ore of Konigsberg, of Tokobanya, between Eperies and Tokay in Hungary, and probably that of the gold ores of Kapnik, Felsobanya, &c., in Transylvania; an arrangement nearly the same with what occurs in Equatorial America. The auriferous veins of Guanajuato, of Real del Monte, of Villalpando, are similar to those of Schrenitz in Hungary, as to magnitude, relative position, the nature of the ores they include, and of the rocks they traverse. These districts have impressed all mineralogists with the evidences of the action of volcanic fire. Breislak and Haecquet have described the gold mines of Transylvania as situated in the crater of an ancient volcano. It is certain that the trachytes which form the principal portions of the rocks including gold, are now almost universally regarded as of igneous or volcanic origin.

It would seem, however, that the primary sources of the gold is not in these rocks, but rather in the sienites and greenstone porphyries below them, which in Hungary and Transylvania are rich in great auriferous deposits; for gold has never been found in the trachyte of the Euganean mountains, of the mountains of the Vicentin, or of those of Auvergne; all of which are superposed upon granite rocks, barren in metal.

Finally, if it be true that the ancients worked mines of gold in the island of Ichia, it would be another example, and a very remarkable one, of the presence of this metal in trachytes of an origin evidently volcanic.

Gold is, however, much more common in the alluvial grounds than among the primitive rocks just described. It is found disseminated in the siliceous, argillaceous, and ferruginous sands of certain plains and rivers, especially in their re-entering angles, at the season of low water, and after storms and temporary floods. On the occurrence of gold, Dr. Ure remarks: "It has been supposed that the gold found in the beds of rivers had been torn out by the waters from the veins and primitive rocks, which they traverse. Some have even searched, but in vain at the source of auriferous streams for the native bed of this precious metal. The gold in them belongs, however, to the grounds washed by the waters as they glide along. This opinion, suggested at first by Delius, and supported by Deborn, Guettard, Robinet, Balbo, &c., is founded upon just observations. 1. The soil of these plains contains frequently, at a certain depth, and in several spots, spangles of gold, separable by washing. 2. The beds of the auriferous rivers and streamlets contain more gold after storms of rain upon the plains than in any other circumstances. 3. It happens almost always that gold is found among the sands of rivers only in a very circumscribed space; on ascending these rivers their sands cease to afford gold; though did this metal come from the rocks above, it should be found more abundantly near the source of the rivers. Thus it is known that the Oron contains no gold except from Font to its junction with the Po. The Ticino affords gold only below the Lago Maggiore, and consequently far from the primitive mountains, after traversing a lake, where its course is slackened, and into which whatsoever is carried down from these mountains must have been deposited. The Rhine gives more gold near Strasburg than near Basle, though the latter be much closer to the mountains. The sands of the Danube do not contain a grain of gold, while this river runs in a mountainous region; that is, from the frontiers of the bishoprick of Passau to Esserding; but its sands become auriferous in the plains below. The same thing is true of the Enns; the sands of the upper portion of this river, as it flows among the mountains of Styria, include no gold; but from its entrance into the plain at Stryer, till its embouchure in the Danube, its sands become auriferous, and are even rich enough to be washed with profit.

The greater part of the auriferous sands, in Europe, Asia, Africa, and America, are black or red, and consequently ferruginous; a remarkable circumstance in the geological position of alluvial gold. M. Napoleon supposes that the gold of these ferruginous grounds is due to the decomposition of auriferous pyrites. The auriferous sand occurring in Hungary almost always in the neighbourhood of the beds of lignites, and the petrified wood covered with gold grains, found buried at a depth of 55 yards in clay, in the mine of Vorospatak near Abrahanya in Transylvania, might lead us to presume that the epoch of the formation of the auriferous alluvia is not remote from that of the lignites. The same association of gold ore and fossil wood occurs in South America, at Micoa. Near the village of Iloro have been discovered, at a depth of 20 feet, large trunks of petrified trees, surrounded with fragments of trap rocks interspersed with spangles of gold and platinum. But the alluvial soil affords likewise all the characters of the basaltic rocks; thus in France, the Cèze and the Gardon, auriferous rivers, where they afford most gold, flow over ground apparently derived from the destruction of the trap rocks, which occur *in situ* higher up the country. This fact had struck Rensselaer, and this celebrated observer had remarked that the sand which more immediately accompanies the gold spangles in most rivers, and particularly in the Rhone and the Rhine, is composed, like that of Ceylon and Espailly, of black protoxide of iron and small grains of rubies, corundum, hyacinth, &c. Titanium has been observed more recently. It has, lastly, been remarked that the gold of alluvial formations is purer than that extracted from rocks."

Principal Gold Mines.

Spain anciently possessed mines of gold in regular veins, especially in the province of Asturias; but the richness of the American mines caused them to be neglected. Julius Cæsar is said to have paid his enormous debts, and have added largely to the Roman treasury, from the wealth which he derived from the Spanish mines. The Tagus, and some other streams of that country, were said to roll over golden sands. France contains no workable gold mines; but it presents in several of its rivers auriferous sands. There are some gold mines in Piedmont; particularly the veins of auriferous pyrites of Macagnagna, at the foot of Monte Rosa, lying in a mountain of gneiss; and although they do not contain 10 or 11 grains of gold in a hundred-weight, they have long defrayed the expense of working them. On the southern slope of the Pennine Alps, from the Simplon and Monte Rosa to the valley of Aoste, several auriferous districts and rivers occur. Such are the torrent Evenson, which has afforded much gold by washing; the Orco, in its passage from the Pont to the Po: the reddish grounds over which this little river runs for several miles, and the hills in the neighbourhood of Chivasso, contain gold spangles in considerable quantity.

In the county of Wicklow, in Ireland, in the year 1796, some fine specimens of gold were found,—one mass weighing twenty-two ounces. The gold is found in the debris of the valley at the base of Crughan-Kinabola; and it would appear to be derived from the granite of that mountain, or the hornblende greenstones by which it is traversed. Messrs. Weaver and Mills, however, prosecuted extensive mine workings in search of the source of the gold without any success. As we have already stated, the pyrites of Wicklow contain gold, but no auriferous veins have been discovered. In Cornwall gold has been found in the tin streams of Carnon vale, and some few other spots; and some of the quartz veins traversing the slate have been found to contain gold. Many of the gossans of the copper lodes are known to have gold in them; but it is only in a few rare instances that the precious metal has been separated.

In Devonshire, near North Molton, at the Britannia mine, gold has been found in small quantities, associated with the minerals of the district; but it has never paid the cost of obtaining it. In Scotland also gold has been found. Pennant says: "In the reigns of James IV. and V. of Scotland, vast wealth was procured in the Lead Hills, from the gold washed from the mountains; in the reign of the latter not less than the value of 300,000*l.* sterling." We are told that in another locality a piece of gold weighing thirty ounces was found; but we cannot find any good authority for this statement.

In North Wales, especially in Merionethshire, the older slaty rocks were declared some ten years since to be auriferous. Professor Ramsay has examined and described the district, and especially the mineral and quartz veins of Cwm-isen-isaf and Dol-y-fwynog, which contain gold. This district has been worked for gold for some time; but in no case, we believe, to a profit. At Gogofau, not far from Llandoverly, the Romans worked for gold, the remains of their workings being still to be discovered. They have been described by Mr. W. Warington Smyth in the *Memoirs of the Geological Survey*.

There are sulphureous sands in some rivers of Switzerland, as the Rhone and the Aar. In Germany no use of gold is worked, except in the territory of Salzburg, amid the chain of mountains which separate the Tyrol and Carinthia.

The mines of Hungary and Transylvania are the only gold mines of any importance in Europe. They are remarkable for their production of the peculiar metals that accompany them, and their product, estimated at about 1400 pounds avoirdupois annually. The principal ones are in Hungary, 1, those of Krasnaberg; the native gold is disseminated in ores of sulphurets of silver, which occur in small masses and in veins in a decomposing felspar rock, and a conglomerate of pumice, constituting a portion of the trachytic formation; 2, those of Borsabánya, Schellenitz; and 3, of Felshánya, ores also of auriferous sulphurets of silver occur in veins of sienite and greenstone porphyry; 4, those of Felshánya, to the south of Kaschan, are in a deposit of auriferous pyrites amid trap rocks of the same volcanic formation.

In Transylvania the gold occurs in veins, often of great magnitude. These veins have no side plates or wall rock, but abut, without intermediate gangues, the primitive rock. They consist of decomposing quartz, ferriferous limestone, heavy spar, fluor spar, and sulphuret of silver. The mine of Kapuská serves as an example, where the gold is associated with arsenic, and that of Várpatak in granite rocks; those of Offhánya, Zalatna, and Nagy-Ag, where it is associated with tellurium. The last is in a sienite rock on the limits of the trachyte.

In Sweden, the mine of Hålfors in Småland may be mentioned, where the gold occurs native and in auriferous pyrites; the veins are a brown quartz, in a mountain of foliated hornstone.

In Siberia, native gold occurs in a hornstone at Schlangenberg or Zerkof, and at Zmeinogorsk in the Altai mountains, accompanied with many other ores.

The gold mine of Beresovsk in the Ural mountains has been long known, consisting of partially decomposed *argyrous pyrites*, disseminated in a vein of gray quartz. This is, according to Marchison, "the only work at which auriferous mining in the solid rock is still practised; there the shaft traverses a mass of apparently metamorphosed and crystalline matrix called 'beresite,' resembling a decomposed granite with veins of quartz, in which some gold is disseminated." About 1820, a very rich deposit of native gold was discovered on the eastern side of the Ural mountains, disseminated at some yards deep in an argillaceous loam, and accompanied with the debris of rocks which usually compose the auriferous alluvial soils, as greenstone, serpentine, protomile of iron, corundum, &c. The rivers of this district possess auriferous sands.

At the Solimanofsk mines, south of Miask, great piles of ancient drift or gravel having been removed for the extraction of gold, the eroded edges of highly inclined crystalline limestones have been exposed, which, from being much nearer the centre of the chain than the above, are probably of Silurian or Devonian age. It is from the adjacent eruptive serpentinous masses and slaty rocks that the gold shingle c (usually most auriferous near the surface of the abraded rock a) has been derived.

The tops of the highly inclined beds a are in fact rounded off, and the interstices between them worn into holes and cavities, as if by very powerful action of water. Now here, as at Beresovsk, mammoth remains have been found. They were lodged in the lowest part of the excavation, at the spot marked m, and at about fifty feet beneath the original surface of overlying coarse gravel c, before it was removed by the workmen from the vacant space under the dotted line. The feeble influence of the streams (a) which now flow, in excavating even the loose shingle is seen at the spot marked o, the bed of the rivulet having been lowered by human labour from its natural level s to that marked n for the convenience of the diggers. — Marchison.

It was from the infillings of one of the gravely depressions between these elevations, south of Miask, that the largest lump of solid gold was found, of which at that time (1824) there was any record. This "pepita" weighs ninety-six pounds troy, and is still exhibited in the museum of the Imperial School of Mines at St. Petersburg.

The quantity of gold raised in Russia during five years was as follows:—

1847	-	-	-	-	-	-	-	1700	poods.
1848	-	-	-	-	-	-	-	1660	"
1849	-	-	-	-	-	-	-	1530	"
1850	-	-	-	-	-	-	-	1490	"
1851	-	-	-	-	-	-	-	1266	"
									7616

Equal to about 296,932 lbs. troy in five years.—*Lectures on Gold, R. Hunt.*

In Erman's "Archææ" we find that in the year 1851, the gold of the Uralian washing and amalgamation works produced 832 poods; the Nertchinsk works, 67 poods; the remaining West and East Siberian washings, 1107 poods; the produce of the Altai Mountains and of Nertchinsk Siberian works, 39 poods, making 1846 poods.

In Asia, and especially in its southern districts, there are many rivers, streams, rivers, and wastes which contain this metal. The Pactolus, a small river of Lydia, rolled over such golden sands, that it was supposed to constitute the origin of the wealth of Croesus. But these deposits are now poor and forgotten. Japan, Formosa, Ceylon, Java, Samatra, Borneo, the Philippines, and some other islands of the Indian Archipelago, are rich in gold streams. Those of Borneo are worked by the Chinese in an alluvial soil on the western coast, at the foot of a chain of volcanic mountains.

Little or no gold comes into Europe from Asia, because its fertile inhabitants place their fortune in treasure, and live to hoard up that precious metal.

Numerous gold mines occur on the two slopes of the chain of the Tians mountains in the Thibet, a province of Little Thibet. The gold lies in quartz veins which traverse a very crumbling reddish granite.

Africa was, with Spain, the source of the greater portion of the gold possessed by the ancients. The gold which Africa still brings into the market is always in dust, showing that the metal is obtained by washing the alluvial soils. None of it is collected in the north of that continent; three or four districts only are remarkable for the quantity of gold they produce.

The first mines are those of Kordofan, between Darfour and Abyssinia. The negroes transport the gold in quills of the ostrich or vulture. These mines seem to have been known to the ancients, who considered Ethiopia to abound in gold. Herodotus relates that the king of that country exhibited to the ambassadors of Cambyzes all their prisoners bound with golden chains.

The second and chief exploitation of gold dust is to the south of the great desert of Zaara, in the western part of Africa, from the mouth of the Senegal to the Cape of Palmas. The gold occurs in spangles, chiefly near the surface of the earth, in the beds of rivulets, and always in a ferruginous earth. In some places the negroes dig pits in the soil to a depth of about 40 feet, unsupported by any props: they do not follow any vein; nor do they construct a gallery; but by repeated washings they separate the gold from the earthy matters.

The same district furnishes also the greater part of what is carried to Morocco, Fez, and Algiers, by the caravans which go from Timbuctoo on the Niger, across the great desert of Zaara. The gold which arrives by Senaar at Cairo and Alexandria comes from the same quarter. From Mungo Park's description, it appears that the gold spangles are found usually in a ferruginous small gravel, buried under rolled pebbles.

The third spot in Africa where gold is collected is on the south-east coast, between the twenty-fifth and the twenty-second degree of south latitude, opposite to Madagascar, in the country of Sofala. Some persons think that this was the kingdom of Ophir, where Solomon obtained his gold.

During the last, and the commencement of the present century, the richest gold mines were found in South America. It occurs there principally in spangles among the alluvial earths, and in the beds of rivers; more rarely in veins.

The gold of Mexico is in a great measure contained in the argenteiferous veins, so numerous in that country, whose principal localities are mentioned under the article SILVER. The silver of the argenteiferous ores of Cinastaxtla contains one 36th of its weight of gold; the annual product of the mines being valued at from 2640 to 7300 pounds avoirdupois.

Oaxaco contains the only auriferous veins explored as gold mines in Mexico; they traverse the rocks of gneiss and mica slate.

All the rivers of the province of Caracas, to ten degrees north of the line, flow over golden sands.

Peru is not rich in gold ores. In the provinces of Huancabamba and Patate, this metal is mined in veins of greasy quartz, variegated with red ferruginous spots, which traverse primitive rocks. The mines called *porcos de oro*, consist of ores of iron and copper oxides, containing a great quantity of gold.

All the gold furnished by New Grenada (New Columbia) is the product of washings established in alluvial granada. The gold exists in spangles and in grains, disseminated among fragments of greenstone and porphyry. At Choco, along with the gold and platinum, hyacinth, zircons, and titanium occur. There has been found, as already stated, in the auriferous localities, large trunks of petrified trees. The gold of Antioquia is 20 carats fine, that of Choco 21, and the largest lump or *pepita* of gold weighed about 37½ pounds avoirdupois. The gold of this also occurs in alluvial formations.

Brazil does not contain any gold mine, properly so called; for the veins containing the metal are seldom worked. Dr. Walsh says gold was first known to exist in the Brazils in 1542. The Indians made their fishing-hooks of it, and from them it was discovered that it was found in the beds of streams, brought down from the mountains. But the first ore found by a white man in that country was in the year 1600; this discovery led to the colonization of the Minas Geraes, and to all those evils resulting from "the cursed lust of gold," with details of which the history of South America abounds.

It is in the sands of the Mandi, a branch of the Rio-Dolce, at Catapreta, that the auriferous ferruginous sands were first discovered in 1682. Since then they have been found almost everywhere at the foot of the immense chain of mountains, which runs nearly parallel with the coast, from the 5th degree south to the 20th. It is particularly near Villa Rica, in the environs of the village Cocora, that the numerous washings for gold are established. The *pepitas* occur in different forms, often adhering to micaceous specular iron. But in the province of Minas Geraes, the gold occurs also in veins, in beds, and in grains, disseminated among the alluvial loams. It has been estimated in annual product, by several authors, at about 2500 pounds avoirdupois of fine metal.

We thus see that almost all the gold brought into the market has come from alluvial lands, and has been extracted by washing.

Californian Gold Mines.—The accident which first revealed the golden treasures of the soil of California, is thus related by a writer in the Quarterly Review, for September, 1822. Captain Sater, the first white man who had established himself in the district where the Americans found the Sacramento, having erected a saw-mill on the former river, whose tall race turned out to be too narrow, took out the wheel, and let the water run freely off. A great body of earth having been carried away by the torrent, laid bare many shining yellow spangles, and on examination Mr. Marshall, his surveyor, picked up several little lumps of gold. He and Captain Sater then commenced a search together, and gathered an ounce of the ore from the sand without any difficulty; and with his knife the captain picked out a lump of an ounce and a half from the rock. A Kentuckian workman employed at the mill had espied their supposed secret discovery, and when after a short absence the gentlemen returned, he showed them a handful of the glittering dust. The captain hired a gang of fifty Indians, and set them to work. The news spread, but the announcement of the discovery was received with incredulity beyond the immediate neighborhood. But presently when large and continuous imports of gold from San Francisco placed the matter beyond doubt, there ensued such a stir in the States, as even in that go-ahead region is wholly without parallel: numbers of every age and of every variety of occupation pushed for the land of promise. Many were accompanied by their families, and most under the excitement of the hour overlooked their physical unfitness, and their inability to procure necessaries. The waters of the Humboldt, from their head to their "sink," a space of nearly 300 miles, are in the dry season strongly impregnated with alkali, and it was here that their first legions faint. Some died from thirst, others from ague, others fell beneath the burdens they attempted to carry when their last animal dropped into the putrid marsh, which grew thicker at every step. Beyond the "sink" the diminished hands had to encounter sixty or seventy miles of desert, where not a blade of herbage grew, and not a drop of pure water could be procured; and those who pushed safely through this ordeal had still to ascend the icy slopes of Sierra Nevada, when the rigours of winter were added to all other difficulties. At different points, one being almost in sight of the golden land, overworn groups had formed encampments, in case perhaps some help might reach them. It is to the credit of the settlers that on hearing this, they strained their resources to the utmost to afford relief. Yet when all was done, a sick, destitute, most wretched horde of stragglers, was all that remained of the multitude, who, full of hope and spirits, had commenced the prairie journey.

It may be advantageous in this place to determine the difference between the amounts of gold passing into the European markets, before the discoveries of the gold fields of California, and especially of those of Australia, to contrast with the total produce of these countries at the present time.

Table of the quantities of Gold which may be considered as having been brought into the European market, every year on an average, from 1790 to 1802.

Continents										Gold.	
ANCIENT CONTINENT.										lbs. Avotr.	
Asia:—Siberia	-	-	-	-	-	-	-	-	-	3740

Austrian States, Hartz and Hessa, Saxony, Norway, Sweden, France, Spain, &c.	-	-	-	-	-	-	-	-	-	165	
Total of the Ancient Continent										8800	
NEW CONTINENT.											
North America	-	-	-	-	-	-	-	-	-	2,560	
South America:—Spanish dominions	-	-	-	-	-	-	-	-	-	22,000	
Brazil	-	-	-	-	-	-	-	-	-	17,400	
Total of the New Continent										40,260	

The mines of America have sent into Europe three and a half times more gold, and twelve times more silver, than those of the ancient continent. The total quantity of silver was to that of gold in the ratio of 55 to 1; a very different ratio from that which holds really in the value of these two metals, which is in Europe as 1 to 15. This difference depends upon several causes, which cannot be investigated here at length; but it may be stated, that gold, by its rarity and price, being much less employed in the arts than silver, the demand for it is also much less; and this cause is sufficient to lower its price much beneath what it would have been, if it had followed the ratio of its quantity compared to that of silver. Thus also bismuth, tin, &c., though much rarer than silver, are, nevertheless, very inferior in price to it. Before the discovery of America, the value of gold was not so distant from that of silver, because since that era silver has been distributed in Europe in a far greater proportion than gold. In Asia the proportion is now actually only 1 to 11 or 12; the product of the gold mines in that quarter, being not so much below that of the silver mines as in the rest of the world.

The total annual production of gold, exclusive of California and Australia, at present, has been estimated as follows:

From the ancient Spanish colonies of America	-	-	10,400 kilogrammes
Brazil	-	-	600
Europe and Asiatic Russia	-	-	6,200
The Indian Archipelago	-	-	4,700
Africa	-	-	14,000?

35,900 = 36 tons nearly,

without taking into account the quantity of gold now extracted from silver.

Report of the production of Gold since its discovery in California,

The history of the production of gold in California and the States of the Union, is well told in the following table, showing the deposits of gold in the limits of the United States. These have been supplied for this work by the obliging kindness of Mr. Rockwell, of Washington.

Statement of Gold of Domestic Production deposited at the Mint of the United States and its Branches, to the close of the Year ending June 30, 1857.

Australian Gold Mines.—The discovery of the great gold field in Australia to the westward of Bathurst, about 150 miles from Sydney, was officially made known in

Great Britain, by a despatch from Sir C. A. Fitzroy to Earl Grey, on the 18th September, 1851, many persons with a tin dish having obtained from one to two ounces per day. On the 25th of May, he writes that lumps have been obtained varying in weight from one ounce to four pounds. On the 29th of May, he writes that gold has been found in abundance, that people of every class are proceeding to the locality, that the field is rich, and from the geological formation of the country, of immense area. By assay the gold is found to consist of 91.1 of that metal and about 8.333 of silver, with a little base metal; or of 22 carats in fineness. July 17th, a mass of gold weighing 106 pounds was found imbedded in the quartz matrix, about 53 miles from Bathurst; and much more, justifying the anticipations formed of the vast richness and extent of the gold field in this colony. This magnificent treasure, the property of Dr. Kerr, surpassed the largest mass found in California, which was 28 pounds; and that in Russia, which was 70 pounds, now in the museum at St. Petersburg. One party of six persons got at the same time 400*l.* in ten days by means of a quicksilver machine; and a party of three, who were unsuccessful for seven days, obtained in five days more than 200 ounces. A royalty of 10 per cent. was ordered to be paid on gold in matrix if found in Crown lands, and 5 per cent. if found in private property.

Numerous claims have been made by persons who have thought that they had given the first indications of gold in Australia. To Sir Roderick Murchison is, however, due the merit of pointing out that gold might probably be found in Australia long before it was known in Europe that gold existed in that important colony. Sir Roderick Murchison thus gives us the facts. — "Having in the year, 1844 recently returned from the auriferous Ural mountains, I had the advantage of examining the numerous specimens collected by my friend Count Strzlecki along the eastern chain of Australia. Seeing the great similarity of the rocks of those two distant countries, I could have little difficulty in drawing a parallel between them; in doing which I was naturally struck by the circumstances that no gold had yet been found in the Australian range, which I termed in anticipation the 'Cordillera,' impressed with the conviction that gold would, sooner or later, be found in the great British Colony. I learnt in 1846 with satisfaction that a specimen of the ore had been discovered. I thereupon encouraged the unemployed miners of Cornwall to emigrate, and dig for gold as they dig for tin in the gravel of their own district. These notices were, as far as I know, the first printed documents relating to Australian gold."

August 25th, 1851, Lieutenant-Governor C. J. Latrobe announced to Earl Grey from Melbourne, the discovery of large deposits of gold in that district of the colony. In a second Parliamentary blue book, issued February 3, 1852, it is stated that 79,310 ounces of gold, worth 237,857*l.* 7*s.*, had been previously forwarded to England, and that the gold fields of the colony of Victoria rival, if they do not exceed in value, the first discovered gold fields of New South Wales; the total value being then 500,000*l.*; and but a little time afterwards about half a million sterling. Mr. E. Hargraves, commissioner for Crown lands, announced from Bathurst, that no part of California which he had seen has produced gold so generally and to such an extent as Summerhill Creek, the Turon River, and its tributaries.

For the purpose of conveying a correct idea of the conditions under which the greatest quantity of the Australian gold occurs, three plans have been selected from different districts. The first of these (fig. 920) represents a longitudinal section

1. Auriferous drift.
2. Boundary of workings.

3. Quartz vein.
4. Shaft.
5. Level.
6. Crown land.
7. Turon River.
8. Summerhill Creek.

along the course of the west quartz vein in the Clunes gold-mining field. We have here, as indicated by the darker portions of the wood-cut, the quartz vein shown in section, with the shaft sunk, and the levels driven upon it. The lighter portions of the figure resting on the quartzose rock is an auriferous drift; and on the left of the section the great basaltic formation is shown.

Fig. 921 is a section of a portion of the Bathurst gold-field. It is an east and west section from the Red Streak-lead across Port Mee Hill, White Flat, the township of

Ballarat West, and the quartz reef west of the township; and it shows the auriferous drift, schist, quartz, and basalt formations of the district.

921

1. The town of Ballarat East.
2. The main road.
3. The Red Creek-lead.
4. The creek.
5. Old Post-office Hill, with quartz reef.
6. Basalt outcrop south of Golden Point.
7. White flat recent auriferous alluvial deposits.
8. Yarrowee Creek.
- 9 and 10 are two shafts sunk into the ancient auriferous drift.

11. The Gravel-Pile level.
 12. Quartz reef beyond the town of Ballarat West, shown in the drawing.
- It is the remains of a lava stream, interrupted by the schist and clay slate hills.
- DD is the gravel strata which invariably rests on the side of the schist hills which surround the Ballarat basin.

In these two sections we have, therefore, all the conditions shown of the processes of mining on the quartz lodes and in the alluvial deposits.

922

Fig. 922 is a section from the Borondara and Bulleen gold mines, a few miles from the capital of Victoria. It is the east and west section of the Carlton Estate quartz reef, and is mainly given to illustrate the unsafe and dangerous condition of many of the workings undertaken by men who have no experience in subterranean operations. The shaft, if such it can be called, is about 40 feet deep; and the reef dips with the solid strata at an angle of about 60 degrees to the horizon.

The wall of the shaft at A is not supported on the footwall by props and proper timbering, which it should be, as indicated

by E E E. The windlass at c and the frame-work at u are both exceedingly insecure. This is the mode of proceeding in a very important working, where almost every piece of quartz broken out contains gold, and also antimony and iron. At the point v the quartz reef was exceedingly rich, and there it branches off into small strings, yielding 22 ounces of gold to the ton.

It is not necessary here to trace the progress of gold-mining in this colony. The quantity of gold discovered and exported has been enormous. Some exceedingly large "nuggets" have been found; one in Forest Creek, weighing 27 lbs. 6 oz. 13 dwts. and the Welcome Nugget, weighing 2217 oz. 16 dwts.

The produce of the gold fields of Victoria in 1856 was as follows. —

The quantities brought to Melbourne and Geelong by escort,

	oz.
From Castlemaine and out stations - - - -	872,897
" Sandhurst and do. - - - -	599,100
" Maryborough and do. - - - -	527,709
" Ballarat and do. - - - -	1,400,822

The remainder being the produce of the gold fields of Victoria.

Gold has been discovered in some considerable quantities in Tasmania. It has been reported as having been found, although as yet not to any great extent, in New Zealand; and it is well known that this precious metal is found in all the islands of the eastern Archipelago.

The recent discoveries of Gold in British Columbia.—The following communication from a correspondent to the *Victoria Gazette*, Vancouver's Island, is especially interesting. It is dated Upper Fraser River, Nov. 28, 1858.

Magnitude of the Gold-fields of British Columbia.—"That the auriferous deposits of this region are spread over a considerable scope of country is apparent from the fact that paying diggings have already been found on the Fraser River, extending from Fort Hope almost to Port Alexander, a continuous distance of nearly 400 miles. Among the tributaries of this stream, Thompson and Bridge rivers are known to be auriferous—the latter sufficiently so to have already richly rewarded those who have laboured upon it as high up as 35 or 40 miles from its mouth, while the former has been ascertained to have many bars that will pay in its bed. On two of its conduits—Nicholas and Bonaparte Rivers—good diggings are reported to have been recently discovered. How many more of the numerous branches of these streams shall yet be found abounding in gold remains to be seen, little or no prospecting having thus far been done upon them. Nor is the extent of this gold-field likely to be limited to these rivers and their sources. Coarse gold was found about six weeks since by some packers while exploring for a trade route around Lake Seton. It was discovered on a large creek flowing into the outlet of the lake at a point about 15 miles from the Fraser. The dust was apparently of high standard value: at two places on the Lillooet River bars having been found that will warrant working with a sluice. The first of these is on the east side of the stream, 10 miles above Port Douglas, where a party are now washing with sluices with very satisfactory results. When I passed the spot they had been at work but two days; the first day three men took out \$14 50c., the next day, \$18. They showed me the gold, which was fine, like that found on the Lower Fraser. The other bar is 20 miles above Port Douglas. It is very extensive, and promises to pay as well as the one first named, though it has not yet been worked. Bars similar to these are abundant on the Lillooet, and the fact of these having been prospected was owing to the accident of a log cabin having been built near them, and not because they seemed more likely to contain gold than the others. For 100 miles above the Pavilion, and beyond what is termed the Canoe Country, the banks of Fraser River have been proved to pay even better than below, the gold being coarser and more easily saved, as well as more plentiful. It will thus be seen that the gold-fields of British Columbia, ascertained to be paying, to say nothing of rumoured discoveries beyond, are tolerably extensive. They do not, it is true, rival those of California or Australia in magnitude; but that they cover a large scope of country, and will give employment to a large population, is settled beyond controversy or question."

Richness of the Mines.—"To claim that the Fraser River mines are as rich, or that

labour has been generally as well rewarded in them as in the mines of California at an early day, would be idle. I might say much in explanation of the numerous failures that attended the first adventurers to these mines, without making myself their apologist—how the miners came too soon and in too great numbers—how the river kept us, and of the many disadvantages under which they laboured; all might be enlarged upon were it not now well known to the public. In regard to this section, however, I may say those pioneers who worked here last winter and spring uniformly made large wages; and that those who came in since have been able to remain, paying the enormous prices they have done for provisions, proves that they must have had good paying claims most of the time. The cost of living here, with other necessary expenditures, could not have been less than \$1 a day to the man, yet I find all have been able to defray their current expenses, while many have accumulated large sums—sufficiently large in a majority of cases, with those who have been here long enough of time, to lay in a winter's stock of provisions, even at the present high prices. That better average wages can be made here than in any part of California at present there is no doubt. This can be done even with the present want of ditches and different appliances for taking out the gold. These diggings, owing to the fineness of the dust and the facility of saving it, require to be worked with sluices—a mode that has been introduced to but a limited extent as yet, owing to the want of lumber, as well as of wheels or ditches for supplying water. When sluices shall have been generally brought into use, more than twice the amount now realized can be taken out to hand. Another cause that will tend to render these mines highly remunerative in the aggregate is, that every man will be able to secure a claim, and that but little capital will be required for starting operations; hence every one will enjoy the full fruits of his own labour, and none need remain idle. For this winter, owing to the lateness with which provisions have been got in, not much will be done; no one here expects it; the utmost that will be attempted, as a general thing, will be to make enough to pay expenses of living, to prospect a little, and be on hand at the breaking up of winter. With the coming of spring large operations will be entered into, and all here enter in the most sanguine anticipations, or rather, I should say, full and confident assurance to the result."

Their durability.—"That these mines will be found not only rich and extensive, but also lasting, I am fully satisfied. Apart from their vast extent of surface, the diggings at one time thought to be shallow, are now known to run downward in many localities to a good depth. It has lately been ascertained that not only the bars along the river, but many of the lower benches or table lands contain sufficient gold to pay where water can be brought upon them, which in most cases can easily be done. These benches are not only numerous, but often of great extent, and would afford employment for a large number of men for many years to come. Little or no search has been made as yet for drift diggings or quartz, though there are abundant indications that both, of a paying character, exist. Fine ledges of quartz, in fact, present themselves almost everywhere, though no thorough examination has been made of their quality. The banks of Bridge River consist of alternate strata of slate and quartz rock, the most favourable possible geological formation for gold. I would venture, then, after having seen considerable of the mines in this quarter, to express the confident opinion that they will prove sufficiently extensive, productive, and lasting to warrant a large immigration to this country in the ensuing season, and that British Columbia is destined to become another great gold-producing region, ranking next to California and Australia in the amount she will hereafter annually yield of this precious commodity."

Such is a general view of the gold producing districts of the world. Much fear has been expressed lest the influx of gold should reduce the value of that metal. Since the discovery of the Californian gold field in 1848, not less than £139,807,184 sterling has been added to the wealth of Europe and America from the great gold-fields of California and Australia. This question cannot be discussed in this place, but it is one of the greatest interest, demanding alike the consideration of the politician and the social philosopher.

GOLD BEATING. This is the art of reducing gold to extremely thin leaves, by beating with a hammer. The processes employed for this purpose may be applied to other metals, as silver, platinum, and copper. The Romans used to gild the ceilings and walls of their apartments; and Pliny tells us, that from an ounce of gold forming a plate of 4 fingers square, about 600 leaves of the same area were hammered. At the present day, a piece of gold is extended so as to cover a space 651,590 times greater than its primary surface when cast.

The gold employed in this art ought to be of the finest standard. Alloy hardens gold and renders it less malleable, so that the fraudulent tradesman who should attempt to debase the gold, would expose himself to much greater loss in the operation, than he could derive of profit from the alloy.

Four principal operations constitute the art of gold beating:—

1. The casting of the gold ingots.
2. The hammering.
3. The lamination.
4. The beating.

1. The gold is melted in a crucible along with a little borax. When it has become liquid enough, it is poured out into an ingot-mould previously heated, and greased on the inside. The ingot is taken out and annealed in hot ashes, which both soften it and free it from grease. The moulds are made of cast-iron, with a somewhat concave internal surface, to compensate for the greater contraction of the central parts of the metal in cooling than the edges. The ingots weigh about 2 ounces each, and are $\frac{3}{4}$ of an inch broad.

2. *The forging*.—When the ingot is cold, the French gold-beaters hammer it out on a mass of steel 4 inches long and 3 broad. The hammer for this purpose is called the forging hammer. It weighs about 3 pounds, with a head at one end and a wedge at the other, the head presenting a square face of $1\frac{1}{2}$ inch. Its handle is 6 inches long. The workman reduces the ingot to the thickness of $\frac{1}{2}$ of an inch at most; and during this operation he anneals it whenever its substance becomes hard and apt to crack. The English gold-beaters omit this process of hammering.

3. *The lamination*.—The rollers employed for this purpose should be of a most perfectly cylindrical figure, a polished surface, and so powerful as not to bend or yield in the operation. The ultimate excellence of the gold leaf depends very much on the precision with which the riband is extended in the rolling press. The gold-beater desires to have a riband of such thickness that a square inch of it will weigh $6\frac{1}{2}$ grains. Frequent annealings are requisite during the lamination.

4. *Beating*.—The riband of gold being thus prepared uniform, the gold-beater cuts it with shears into small squares of an inch each, having previously divided it with compasses, so that the pieces may be of as equal weight as possible. The squares are piled over each other in parcels of 150, with a piece of fine calf-skin vellum interposed between each, and about 20 extra vellums at the top and bottom. These vellum leaves are about 4 inches square, on whose centre lies the gold lamina of an inch square. This packet is kept together by being thrust into a case of strong parchment open at the ends, so as to form a belt or band, whose open sides are covered in by a second case drawn over the packet at right angles to the first. Thus the packet becomes sufficiently compact to bear beating with a hammer of 15 or 16 pounds weight, having a circular face nearly 4 inches diameter, and somewhat convex, whereby it strikes the centre of the packet most forcibly, and thus squeezes out the plates laterally.

The beating is performed on a very strong bench or stool, framed to receive a heavy block of marble, about 9 inches square on the surface, enclosed upon every side by wood-work, except the front, where a leather apron is attached which the workman lays before him to preserve any fragments of gold that may fall out of the packet. The hammer is short handled, and is managed by the workman with one hand; who strikes fairly on the middle of the packet, frequently turning it over to beat both sides alike; a feat dextrously done in the interval of two strokes, so as not to lose a blow. The packet is occasionally beat or rolled between the hands, to loosen the leaves and secure the ready extension of the gold; or it is taken to pieces to examine the gold, and to shift the central leaves to the outside, and vice versa, that everything may be equalised. Whenever the gold plates have extended under this treatment to nearly the size of the vellum, they are removed from the packet, and cut into four equal squares by a knife. They are thus reduced to nearly the same size as at first, and are again made up into packets and enclosed as before, with this difference, that skins prepared from ox-gut are now interposed between each gold leaf, instead of vellum. The second course of beating is performed with a smaller hammer, about 10 pounds in weight, and is continued till the leaves are extended to the size of the skins. During this period, the packet must be often folded, to render the gold as loose as possible between the membranes; otherwise the leaves are easily chafed and broken. They are once more spread on a cushion, and subdivided into four square pieces by means of two pieces of cane cut to very sharp edges, and fixed down transversely on a board. This rectangular cross being applied on each leaf, with slight pressure, divides it into four equal portions. These are next made up into a third packet of convenient thickness, and finally hammered out to the area of fine gold leaf, whose average size is from 3 to 3 $\frac{1}{2}$ inches square. The leaves will now have obtained an area 192 times greater than the plates before the hammering began. As these were originally an inch square, and 75 of them weighed an ounce ($= 6\frac{1}{2} \times 75 = 487\frac{1}{2}$), the surface of the finished leaves will be $192 \times 75 = 14,400$ square inches, or 100 square feet per ounce troy. This is by no means the ultimate degree of attenuation, for an ounce may be hammered so as to cover 160 square feet; but the waste incident in this case, from the number of broken leaves, and the increase and nicety of the labour, make this an unprofitable

refinement; while the gilder finds such thin leaves to make less durable and satisfactory work.

The finished leaves of gold are put up in small books made of single leaves of soft paper, rubbed over with red chalk to prevent adhesion between them. Before putting the leaves in these books, however, they are lifted one by one with a delicate pair of pincers out of the finishing jacket, and spread out on a leather cushion by blowing them flat down. They are then cut to one size, by a sharp-edged square moulding of cane, glued on a flat board. When this square-framed edge is pressed upon the gold, it cuts it to the desired size and shape. Each book commonly contains 25 gold leaves.

We must now describe some peculiarities of the French practice of gold beating. The workman cuts the laminated ribands of an inch broad into portions an inch and a half long. These are called *quarters*. He takes 24 of them, which he places exactly over each other, so as to form a thickness of about an inch, the riband being $\frac{1}{2}$ of a line, or $\frac{1}{16}$ of an inch thick; and he beats them together on a steel slab with the round face (*patane*) of the hammer, so as to stretch them truly out into the square form. He begins by extending the substance towards the edges, then after advancing towards the middle; he then does so much on the other side, and finally hammers the centre. By repeating this mode of beating as often as necessary, he reduces at once all the *quarters* (squares) of the same packet, till none of them is thicker than a leaf of grey paper, and of the size of a square of 2 inches each side.

When the *quarters* are brought to this state, the workman takes 36 of them, which he piles over each other, and with which he forms the first packet (*caucher*) in the manner already described; only two leaves of vellum are interposed between each gold leaf. The empty leaves of vellum at the top and bottom of the packet are called *emplures*. They are 4 inches square, as well as the parchment pieces.

The packet thus prepared forms a rectangular parallelopiped; it is enclosed in two sheathes, composed each of several leaves of parchment applied to each, and glued at the two sides, forming a bag open at either end.

The block of black marble is a foot square at top, and 18 inches deep, and is framed as above described. The hammer used for beating the first packet is called the flat, or the enlarging hammer; its head is round, about 3 inches in diameter, and very slightly convex. It is 6 inches high, and tapers gradually from its head to the other extremity, which gives it the form of a hexagonal truncated pyramid. It weighs 14 or 15 pounds.

The French gold-beaters employ besides this hammer, three others of the same form; namely, 1. The *commencing hammer*, which weighs 6 or 7 pounds, has a head 4 inches in diameter, and is more convex than the former. 2. The *spreading hammer*, (*marteau à chasser*); its head is two inches diameter, more convex than the last, and weighs only 4 or 5 pounds. 3. The *finishing hammer*; it weighs 12 or 13 pounds, has a head four inches diameter, and is the most convex of all.

The beating processes do not differ essentially from the English described above. The vellum is rubbed over with fine calcined Paris plaster, with a hare's foot. The skin of the gold-beater is a pellicle separated from the outer surface of ox gut; but before being employed for this purpose, it must undergo two preparations. 1. It is sweetened, in order to expel any grease it may contain. With this view, each piece of membrane is placed between two leaves of white paper; several of these pairs are piled over each other, and struck strongly with a hammer, which drives the grease from the gut into the paper.

2. A lody is given to the pieces of gut; that is, they are moistened with an infusion of cinnamon, nutmeg, and other warm and aromatic ingredients, in order to preserve them; an operation repeated after they have been dried in the air. When the leaves of skin are dry, they are put in a press, and are now ready for use. After the parchment, vellum, and gut membrane have been a good deal hammered, they become unfit for work, till they are restored to proper flexibility, by being placed leaf by leaf, between leaves of white paper, moistened sometimes with vinegar, at others with white wine. They are left in this predicament for 3 or 4 hours, under compression of a plank loaded with weights. When they have imbibed the proper humidity, they are put between leaves of parchment 12 inches square, and beat in that situation for a whole day. They are then rubbed over with fine calcined gypsum, as the vellum was originally. The gut-skin is apt to contract damp in standing, and is therefore dried before being used.

The average thickness of common gold leaf is $\frac{1}{100}$ of an inch.

GOLD, METALLURGIC TREATMENT OF. The gold found in the sands of rivers, or in auriferous soils, needs not be subjected to any metallurgic process, properly speaking. The gold seekers separate it from the sands, by washing them first upon inclined tables, sometimes covered with a cloth, and then by hand in wooden bowls of a particular form. The methods of working vary in different localities.

The people called Bohemians, Cigano, or Tchinganes, who wash the auriferous sands in Hungary, employ a plank with 24 transverse grooves cut in its surface. They hold this plank in an inclined position, and put the sand to be washed in the first groove; they then throw water on it, when the gold mixed with a little sand collects usually towards the lowest furrow. They remove this mixture into a flat wooden basin, and by a peculiar sight of hand separate the gold entirely from the sand. The richest of the auriferous ores consist of the native gold quite visible, disseminated in a gangue, but the veins are seldom continuous for any length. The other ores of this district are auriferous metallic sulphides, such as sulphides of copper, silver, arsenic, &c., and particularly iron.

The stony ores are first ground in the stamping mill, and then washed in hand-basins, or on wooden tables.

The auriferous sulphides are much more common, but much poorer than the former ores; some contain only one 200,000th part of gold, and yet they may be worked with advantage, when treated with skill and economy.

The gold of these ores is separated by two different processes; namely, by *fusion* and *amalgamation*.

The auriferous metallic sulphides are first roasted, then melted into *mattes*, which are roasted anew; next fused with lead, whence an auriferous lead is obtained, which may be refined by the process of cupellation.

When the gold ores are very rich, they are melted directly with lead, without preliminary calcination or fusion. These processes are however little practised, because they are less economical and certain than amalgamation, especially when the gold ores are very poor.

If these ores consist of copper pyrites, and if their treatment has been pushed to the point of obtaining auriferous rose copper, or even black copper including gold, the precious metal cannot be separated by the process of lixiviation, because the gold, having more affinity for copper than for lead, can be but partially run off by the latter metal. For these reasons the process of amalgamation is far preferable. This process being the same for silver, we reserve its full description for that metal. See SILVER.

The rich ores in which the native gold is apparent, and merely disseminated in a stony gangue, are directly triturated with quicksilver, without any preparatory operation. As to the poor ores, in which the gold seems but amid a great mass of iron, sulphide of copper, &c., they are subjected to a roasting process before being amalgamated. This process serves requisite to lay bare the gold enveloped in the sulphurets. The quicksilver with which the ore is now ground seizes the whole of its gold, in however small quantity this metal may be present.

The gold produced by the refining process with lead is free from copper and lead, but it may contain iron, tin, or silver. It cannot be separated from iron and tin without great difficulty and expense, if the proportion of gold be too small to admit of the employment of muriatic acid.

By cupellation with lead, gold may be deprived of any antimony united with it.

Tin gives gold a remarkable hardness and brittleness; a piece of gold, exposed for some time over a bath of red hot tin, becomes brittle. The same thing happens more readily over antimony, from the volatility of this metal. A two-thousandth part of antimony, bismuth, or lead destroys the ductility of gold. The tin may be got rid of by throwing some corrosive sublimate or nitre into a crucible, containing the melted alloy. By the first agent, perchloride of tin is volatilised; by the second, stannate of potash forms, which is carried off in the resulting alkaline scoria.

Gold treated by the process of amalgamation contains commonly nothing but a little silver. The silver is dissolved out by nitric acid, which leaves the gold untouched; but to make this *parting* with success and economy on the great scale, several precautions must be observed.

If the gold do not contain fully two-thirds of its weight of silver, this metal, being thoroughly enveloped by the gold, is partially screened from the action of the acid. Whenever, therefore, it is known by a trial on a small scale, that the silver is much below this proportion, we must bring the alloy of gold and silver to that standard by adding the requisite quantity of the latter metal. This process is called *quartation*.

This alloy is then granulated or laminated; and from twice to three its weight of sulphuric or nitric acid is to be boiled upon it; and when it is judged that the solution has been pushed as far as possible by this first acid, it is decanted, and new acid is poured on. Lastly, after having washed the gold, some sulphuric acid is to be boiled over it, which carries off a two or three thousandth part of silver, which nitric acid alone could not dissolve. Thus perfectly pure gold is obtained.

The silver held in solution by the sulphuric or nitric acid is precipitated in the metallic state by copper, or in the state of chloride by ammonia. See ASSAY, METALLURGY.

Gold has less affinity for oxygen than any other metal. When alone, it cannot be

oxidised by any degree of heat with contact of air, although in combination with other oxidised bodies, it may pass in a state of an oxide, and be even vitrified. The purple colour is one which gold leaf is converted by an electric discharge into an oxide, for it is equally formed when the discharge is made through it in hydrogen gas. There are two oxides of gold; the first or protoxide is a green powder, which may be obtained by pouring, in the cold, a solution of potash into a solution of the metallic chloride. It is not durable, but soon changes in the atmosphere into metallic gold, and peroxide. Its constituents are 96.15 metal, and 3.87 oxygen. The peroxide is best prepared by adding magnesia to a solution of the metallic chloride, washing the precipitate with water till this no longer takes a yellow tint from muriatic acid; then digesting strong nitric acid upon the residuum, which removes the magnesia, and leaves the peroxide in the form of a black or dark brown powder, which seems to partake more of the properties of a metallic acid than a base. It contains 10.77 per cent. of oxygen. For the curious combination of gold and tin, called the *PEARL PRECIPITATE* or *CASSIDIA*, see *CASSIDIA*, *FIGURETS*.

Gold refining.—The following process has been patented as a foreign invention by Mr. W. E. Newton in January, 1851.

It consists, 1, in reducing auriferous or any other gold bullion to a granulated, or spongy, or dilated molecular condition by fusion therewith of zinc, or some other metal baser than silver, and the subsequent removal of the zinc by dilute sulphuric or other acid; that is, the reducing of the gold bullion to a state to allow of the removal by acids of the silver and other impurities contained therein, so as to fit it for coinage and other purposes without quotation with silver, or any other intermediate process; and 2, in pulverising, by grinding or concussion, gold bullion rendered brittle by union with lead, solder, or other suitable metal, the silver and other impurities being removed by acids in the case in the preceding case, and recovered from the acid solution by any of the known chemical means. This operation, if properly conducted, will produce fine ductile gold in a state of great purity; that is, containing from 98.5 to 99.5 per cent. of pure gold.

GOLD-BEATER'S SKIN. This substance is the peritoneal or serous membrane, separated from the intestinal tube of the ox, and sometimes from other animals; it is attenuated by being beaten with a hammer, and subsequently prepared so as to resist putrefaction.

GOLD, MANNHEIM. A brass composed of from 3 to 4 oz. of zinc to one pound of copper. See *BRASS*.

GOLD, MOSAIC. A brass of very fine colour used in common jewellery. Hamilton and Parker's patent mosaic gold consists of 16½ ounces of zinc to 16 ounces of copper. It is of a dark colour when first cast, but on dipping assumes a beautiful golden tint. The patentees say, "when cooled and broken all yellowness must cease, and the tinge vary from reddish fawn or salmon colour, to a light purple or lilac, and from that to whiteness." See *BRASS ALLOYS*.

GOLD OF PLEASURE. A plant cultivated on the continent for its seeds, which yield a fine oil, while its fibres can be employed in the manufacture of sail-cloth, packing, and other coarse articles. It is the *Camelina sativa* of botanists. It has not attracted much attention in this country.

GOLD THREAD, or *open gold*, is a flattened silver-gilt wire, wrapped or laid over a thread of yellow silk by twisting with a wheel or iron bobbin. By the aid of a mechanism like the braiding machine, a number of threads may thus be twisted at once by one master wheel. The principal object consists in so regulating the movements that the successive volutions of the flattened wire on each thread may just touch one another, and form a continuous covering. The French silver for gilding is said to be alloyed with 5 or 6 pennyweights, and ours with 12 pennyweights of copper in the pound troy. The gold is applied in leaves of greater or less thickness, according to the quality of the gilt wire. The smallest proportion formerly allowed in this country by act of parliament was 100 grains of gold in one pound, or 57.60 grains of silver; but more or less may now be used. The silver rod is focused in the gold leaf, and the compound cylinder is then drawn into round wire down to a certain size, which is afterwards flattened in a rolling mill, such as is described under *MIXT*.

The liquor employed by goldsmiths to bring out a rich colour on the surface of their trinkets, is made by dissolving 1 part of sea-salt, 1 part of alum, 2 parts of nitre, in 3 or 4 of water. The pickle or more, as it is called, takes up not only the copper alloy, but a notable quantity of gold; the total amount of which in the Austrian empire has been estimated annually at 47,000 francs. To recover this gold, the liquor is diluted with at least twice its bulk of boiling water, and a solution of very pure green sulphate of iron is poured into it. The precipitate of gold is washed upon a filter, dried, and purified by melting in a crucible along with a mixture of equal parts of nitre and borax.

GOLD WIRE, is formed by drawing a cylindrical rod of the metal as pure as may be, through a series of holes punched in an iron plate, diminishing progressively in size. The gold, as it is drawn through, becomes hardened by the operation, and requires frequent annealing.

GOLDEN MARCASITE. A name given at one time to the metal zinc. Albertus Magnus calls it *marcasita aurea*. "This was properly a stone, the metallic particles of which were so entirely stimulated by fire, that nothing but useless ashes remained behind. It contained fixed quicksilver, communicated a colour to metals, on which account it was well known to the alchemists, burned in the fire, and was at length entirely consumed. It was found in various parts, but that at Gaslar was the best, because the copper it contained seemed to have in it a mixture of gold. To give this copper, however, a still greater resemblance to gold, some tin was added to it, by which means it became more brittle. This *marcasita* also rendered copper white as silver. Thus far Albertus. It obtained without doubt the name of *marcasita aurea* because zinc communicates a yellow colour to copper; and for the same reason the Greeks and the Arabians called *Cadmia gublen*, or *Aurea*."—*Bechmann*.

GOLDEN SULPHURET OF ANTIMONY. *Stibium Sulphuratum Aurantius*. The pentasulphide of antimony, a golden yellow powder, its formula being SbS_5 . See ANTIMONY.

GONG-GONG, or *tun-tun* of the Chinese. A kind of cymbal made of a copper alloy. See CUPPER.

GONIOMETER. An instrument employed to measure the angles of crystals. The most perfect instrument is the reflecting goniometer of Wollaston. The angle of two crystal is measured by determining through what angular space the crystal must be turned, so that two rays reflected from two surfaces successively shall have the same direction. A simpler form of the instrument consists merely of a semicircular graduated scale of degrees with a movable and a fixed radius. It is a most important instrument to the scientific mineralogist.

GOSSAN, a Cornish mining term. An oxide of iron, mixed with other matters. Go-sans are found on the upper portions of lodes, and according to their characters are regarded by the miners as favourable or unfavourable indications. The gossans are probably the result of the slow decomposition of the sulphate of iron from the fluid in which the metalliferous matter, deposited in the lode, has been precipitated, or of the sulphides which may have been previously formed. The gossans are frequently very rich in silver, and sometimes they contain gold.

GOSSIPHUM. The cotton-tree. See COTTON.

GOVERNOR. A mechanical arrangement usually attributed to Watt, for regulating the motion of a steam-engine.

GRADIATOR. A vessel employed in vinegar manufacture. See ACETIC ACID.

GRAINS OF PARADISE. The fruit of several ringiberaceous plants; sometimes it is called *Malacca pepper*. Pereira distinguishes between the two, but it appears that they commonly pass for the same in commerce. Grains of paradise are imported in casks, barrels, and purchases from the coast of Guinea. They are used to give a piquant strength and pungency to beer and cordials.

By 56 Geo. III. c. 53, no brewer or druder in beer shall have in his possession or use grains of paradise, under a penalty of 200*l*. for each offence: and no druggist shall sell it to a brewer under a penalty of 500*l*. for each offence.

GRAIN TIN. See TIN.

GRANITE, in the common and original acceptation of the term, denotes a rock, composed of felspar, quartz, and mica. It sometimes contains, in addition to these, some other minerals.

These component minerals of granite, both essential and accidental, are united together by a confused crystallisation, not only mutually penetrating and interfering with each other, but sometimes the small crystals of one are completely enveloped in the large crystals of a different kind of mineral, and it is a very common occurrence for one or even more of these minerals to be developed in large crystals, in a granular basis of the whole, so as to constitute a porphyritic granite. This character is generally imparted by the felspar, and rarely by the quartz or mica.—*Fluor*.

The chemical composition of ordinary granite is generally as follows:—

Silica	-	-	-	-	-	-	-	-	-	72.3
Alumina	-	-	-	-	-	-	-	-	-	13.3
Alkalies	-	-	-	-	-	-	-	-	-	7.4
Lime and magnesia and iron	-	-	-	-	-	-	-	-	-	5.0

This rock consists generally of about 40 per cent. of felspar, 30 or 40 per cent. of quartz, and from 10 to 20 per cent. of mica.

The granites of Cornwall have been long celebrated for their exceeding durability. Sir Henry de la Berbe thus describes the situation of the workable granites:—

"There is much good granite on Dartmoor, though it is not always sufficiently accessible to be carried long distances: the chief places where it is worked in large quantities and afterwards exported are, Hey or High Tor on the east, and near King Tor on the west. The granite from the former place is conveyed by a train-road to the Stover canal, down which it is carried in boats, and afterwards down the Teign to Teignmouth, to be shipped for its destination. That from the west side of the moor is conveyed by the Prince's town and Plymouth tram-road to the latter place and shipped.

"The continuation of the Hingston Down granite is worked up the Tamar near New Bridge and exported from Morw Iham. A very hard variety is obtained upon the higher part of the Down, and has been employed advantageously for pavements.

"The chief quarries in the eastern or hard part of the Hensborough mass of granite are those of (the late) Mr. Austin Trefry, up the Par Valley, commonly known as Lostwithiel granite. Extensive quarries are there worked, and the stone is brought to the head of the canal near Pons-mill, upon which it is conveyed to Par harbour, and there shipped. The Carn Meneldre mass has furnished the granite most commonly known as Cornish. It is nearly altogether shipped at Penryn, where it is brought variable distances from different quarries in the vicinity, many situated in the parish of Mabe."

Since the above report was written, the quarries at the Cheeswring near Liskeard have been opened, and stone of a beautiful quality is raised and exported in large quantities. The Lamorna quarries have also been worked; the stone obtained from them is of excellent quality, and it can be obtained of almost any size.

The quantity of granite exported from the several ports of Cornwall in 1855, is estimated as being 473,716 feet, or about 35,000 tons, the value of which was at least 75,700*l*. Of Devonshire granites the quantities exported from the eastern and western sides of Dartmoor was probably about 5,000 tons.

The following great works, amongst many others, have been constructed entirely or in part of Cornish granites. The Penryn and Lamorna granites have supplied Portland Break-water; Keyham Docks for the Steam Navy; Commercial Docks, London; the Hull, Great Western, and Birkenhead Docks, and the National Works at Chatham and Portsmouth, together with the Sentari Monument. The plinth for the railings of the British Museum was from the Carnaeu quarries, and the towers, including the lodge, for gates, &c., from Constantine. From Lamorna blocks of 12 feet square are readily obtained; these quarries produce about 60,000 feet per annum; some stones have been raised 25 feet in length and 11 feet in diameter.

The Cheeswring granite has been used in the London Docks, Westminster Bridge, the Thames embankment, Rochester Bridge, the Docks at Copenhagen, the Great Russes Lighthouse near the island of Ceylon, and for the tomb of the Duke of Wellington in the crypt of St. Paul's Cathedral. These quarries produce from 5,000 to 10,000 tons of stone per annum, and about a similar quantity is annually shipped from the quarries near Par.

The granites of Scotland are chiefly produced from the county of Aberdeen.

The granite of Aberdeen, especially from the quarries of Dancing Cairn, Rubislaw, and Tyrebagger, is much used in the metropolis for kerb and paving stones; some red granite is also quarried. Around Peterhead the red granite prevails, hence it is usually distinguished as the *Peterhead granite*. The principal quarries are those of Black Hill, four miles west of Peterhead, belonging to the Governors of the Merchant Maiden Hospital of Edinburgh; those on the estates of the Earl of Errol,—at Bod-dam,—at Longhaven,—at Cairnrag and at Bova. The Sheerness Docks were built mostly with stone from these quarries. The Stirling Hill quarries, at Bodham, furnished the pillar of the Duke of York's monument; the Saffield quarries the abacus. The beautiful pillars in the library of the British Museum were obtained from Longhaven, the cost for transport, at the time they were worked, being something almost fabulous, so great were the difficulties attending their removal. The pillars in Fishmongers' Hall are from the Stirling quarries, as are also the bases of the monuments of Pitt and Fox; and the polished pillars of the Carlton Club House, in Pall Mall, are from the quarries near Peterhead.

The granites of Ireland.—The most extensive granite district in Ireland stretches south from Dublin, through the counties of Wicklow and Carlow into Kilkenny; it occurs on the south-eastern coast of Down, and around Newry; the range of the Mourne mountains is granitic, which again appears in small and isolated portions in Derry and Tyrone, and in Cavan. In the western portion of Donegal there is a large extent of this rock, which here partakes of a gneissous character, and again, in

the west of Galway, granite covers a considerable area. The granite of the Wicklow range is the most extensively used. It varies in its quality, that near Kingston being coarse and hard, while that from Ballyknocken, or Golden Hill, is much finer, and therefore fitted for ornamental work. The granite of Down is of a darker colour and finely crystallised. It is extensively quarried at Newry, and sent by water to the north of Ireland.

The Galway granite is of a reddish colour, containing large crystals of flesh red felspar. That of Mayo is of a dark bluish grey colour, while that of Tyrone is reddish.

The Irish granite averages 170 lbs. per cubic foot, its extreme weights being 143 lbs. and 176 lbs. After 88 hours' immersion in water it was found that a cubic foot of the granite of Newry and Kingston absorbed about a quarter of a pound, that of Carlow nearly two pounds, and the granite of Donegal four pounds of that fluid. These facts are important in connexion with the use of these rocks for building purposes. — *Williamson's Practical Geology and Ancient Architecture of Ireland.* — *Sir R. Kane's Industrial Resources of Ireland.*

Granite is worked to a small extent at Shap Fell in Westmoreland, and at Mount Sorrow in Leicestershire. The rocks worked as and called the Grooby granite may perhaps be more properly termed Sienites, in some cases assuming the character of a sienitic granite, in others of a sienitic greenstone. These are worked extensively for "pitching" and for macadamising roads.

GRANULATION, is the process by which metals are reduced to minute grains. It is effected by pouring them, in a melted state, through an iron cullender pierced with small holes, into a body of water; or directly upon a bundle of twigs immersed in water. In this way copper is granulated into bean shot, and silver alloys are granulated preparatory to refining. See **METALLURGY**.

GRAPE SUGAR. So called from its being produced in the grape. See **SUGAR**. Its formula is $C^{12}H^{12}O^{11}$.

GRAPHITE (*Plumbagine*, Fr.; *Reissblei*, Germ.) is a mineral substance of a lead or iron grey colour, a metallic lustre, soft to the touch, and staining the fingers with a lead grey hue. H=1 to 2. Spec. grav. 2.08 to 2.45. It is easily scratched, or cut with a steel edge, and affords a black streak, displaying the metallic lustre in its luster. H.D. Infusible both alone and with reagents: but burns with great difficulty in the outward flame without flame or smoke, generally leaving a residue of oxide of iron. It consists of carbon in a peculiar state of aggregation, with an extremely minute and apparently accidental impregnation of iron. Graphite, called also plumbago and black lead, occurs in gneiss, mica slate, and their subordinate clay slates and limestones, in the form of masses, veins, and kidney shaped disseminated pieces. It has been found also among the coal strata, as near Cummeck in Ayrshire. This substance is employed for counteracting friction between rubbing surfaces of wood or metal, for making crucibles and portable furnaces, for giving a gloss to the surface of cast iron, &c. See **PLUMBAGO**.

GRASS OIL. A fragrant oil which is extracted from a peculiar Indian grass; it is generally called the *grass oil of Nemsur*, and it probably bears a close relation to the spikenard of Scripture.

GRATE, a mining term. A metal plate pierced with small holes; it is fixed in front of the stamps in which the ore is pounded, and through the holes the finely divided matter makes its escape.

GRAUWACKE or **GREYWACKE**. *Grav*, grey; *wacké*, clay. A German name, often adopted by geologists for some of the most ancient fossiliferous strata. The rock is often of a grey colour, hence *grau*, German for grey; *wacké* being a provincial miner's term.

The Greywacke rocks are stratified or slaty rocks, which may be regarded as bearing the same relation to clay slates that argillaceous sandstones and conglomerates bear to common clay. Argillaceous slate, by including rolled fragments or minute grains of quartz sand, with or without mica, becomes the *grauwacke* or *grauwacke slate* of Werner. Although at one period the term *grauwacke* or *greywacké* was employed to include the Cambrian and Silurian slates, the term has now nearly dropped out of the geological nomenclature.

GRAVITY. The term usually applied to the action of the earth's gravitation.

GRAVITY, SPECIFIC. The difference in weight between a given mass of any body weighed in air, and the same mass weighed in water, is its specific gravity. For a description of the several methods by which the specific gravity of any body, either solid, fluid, or aeriform, may be determined, we must refer to *Urra's Dictionary of Chemistry*, or to any works treating of the manipulating details of physics or chemistry. The following table may be found useful:—

Table of Specific Gravity.

GREEN EBONY of Jamaica. This is a wood of a brown green colour. It is derived from the *Americum Ebonum*, and is used in turnery and for marquetry work. — See MARQUETRY and PARQUETRY.

GREENHEART. A wood brought from Jamaica and Guiana, the produce of the *Laurus chloroxylon*. It is used in shipbuilding. Bancroft, in his *Guiana*, thus describes it: "The Sipiera or Greenheart tree is in size like the locust-tree, about 60 or 70 feet high; there are two species, the black and the yellow, differing only in the colour of their bark and wood."

GREEN PAINTS. (*Couleurs vertes*, Fr.; *Grüne pigmente*, Germ.) Green, which is so common a colour in the vegetable kingdom, is rare in the mineral. There is only one metal, copper, which affords in its combinations the various shades of green in general use. The other metals capable of producing this colour are, chromium in its sesquioxide, nickel in its hydrated oxide, as well as its salts, the selenite, arsenite, and sulphate; titanium in its prussiate; and some of the salts of uranium.

Green pigments are prepared also by the mixture of yellows and blues; as, for example, the green of Rinman and of Gellert, obtained by the mixture of cobalt blue and flowers of zinc; that of Barth, made with yellow lake, prussian blue, and clay; but these paints seldom appear in the market, because the greens are generally extemporaneous preparations of the artists.

Mountain green consists of the hydrate, oxide, or carbonate of copper, either factitious or as found in nature.

Brown or Brunswick green is a mixture of carbonate of copper with chalk or lime, and sometimes a little magnesia or ammonia. It is improved by an admixture of white lead. It may be prepared by adding ammonia to a mixed solution of sulphate of copper and alum.

Fine green is prepared with sulphate of copper and sal ammoniac.

Matis green is an arsenite of copper, made by mixing a solution of acetate or sulphate of copper with arsenite of potash. It is in fact Schæele's green.

Sap green is the inspissated juice of buckthorn berries. These are allowed to ferment for 8 days in a tub, then put in a press, adding a little alum to the juice, and concentrated by gentle evaporation. It is lastly put up in pigs' bladders, where it becomes dry and hard. See COLOURS, Table of.

GREENSAND. The term greensand applies to the strata lying between the Chalk and the Wealden deposits. They are of marine origin, as is denoted by the presence throughout their entire thickness of sea-shells, and are divided into an upper and lower series, separated by a stratum of clay, called Gault (which see). The *Upper Greensand*, which underlies the Chalk Marl, is composed chiefly of calcareous sand in

the lower, and Sandstone and layers of Chert in the uppermost part (see FIRESTONE). The sandstone affords a good and durable building stone. The Chert is well adapted from its toughness for making roads, and the sandy portion, in addition to its usefulness as a component of mortar, furnishes an excellent agricultural soil, from the calcareous matter it contains, in addition to the large percentage of soluble silica entering into its composition, which sometimes amounts to more than 40 per cent. In Sussex, Surrey, and Kent, the land based upon the Upper Greensand is known by the name of malm, and produces the greater part of the hops for which these counties are celebrated. In the neighbourhood of Godstone and Merstham, in Surrey, extensive quarries are driven into the hills, at the base of the chalk downs, for the purpose of procuring the soft and chalky stone which occurs there in the higher portion of the Upper Greensand, for which there is a large demand in London, for cleaning door-steps, and stonework in the fronts of houses, under the name of *hearthstones*. A plentiful supply of pure water is borne up by the impermeable strata, forming the uppermost part of the upper greensand, which finds its way out of the ground near the base of the chalk, and forms the sources of many streams and rivers.

The Lower Greensand consists of alternations of sands, sandstones, and clays, which are often very ferruginous, so much so sometimes as to constitute a siliceous ore of iron, as is the case at Seend in Gloucestershire, and Shotover in Oxford. The ferruginous sands form the iron-sand of Dr. Smith. The Lower Greensand, also, contains beds of Fuller's Earth, which are worked at Reigate, and furnishes a durable and useful building stone, known by the name of Kentish Rag, and quarried extensively in the neighbourhood of Maidstone.

The term Greensand, though applied to deposits of considerable thickness, is, in fact, only strictly applicable to certain minor portions of them, which are marked by the presence of minute grains of green silicate of iron (the glauconites of American mineralogists). These impart a colour to the beds in which they occur, which has given the name to the entire formation.—H. W. H.

GREEN SLOKE. *Ulex latifolius*, the broad green laver. See **ALOE**.

GREENSTONE. Mineralogically, *greenstone* or *diabase* is pyroxene with Labradorite or oligoclase. Popularly, the term is applied to varieties of trap. "Greenstone is a dark and heavy blackish-green or brownish rock, consisting of felspar and hornblende; it usually has a crystalline texture, but is sometimes compact."—Dana.

GREEN ULTRAMARINE. This is artificially prepared in France and Germany, and employed, instead of the arsenical greens, for printing upon cotton and paper. See **ULTRAMARINE**.

GREEN VITRIOL. Sulphate of iron.

GRENADA COCUS or GRENADILLO. This wood, imported from the West Indies, is called red ebony by the French cabinet makers.

GREY DYE. (*Tenure grise*, Fr.; *Gräufarbe*, Germ.) The grey dyes, in their numerous shades, are merely various tints of black, in a more or less diluted state, from the deepest to the lightest hue.

The dyeing materials are essentially the tannic and gallic acid of galls or other astringents, along with the sulphate or acetate of iron, and occasionally wine stone or erod-tartar. Ash grey is given for 30 pounds of woollen stuff, by one pound of gall nuts, $\frac{1}{2}$ lb. of wine stone, and 2 lb. of sulphate of iron. The galls and the wine stone being boiled with from 70 to 80 pounds of water, the stuff is to be turned through the decoction at a boiling heat for half an hour, then taken out, when the bath being refreshed with cold water, the copperas is to be added, and, as soon as it is dissolved, the stuff is to be put in and fully dyed. Or, for 36 pounds of wool; 2 pounds of tartar, $\frac{1}{2}$ pound of galls, 3 pounds of samach, and 2 pounds of sulphate of iron are to be taken. The tartar being dissolved in 80 pounds of boiling water, the wool is to be turned through the solution for half an hour, and then taken out. The copper being filled up to its former level with fresh water, the decoction of the galls and samach is to be poured in, and the wool boiled for half an hour in the bath. The wool is then taken out, while the copperas is being added and dissolved; after which it is replaced in the bath, and dyed grey with a gentle heat.

If the grey is to have a yellow cast, instead of the tartar, its own weight of alum is to be taken; instead of the galls, one pound of old fustic; instead of the copperas, $\frac{3}{4}$ of a pound of Saltsburg vitriol, which consists, in 92 parts, of 17 of sulphate of iron, and 5 of sulphate of copper; then proceed as above directed. The stuff may be first stained in a bath of fustic, next in a weak bath of galls with a little alum; then the wool being taken out, a little vitriol (common or Saltsburg) is to be put in, previously dissolved in a decoction of logwood; and in this bath the dye is completed.

Pearl-grey is produced by passing the stuff first through a decoction of sumach and logwood (2 lbs. of the former to 1 of the latter), afterwards through a dilute solution of sulphate or acetate of iron; and finishing it in a weak bath of weld containing a little alum. *Mouse-grey* is obtained when, with the same proportions as for ash-grey, a small quantity of alum is introduced.

For several other shades, as tawny-grey, iron-grey, and slate-grey, the stuff must receive a previous blue ground by dipping it in the indigo vat; then it is passed first through a boiling bath of sumach with galls, and lastly through the same bath at a lower temperature after it has received the proper quantity of solution of iron.

For dyeing silk grey, fustet, logwood, sumach, and elder tree bark, are employed instead of galls. Archil and annatto are frequently used to soften and beautify the tint.

The mode of producing grey dyes upon cotton has been explained in the articles CALICO PRINTING and DYING.

GRINDING AND CRUSHING MACHINERY *Crushing Mill.* This machine was introduced into the mines of Cornwall and Devon in the early part of the present century. In its simplest form it consists of two rollers mounted in a strong iron frame, and kept in contact by means of screws; motion is communicated to one of the rolls, either by a water-wheel or steam-engine, but the other is made to revolve by the friction generated between the moving roll and the stuff to be crushed. This mill is usually employed for reducing mineral substances which have already received some mechanical preparation, but machines have been contrived with a series of rolls, set below each other, into which the stuff is introduced as brought from the lode under-ground. In order to effect this operation, the upper rolls are fluted, and the lower ones have various speeds and diameters, but it may be remarked that although this arrangement has been somewhat extensively employed in the north of England, yet it has found few advocates either in Wales or Cornwall.

The practice of keeping the rolls together by screws acting on the bearings is objectionable, since the entrance of a piece of steel, or other hard substance of greater

923

width than the fixed opening between the rolls, immediately produces a stoppage and strains the apparatus, or otherwise causes serious breakages to some of the parts. In order to obviate these evils, the rolls are usually adjusted and kept in position by weighted levers pressing on their axis.

As the machines employed in Cornwall may be considered the most effective in

operation as well as complete in their construction, that type is selected for representation.

n n (fig. 923), are the crushing rollers fitted in a strong frame-work of cast iron, which is stayed by a wrought iron bar *b*, and firmly bolted to longitudinal beams inserted in the walls of the crushing-house. The rollers revolve in bearings, which are so arranged as to slide in grooves, and therefore admit of the cylinders being brought nearer to or separated farther from each other. To keep the rollers in contact and yet allow the action to take place, a weighted lever *a* is placed on each side, which by means of tension bars connected with one of the bearings, keeps a constant pressure upon the rollers. The ore to be crushed is lodged upon a floor *c*, and introduced into a hopper *n*, from which it falls between the rolls; the requisite crushing pressure being attained by increasing or decreasing the weights applied to the end of the lever. The crushed ore passes from between the rollers *n n* into the higher extremity of an inclined cylinder *e*, made of coarse gauze, or perforated plate, which being set in motion by the same power as the rollers themselves, separates the pulverised material into two classes. That portion which passes through the sieve falls into a waggon placed on the floor of the house, whilst the other, which is too large to escape through the openings, is carried to the lower end of the cylinder from whence it passes into an inverted bucket-wheel *r*, by which it is again conveyed into the hopper to be re-crushed.

The modifications to the foregoing arrangement may be thus briefly noticed.

In some machines the feed hopper is made of sufficient capacity to hold from 20 to

25 cwt. of stuff, which is introduced by means of a tram waggon, and renders hand feeding unnecessary. The shoot conveying the crushed ore to the rotating sieve, *e*, is sometimes divided at the bottom into two parts, one to deliver rough, and the other

fine stuff. In connection with each division, is a cylindrical riddle revolving and separating the work according to the form or coarseness of the mesh employed.

A circular sieve divided midway into two parts, each of a different mesh, is in some instances, advantageously substituted for two sets of sieves; whilst, in other cases, circular sieves are omitted, the operation of sifting being performed by fixing perforated plates on the periphery of the inverted wheel.

Instead of one roll being drawn towards the other, they are more commonly kept in contact by direct pressure, which is effected as shown in *figs. 924, 925*.

A lever hung to the cast-iron frame *b* at *c*, and pressing upon pin at *d*. When it is required to change the rollers, the pressure resulting from the lever *a* and weighted box *e*, is relieved by means of the screw tackle *f*.

The considerations which should be attended to in constructing a crushing mill, are, first to make all the parts sufficiently strong to meet the varying resistances which continually occur in crushing. For this purpose, the framework to receive the rolls ought to be of good cast iron, the axes of the rollers of best wrought iron, and the cylinders of the hardest and most uniform metal. 2dly. To design the machine, so that the matter to be crushed may be readily delivered into the hopper, and by the circular sieves, for the dressing process, and such portions as are not properly crushed, returned to the rolls without the intervention of manual labour. In order to effect this, the inverted, or ruff wheel *n*, *fig. 925*, shown in section, ought to be made of sufficient diameter to allow the stuff, on being discharged, to descend by its own gravity, into the feed-hopper. 3dly. To extend from the axis of the rollers, long tumbling shafts, *aa*, *fig. 925*, and fix on their ends the driving wheels *m*, *n*, allowing a little play in the plummer blocks, so that any undue opening of the rolls may not vary the pitch line of the wheels, *m*, *n*, to such an extent as to endanger the safety of the teeth. 4thly. To construct the roll so that it may be readily changed, yet maintained on its axis without slipping when in motion. One of the most efficient plans for this purpose, is shown in the following woodcut, in which *a* is the axis or arbor, and *p* the roll.

926

It will be seen that the cylinder roll is fitted with four internal projections; these are of the same length as the portion of the groove marked *m'*, but no wider than the narrower part of the groove *c*. When the cylinder is to be fixed on the axis, the studs are introduced into the recesses *c*, and the cylinder advanced into its working position, when it is turned until the studs fit into that portion of the recess between *n'*, and which are then wedged to the roll by a close-fitting cutter.

5thly. The diameter of the rolls should be decreased, and the length increased in proportion to the fineness of the stuff to be crushed, since a fine material requires a longer line of contact, and not so large a grip as coarser substances.

In practice it has been found advantageous to make the roller placed on the driving shaft somewhat longer than that which is opposite, and to work the rolls by spur gearing rather than by friction, since the latter is proved to furnish less economical results than the former. It has also been found injudicious to harden the rolls by chilling; hence ordinary and cast rolls are most frequently employed.

The speed of the rolls varies from 45 to 60 feet per minute, but this necessarily differs with the character of the stuff to be crushed. Again great variation is experienced in the quantities crushed within a given period, since a small amount of moisture in vein stuff of a certain class, makes it cake, and will thus considerably reduce the produce of the mill. On the other hand, if the matter operated upon, be very dry, heavy, and brittle, as in the case of some varieties of lead ore, the produce may be much increased, since the mill can be driven at a great speed; a less bulk will have to pass for a given weight, and there will be a smaller quantity of material carried back by the ruff wheel to be re-crushed.

Variable speeds have sometimes been tried in order to produce friction together with pressure at the line of contact, but it has been found that any departure from a uniform speed on the two surfaces, absorbs a considerable additional amount of power, without materially augmenting the results.

The various dimensions and velocities of the rolls, crushing force, and power employed, effective value of different mills, &c., now in use, may be gathered by referring to the following table:—

NAME OF MINE.	ROLLERS.					SIFTER.					Diameter of Self Wheel.	Horse Power.	The ability of mill Crushed in 10 hours.	Cost of crushing per Ton.				
	Diameter of Roller.	Length of Roller.	No. of Revs. turn per Min.	Total Crushing Area per Min.	Total grinding Feet at 10 Hrs.	Diameter of Sifter.	Length of Sifter.	No. of Turns in 10 Hrs.	Revolutions per Minute.

Arrastre or tahona.—This machine is extensively employed in the mining districts of Mexico, for grinding silver ores previous to their amalgamation. It consists of a strong wooden axle A (fig. 927), moving on a spindle in a beam B above

927

it, and resting on an iron pivot beneath, turning in an iron bearing, which is inserted into a post of wood C, which rises about a foot above the ground in the centre of the arrastra. The shaft A is crossed at right angles by two strong spars D D, which form four arms, each about 5 feet long, one excepted, which is 9 feet long, to admit of two mules being attached to it; by this arm the machine is worked. The grinding is per-

formed by four large porphyritic or basaltic stones, two of which are shown, *x x*. These are loosely attached by thongs of leather, or small sized rope, to the four arms, and are dragged round over the ore, which is put in with water, until it is ground to a very fine slime or mud, called the *lama*. One of these machines, when in good working condition, will grind from 600 to 800 pounds weight of ore in twenty-four hours. In Guanaxato, where the best and finest grinding is obtained in the arrastres, the lining or foundation and the grinding stones, are of course, grained porphyry, and form a rough surface. The cost of this apparatus in Mexico, including the paving of the bottom, and the four *metapiles* or stones, is on an average 7*l*. The original weight of a metapile, is about 700 pounds, its dimensions are 2 feet 8 inches long, 18 inches broad, and 18 inches deep. Notwithstanding the hardness of the stones employed, they are so worn as to become unserviceable in the course of ten or twelve weeks; the bottom, however, is only replaced once in twelve months.

This apparatus is well suited to patio amalgamation, but it affords bad results for the power expended.

Edge mill.—This machine is employed for the purpose of reducing gold and silver ores to an impalpable powder. It is also used extensively in grinding flint stones, slugs, and a variety of other products. However much the details of this apparatus may vary, its principle is the same in all cases. Two vertical runners rotate on the outer circumference of a flat or slightly conical basin and afford a frictional or grinding area equal to the difference of distance performed by the inner and outer edges.

The subjoined woodcut, *fig. 925*, represents a mill constructed at the Mould Foundry,

Flintshire. A, rotating pan, resting upon frictional wheels *B*; C, vertical shaft firmly keyed to pan A, to which motion is communicated by wheel gearing *D*. The runners *X X* revolve on arm *F*, and may be of cast iron or of stone bound with a ring of iron.

These runners have no progressive motion but have free play to rise or fall on axis c. and in the stay slots a c.

The following dimensions and particulars are derived from one of the edge mills recently working at the Fabrica la Constante in the province of Guadalajara, Spain.

Diameter of edge runner	-	-	-	-	6 feet.
Width of do. do.	-	-	-	-	Centre 20 in. edge 16 in.
Weight of do. do.	-	-	-	-	5 tons 15 cwt.
Speed of runner	-	-	-	-	200 feet per minute.
Diameter of interior circle of runner	-	-	-	-	4 feet.
Gauge of stuff previous to its being ground	-	-	-	-	10 holes to the lineal inch.
Do. after it leaves the mill	-	-	-	-	60 " "
Quantity of stuff reduced per 10 hours	-	-	-	-	350 lbs.
Horse power employed	-	-	-	-	7.

In some machines erected at the Real-del-Monte mines in Mexico the stones were 6 feet in diameter and 12 inches wide. They were fitted with a ring of wrought iron 3 inches thick. Each pair of runners revolved round a centre on its own axis, in a cast iron basin of which the bottom was 7 inches thick. At first good results were obtained, each mill if kept constantly at work ground nearly ten tons per week; but as their axes, and particularly the wrought iron rings and cast iron bottoms, began to wear hollow and to lose an even surface, the grinding rapidly diminished, and with one year's work they were completely worn out.

The chief advantage of this machine is its simplicity of construction and consequent small first cost; but all its parts require to be made of great strength, and therefore of proportionate weight; hence, in addition to the rapid wear to which it is liable, this apparatus becomes objectionable for countries where transit of heavy machinery is more than ordinarily difficult and expensive.

Horizontal mill. — For the purpose of reducing auriferous and argentiferous ores to an exceedingly fine powder, and where dry grinding is essential, no apparatus has

been found more effectual than the horizontal mill. It affords the largest area of frictional surface for the least wear and tear, and accomplishes equal results at a cost not exceeding one-fourth of that incident to the edge mill.

The construction of the horizontal mill will be rendered intelligible by the aid of the preceding illustration, fig. 929, in which one pair of stones is shown in section. *A* is a circular hopper, into which the stuff to be ground is introduced; *a a*, small pipes of sheet iron, for delivering the stuff between the surfaces of the runner *c* and bed-stone *c'*; *b*, casting enclosing the runner into which the ground material is delivered; *e*, hole in centre of runner; *f*, driving-shaft, with continuation shaft *g*, for giving motion to a Jacob's ladder if requisite; *h h'*, regulating screw for elevating runner *c*; *j*, driving-wheel; *k*, crown-wheel; *l*, wheel giving motion to pinions *m m'*; and *n*, vertical shaft, to drive any supplementary apparatus which may be requiring such, as sising sieve, &c. Four pairs of stones are usually driven by the wheel *l*. The surface of the runner is in contact with the bed-stone, from the periphery to within one-third of its diameter. The lips of the runner then feathers upwards, in order to receive the stuff freely and to equalise the resistance throughout the area of the bed-stone.

The following particulars will convey much practical information relative to this machine:—

Diameter of stones	- - -	- 4 feet 2 inches.
Thickness of bed-stone	- - -	- 12 inches.
Ditto runner	- - -	- 14 inches.
No. of revolutions of stone per minute	- - -	- 108.
Gauge of stuff in stopper	- - -	- 100 holes to the square inch.
Ditto on delivery	- - -	- 3600 ditto.
Quantity of stuff ground per 10 hours	- - -	- 1 ton per pair of stones.
Power employed in horses	- - -	- About 5 per ditto.
Revolutions of sising sieve	- - -	- 23 per minute.
Diameter of ditto	- - -	- 30 inches.
Length of ditto	- - -	- 108.
No. of holes per square inch in sising sieve	- - -	- 3600.
Character of runner	- - -	- Coarse conglomerate.
Ditto bed-stone	- - -	- Compact quartz, moderately hard.
Duration of runner	- - -	- Average 18 weeks.
Ditto bed-stone	- - -	- Ditto 22 ditto.
When dressed	- - -	- Every third day.

From a series of practical experiments made on the same stuff by these several mills, the following results have been obtained:—

	No. of Holes per sq. ft. in Sising Sieve.	Quantity of Stuff ground in 10 Hours.	Horse Power.	Cost per Ton
1. Horizontal mill - - -	3600	Cwt. 20	5	s. d. 2 3
2. Crushing mill - - -	3600	13	8	1 7
3. Edge mill - - -	3600	13	7	6 10

J. D.

The crushing machines which are in general use at Alston Moor and the northern mines of this country, and where they have been employed for upwards of fifty years, differ in some respects from those described.

This machine is composed of one pair of fluted cylinders, *x x*, fig. 930, and of two pairs of smooth cylinders, *x x*, *x' x'*, which serve altogether for crushing the ore. The two cylinders of each of the three pairs turn simultaneously in an inverse direction, by means of two toothed wheels, as at *m*, fig. 931, upon the shaft of every cylinder, which work by pairs in one another. The motion is given by a single water wheel, of which the circle *a a* represents the outer circumference. One of the fluted cylinders is placed in the prolongation of the shaft of this wheel, which carries besides a cast iron toothed wheel, geared with the toothed wheels *e e*, fixed upon the ends of two of the smooth cylinders. Above the fluted cylinders there is a hopper, which discharges down between them, by means of a particular mechanism, the ore brought forward by the waggons *A*. These waggons advance upon a railway, stop above the hopper, and empty their contents into it through a trap-hole, which opens outwardly in the middle of their bottom. Below the hopper there is a small bucket called a shoe, into which the ore is shaken down, and which throws it without ceasing upon the cylinders,

in consequence of the constant jolts given it by a crank-rod, *i* (fig. 931), attached to it, and moved by the teeth of the wheel *m*. The shoe is so regulated, that too

much ore can never fall upon the cylinders and obstruct their movement. A small stream of water is likewise let into the shoe, which spreads over the cylinders, and prevents them from growing hot. The ore, after passing between the fluted rollers, falls upon the inclined planes *x x*, which turn it over to one or other of the pairs of smooth rolls.

These are the essential parts of this machine; they are made of iron, and the smooth ones are case hardened, or *chilled*, by being cast in iron moulds. The gudgeons of both kinds move in brass bushes fixed upon iron supports *A*, made fast by bolts to the strong wood-work basis of the whole machine. Each of the horizontal bars has an oblong slot, at one of whose ends is solidly fixed one of the plummer-block or bearers of one of the cylinders *f*, and in the rest of the slot the plummer-blocks of the other cylinder *g* slides; a construction which permits the two cylinders to come into contact, or to recede to such a distance from each other as circumstances may require. The movable cylinder is approximated to the fixed ones by means of the iron levers *x x*, which carry at their ends the weights *r*, and rest upon wedges *n*, which may be slid upon the inclined plane *n*. These wedges then press the iron bar *o*, and make it approach the movable cylinder by advancing the plummer-block which supports its axis. When matters are so arranged, should a very large or hard piece present itself to one of the pairs of cylinders, one of the rollers would move away, and let the piece pass without doing injury to the mechanism.

Besides the three pairs of cylinders which constitute essentially each crushing machine, there is sometimes a fourth, which serves to crush the ore when not in large fragments, for example, the *chats* and *cuttings* (the moderately rich and poorer pieces), produced by the first sifting with the brake sieve. The cylinders composing that accessory piece, which, on account of their ordinary use, are called *chats-rollers*, are smooth, and similar to the rollers *x z* and *x' z'*. The one of them is usually placed upon the prolongation of the shaft of the water-wheel, of the side opposite to the principal machine; and the other, which is placed alongside, receives its motion from the first, by means of toothed wheel-work.

Mackworth's Patent Crushing Rollers, figs. 932 and 933, for Coal and other Minerals. These rollers are made conical to equalise the wear, and as one roller travels faster than the other, the fragments are partially turned over, so as to present their weakest line of fracture to the direction of the crushing force. Less power is required to work these rollers. In lieu of the counterbalance weight usually employed to allow the rollers to separate and pass excessively hard fragments, and to bring the rollers together again, the machine is made more compact and simplified by connecting 2 brass collars, in which the rollers work by a number of bands or cords, of vulcanised indiarubber strongly stretched. A compound cord of indiarubber, 2 inches in diameter, composed of 144 small and separate cords, when stretched

in double its natural length gives a strain of 3 tons. The brass collars do not revolve.

932

933

GRINDSTONE. Grinding-stones or grit-stones, are varieties of sandstone, most of those which are celebrated being obtained from the sandstones and millstone grits of the coal measures. Mr. Knight describes the best known varieties, which are the following:—

NEWCASTLE GRINDSTONES. These abound in the coal districts of Northumberland, Durham, Yorkshire, and Derbyshire. They are selected of different degrees of coarseness and density, according to the work for which they are required.

HILTON GRINDSTONE is a similar description of stone, of great excellence, of a lighter colour, much finer, and of a very sharp nature, and at the same time not too hard. It is confined to a small spot of limited extent near Blaton in Staffordshire, where it lies above the coal.

WICKESLEY GRINDSTONE. These are obtained from a village about 9 miles east of Sheffield, and are much used for the finer description of edge tools.

SHEFFIELD GRINDSTONE. A hard coarse grit stone, used for grinding large files and the like; it is obtained from Hardsley, about 14 miles north of Sheffield.

DEVONSHIRE GRITTS, are obtained near Collumpton.

YORKSHIRE GRIT and **COLLETON GRIT**, are other varieties from which grindstones are manufactured.

BERR STONES. These are very celebrated; they are found at La Ferté-sous-Jouarre (Seine et Maine), and are said to be unequalled for grist mills. The combined roughness and hardness of this tertiary quartz deposit give it immense advantages. The stones formed of this rock are usually pieced, which renders them very expensive.

GRIT. A peculiar hard sandstone. See **MILLSTONE GRIT**.

GROATS, EMBDEN. — When oats are deprived of their integuments, they are called *groats*, and when these are crushed, they are known as *Embsen groats*. Oatmeal is prepared by grinding the groats.

GROVE or GROOVE. A mining term in Derbyshire. "The mine, or work that a man is employed in. Hence it is, if a question be asked, Where is Tom to day?—He is gone to the groove, he is at the groove. Sometimes it is used for the shaft, and miners are commonly called *groovers*."—*Hobson's Miner's Dictionary*.

GROWAN. A local term applied in Cornwall to granite in an imperfect state, either through decomposition, or irregular formation. It is said that the term is sometimes applied to the solid granite. We have never heard it so used, and the miners and the quarrymen draw a well defined line between a granite and a growan.

GUAIACUM. (*Guaiac*, Fr.; *Guajubarz*, Germ.) Both the wood and resin are imported; they are used medicinally. It is known that, after the discovery of the New World, when the first syphilitic diseases showed themselves in Europe, the origin of which was erroneously ascribed to Santo Domingo, the guaiacum wood was considered as specific against this disease. The historian Herrera informs us that one pound of the wood was at that period paid in Spain with seven piastres. The gum which exudes from the wood, and possesses, as it may be conceived, the medicinal qualities in a much higher degree, is now valued at seven pence per pound. The quantity exported from Santo Domingo in 1855 amounted to 11,883 lbs., valued at £371.—*Consul's Report*.

GUANO. This extraordinary excrementitious deposit of certain sea-fowls, which occurs in immense quantities upon some parts of the coasts of Peru, Bolivia, and Africa, has lately become an object of great commercial enterprise, and of intense interest to our agricultural world. More than twenty years ago it was exhibited and talked of merely as a natural curiosity, but since that time the quantity imported into England alone has risen from 80,000 to 300,000 tons (in 1855), the value of which was estimated at no less than £3,000,000, as shown by the following numbers, from the "Statistical Abstract of the United Kingdom, from 1842 to 1856."

Imports of Guano, from 1842 to 1856.

Year	Quantity imported in Tons.	Year	Quantity imported in Tons.
1842	20,395	1850	116,925
1843	30,002	1851	243,014
1844	104,251	1852	129,889
1845	283,300	1853	128,166
1846	89,203	1854	235,111
1847	82,392	1855	305,061
1848	71,414	1856	191,501
1849	83,435		

During the last two years the quantity imported has somewhat diminished and hence the rise in price, from £11 to £14 per ton. It is curious that, though situated at so great a distance from the sources of supply, Great Britain is by far the largest consumer of Guano, if we may credit the following.

Statement of the Quantities Exported from the Cincha Islands during the Years 1850-1.

Tons of Guano sent to—	1850.	1851.
England	102,421	150,655
France	1,429	
United States	14,250	38,371
China	252	
Total	118,352	189,024

Natural History and Geography.—Guano in the language of Peru, signifies dung; a word spelt by the Spaniards, guano.

The conditions essential for the preservation of these excrements appear to be the existence of a soil consisting of a mixture of sand and clay, in a country where the birds are allowed to live for ages undisturbed by man or man's works, and where, moreover, the climate is very dry, free not only from rain, but also from heavy dews.

These conditions appear to have been combined to a remarkable extent on the coasts of Peru and Bolivia, between latitudes 15° north, and 21° south of the equator, for although beyond this region the flocks of cormorants, flamingoes, cranes, and other sea-fowl, appear to be equally numerous, yet the excrement is rapidly carried away by the rain or dew.

It is then the dryness of the climate chiefly which has permitted the guano to accumulate on these coasts, for, says Mr. Darwin:—"In Peru real deserts occur over wide tracts of country. It has become a proverb that rain never falls in the lower part of Peru." And again: "The town of Iquique contains about 1000 inhabitants, and stands on a little plain of sand at the foot of a great wall of rock, 2000 feet in height, the whole utterly desert. A light shower of rain falls only once in very many years." Indeed since three fifths of the constituent parts of guano are soluble in cold water Prof. Johnston very justly observes that, "A single day of English rain would dissolve out and carry into the sea a considerable portion of one of the largest accumulations; a single year of English weather would cause many of them entirely to disappear."

Such being the case, we might expect to find similar accumulations in other hot and dry climates, as in Egypt, and in Africa, e. g. in the neighbourhood of the Great Desert; and only a few years since a considerable deposit of guano was found in the Kooria Mooria Islands.

In Peru the natives have employed it as a manure from the remotest ages, and have by its means given fertility to the otherwise unproductive sandy soils along their coasts. While Peru was governed by its native Incas, the birds were protected from violence by severe laws. The punishment of death was decreed to the persons who dared to land on the guanoiferous islands during the breeding period of these birds, and to all persons who destroyed them at any time. Overseers were appointed by the government to take care of the guano districts, and to assign to each claimant his due share of the precious dung. The celebrated Baron Von Humboldt first brought specimens to Europe in 1804, which he sent for examination to Fourcroy, Vauquelin, and Klaproth, the best analytical chemists of the day; and he spoke of it in the following terms:—"The guano is deposited in layers of 50 or 60 feet thick upon the granite of many of the South-sea islands off the coasts of Peru. During 300 years the coast birds have deposited guano only a few lines in thickness. This shows how great must have been the number of birds, and how many centuries must have passed over in order to form the present guano beds."

There appear to be three varieties in Peru; the white, grey, and red, the first being the most recent, and the last the oldest; and in the midst of the great accumulations of the last kind, bones and feathers of birds are found (*Ferrier*), as if to remove any doubt which might still remain as to its origin.

Cincha Island Guano.—Much of the so-called Peruvian guano, is exported from the Cincha Islands. They are three in number, and lie in one line from north to south about half a mile apart. Each island is from 5 to 6 miles in circumference, and consists of granite covered with guano in some places to a height of 200 feet, in successive horizontal strata, each strata being from 3 to 10 inches thick, and varying in colour from light to dark brown. No earthy matter whatever is mixed with this vast mass of excrement. At Mr. Elford's visit to these islands in 1842, he observed a perpendicular surface of upwards of 100 feet of perfectly uniform aspect from top to bottom. In some parts of these islands, however, the deposit does not exceed 3 or 4 feet in thickness. In several places, where the surface of the guano is 100 feet or more above the level of the sea, it is strewed here and there with masses of granite, like those from the Alpine mountains, which are met with on the slopes of the Jura chain. These seem to indicate an ancient formation for the guano, and tortuous convulsions since that period. No such granite masses are found imbedded within the guano, but only skeletons of birds.

The accompanying wood-cut, *fig. 934*, shows the nature of the formation.

The export of the guano has increased considerably during the last few years: between 300,000 and 400,000 tons are the annual amount at present, which is effected by the aid of 900 working hands, 320 of them being Chinese, who enter into contracts to serve their employer (the Government contractor), Don Domingo Eliza, for 4 dollars a month, renewing it, if they choose, with the increase of 4 dollars monthly, and a bonus of 120. Those who work on their own account are paid 8 and 10 rials, 4 and 5 shillings, for each cart that they load. They live in a collection of dirty huts made of bamboo and mud; they, nevertheless, appear to be happy and contented, and in

* *Researches in Geology and Natural History*, p. 420.

† *On Guano*. Journal of the Agricultural Society of England, vol. II. p. 214.

general are well conducted. The men with pickaxes work their way into the guano, leaving a sort of wall on either side; here it is so hard that it requires a heavy blow

234

to remove it. It is then conveyed in wheelbarrows either direct to the mouths of the shoots on the edge of the cliffs, or to the huge carts running on tramways for the same purpose. The colour varies very much—in some parts being as dark as warm tea, and in others as light as that of a Bath brick.

235

The smell of ammonia is said to be very powerful, so much so, in fact, as to affect the eyes of the workmen; crystalline deposits of various ammoniacal salts are also

found amongst the guano. The guano heaps are surrounded by a high fence to prevent its being blown away by the wind, near the mouths of the canvas tubes or shoots, which are sometimes 70 feet long, through which it is conducted to the boats. See fig. 975.

As in Peru, the surface of the guano is covered with skeletons of birds, and bones of *arats*. It is also perforated by numberless holes, running in every direction, like a rabbit warren. These are made by a bird about the size of a pigeon, which remains hidden during the day, sallying forth at dark to fish. Gold and silver ornaments are also discovered occasionally, having been buried by the ancient inhabitants more than three centuries ago.

It is quite unnecessary here to insist on the value of guano as a manure. This is a point established beyond all question by nearly every agriculturist in the kingdom and recorded by all classes of writers on agricultural subjects; it has been the means moreover of converting the sandy desert around Lima into a soil capable of raising abundant crops of maize; hence the Peruvian proverb, "Guano, though no saint, works many miracles."

Commercial varieties.—The following appear to be the chief:—

1. Peruvian.	5. Saldanha Bay.
2. Augamao.	6. Kooria Moorla.
3. Ichabue.	7. African.
4. Patagonian.	8. Indian.

Chemistry.—Guano being an article of so great value to the agriculturist as a manure, and being liable not only to adulteration to a very great extent, but also varying when genuine considerably in quality, it is highly important to have some means of ascertaining its value. This cannot be done satisfactorily by ever so experienced a dealer by mere inspection, and therefore, both for the buyer and the seller, resort is necessary, for a knowledge of its compound parts, to the analysis of the chemist.* Such being the case, we must first ascertain the composition of genuine guano, and then inquire upon which of its several constituents its value as a manure depends.

The following is one of the earliest analyses by Fooreroy and Vanquelin, of a sample of guano presented to them by Baron Von Humboldt, showing the composition in 100 parts:—

Urate of ammonia	-	-	-	-	-	9.0
Oxalate of ammonia	-	-	-	-	-	10.6
Oxalate of lime	-	-	-	-	-	7.0
Phosphate of ammonia	-	-	-	-	-	6.0
Phosphate of ammonia and magnesia	-	-	-	-	-	2.6
Sulphate of potash	-	-	-	-	-	5.5
—soda	-	-	-	-	-	3.3
Sal ammoniac	-	-	-	-	-	4.2
Phosphate of lime	-	-	-	-	-	14.3
Clay and sand	-	-	-	-	-	4.7
Water and organic matter	-	-	-	-	-	32.2

But perhaps the constitution of guano is better exhibited by the following analysis of three sorts by Denham Smith.

AMERICAN GUANO. — *Analysis of three sorts by Denham Smith.*

1. *Constituents soluble in hot Water (in 100 parts of guano).*

	I.	II.	III.
Phosphate of lime	0.196	-	0.110
Phosphate of soda	0.120	-	-
Phosphate of ammonia and magnesia	0.561	0.784	0.133
Uric acid	2.516	-	-
Urate of ammonia	15.418	-	-
Organic matter	1.180	0.860	0.756

Valuable as these elaborate analyses are in a scientific point of view, they are quite unnecessary for practical purposes in ascertaining the value of any given sample, for on which of the various constituents does the chief efficiency of guano depend?

Ammonia.—Undoubtedly one of the most, if not the most, important constituents of guano is the ammonia. Authors differ as to the precise manner in which ammonia and its salts act in promoting the growth, and especially in the development of the nitrogenised compounds of plants; but the fact is placed beyond dispute, whether it be that the ammonia contained in the air is decomposed by the leaves, or that the salts of ammonia are absorbed by the spongyules of the roots in solution in water. Now, it is quite possible that, in the mysterious economy of the life of the plant, the ammonia may perform a slightly different function when in different states of combination, either with hydrochloric, sulphuric, nitric, phosphoric, carbonic, uric, humic, or oxalic acids, and although, as a general rule, we should be inclined to yield the palm in point of utility to the more soluble combinations, yet all experience goes to show that the value of an ammoniacal manure may be measured chiefly, if not entirely, by the quantity of that compound present, and is in a great measure independent of its state of combination.

Dr. Ure drew a distinction between what he called the *actual* and *potential* ammonia, i. e. between ammonia and ammoniacal salts ready formed, and compounds, such as uric acid, which during their decay are gradually converted into ammonia. It appears that recent guano contains from 3 to 5 per cent. of uric acid, whilst the older deposits contain generally less than 1 per cent. No doubt the guano at the time of its deposition consisted chiefly of uric acid; and it is this uric acid which has become converted into salts of ammonia; for the excrements of birds which live chiefly on fish are found to contain from 50 to 80 per cent. of uric acid. It is also an established truth in agricultural chemistry that a manure which contains bodies capable of gradually yielding up any valuable compound, such as ammonia, are more useful than those which contain that compound ready formed, and in the state of soluble combination, which the first storm of rain may wash away from the roots of the plants, where they are required. Nevertheless, admitting the truth of all this, the writer is of opinion (and he believes this is the general experience of agriculturists) that the importance of this distinction between *actual* and *potential* ammonia has been rather exaggerated; and that generally it is enough for all practical purposes, in estimating the value of a guano, to determine the total quantity of nitrogen present in every form, and to consider it as representing an equivalent quantity of ammonia "in esse" or "in posse."

The amount of ammonia corresponding to the total quantity of nitrogen in the several varieties of guano ranges as follows, —

	Maxi- mum.	Mini- mum.	Me- an.
1. <i>Peruvian</i> .			
(From 9 analyses by Way*) of samples imported in 1847-8	17.24	16.40	17.07
From Mr. Way's analyses of 10 samples imported in 1848-9	17.81	16.94	16.17
From Mr. Way's analyses of 14 samples imported in 1849	18.94	16.82	17.88
Mean	-	-	17.346
So that the average quantity of ammonia, either existing in, or capable of being yielded by genuine Peruvian guano, may be estimated at about 17 per cent.			
2. <i>Angoscos</i> guano.			
Ammonia (actual and potential) from two analyses by Dr. Ure	20.80	20.41	20.64
So that this variety is slightly richer in ammonia and nitrogenised compounds than the Peruvian.			
3. <i>Isaboe</i> guano.			
Ammonia (actual and potential) from 11 analyses by Dr. Ure and Mr. Teschemacher	2.5	4.5	7.5
Showing that this variety, as far as regards nitrogenised compounds, is far inferior to the preceding; and the same remark applies to the succeeding varieties, e.g. :—			
4. <i>Patagonian</i> guano.			
From analyses of 14 samples by Dr. Ure and Mr. Teschemacher	4.63	1.80	2.54
5. <i>Sakishka Bay</i> guano.			
From results of analyses of 9 samples by Mr. Way	2.45	0.94	1.69
From results of 9 analyses by Dr. Ure and Mr. Teschemacher	2.10	1.25	1.56
6. <i>Kooria Moorla</i> .			
From results of 3 analyses by Mr. Nashit	0.34	0.17	0.25
From results of 3 analyses by Mr. Apjohn	0.31	0.127	0.22

So that the average quantity of ammonia in the several varieties is —

Peruvian	-	-	17 per cent.	Patagonian	-	-	2.5 per cent.
Angoscos	-	-	20 "	Sakishka Bay	-	-	1.5 "
Isaboe	-	-	7 "	Kooria Moorla	-	-	0.25 "

Potash. — Of the two alkalies, potash and soda, the soil usually contains more than sufficient soda for the supply of vegetation; it is therefore chiefly potash which it is necessary to add in the form of manure.

Besides, even the best guano always contains a considerable quantity of common salt, viz. from 1.0 to 2.5 and even 5 per cent.

Mr. Way, in his valuable paper, "On the Composition and Value of Guano," only gives the quantity of alkaline salts, not having determined the potash; but the average quantity of potash in genuine guano may be seen by referring to the analyses before given in detail, and will be found to vary from 3 to 4 per cent.

However, in estimating the value of guano the knowledge of the quantity of potash is by no means of the same importance as of the ammonia, or the phosphoric acid.

Phosphoric acid. — The phosphoric acid is second in importance to no other constituent than the ammonia; being essential for the development of the seeds and all those parts of the vegetable organism, which serve as foods in the production and restoration of the flesh and bones of animals. It exists in the guano (as is shown by the preceding detailed analyses) in combination with ammonia, potash, soda, and lime.

In most analyses the quantity of phosphate of lime, $3\text{CaO}, \text{P}^{\text{O}}_5$, is given instead of phosphoric acid, P^{O}_5 or $3\text{H}^{\text{O}}, \text{P}^{\text{O}}_5$; but 156 parts of phosphate of lime ($3\text{CaO}, \text{P}^{\text{O}}_5$) correspond to 72 of phosphoric acid (P^{O}_5), or as 13 to 6.

* On the composition and money value of the different kinds of Guano. By S. Thomas Way, &c. — "Journal of the Agricultural Society of England," p. 1, &c.

The amount of phosphate of lime in the several varieties of guano is as follows:—

	Max. Result.	Min. Result.	Mean.
<i>Peruvian.</i>			
From analyses of 9 samples by Way, imported in 1847-8	31.45	19.46	26.95
From Mr. Way's analyses of 10 samples, imported in 1848-9	25.30	21.31	23.00
From Mr. Way's analyses of 14 samples, imported in 1849	24.08	21.28	22.13
<i>Angamos.</i>			
From 2 analyses by Dr. Uro	22.00	19.30	20.65
<i>Ichaboe.</i>			
From 11 analyses by Dr. Uro and Mr. Teschemacher	37.00	26.00	31.50
<i>Patagonian.</i>			
From analyses of 14 samples by Dr. Uro and Mr. Teschemacher	65.5	39.5	47.4
<i>Saldanha Bay.</i>			
From analyses of 9 samples by Mr. Way	60.76	49.01	54.99
From analyses of 9 samples by Dr. Uro and Mr. Teschemacher	62.3	51.0	56.7
<i>Kooru Moorla.</i>			
From analyses of 3 samples by Mr. Nesbit	25.50	24.0	14.15
From analyses of 3 samples by Mr. Apjohn	28.30	5.84	17.17

So that the average quantity of phosphate of lime in the several specimens is as follows:—

Peruvian - - -	25.12	Patagonian - - -	47.4
Angamos - - -	20.25	Saldanha Bay - -	55.84
Ichaboe - - -	31.50	Kooru Moorla - -	15.66

These facts are very suggestive as showing how guano, by exposure to air and moisture, has the ammoniacal salts washed out, at the same time, as a consequence, increasing the ratio of phosphates.

Organic Matter.—The amount of organic matter in guano, other than ammonia and its salts, is of an great importance in estimating its value as a manure. Not unfrequently the amount of organic matter, containing uric acid or ammoniacal salts, is stated in analyses, as organic matter "rich in" or "containing ammonia," but it is obvious such analyses are nearly worthless, the value of the guano depending essentially on the quantity of nitrogen, either existing as ammoniacal salts or capable of being converted into them. Good guano contains on an average about 50 per cent. of ash (mineral matters) and 50 per cent. of combustible (organic) matters.

Sand.—The knowledge of the proportion of sand in a guano is of some importance as determining its purity or otherwise. It is easy to understand how a deposit like guano, existing often near the sea-shore, and frequently on a sandy soil, should contain a certain admixture of sand. Some specimens are almost free from it, and few genuine specimens contain more than 1 to 2 per cent.

Common salt.—The presence of common salt in a guano need not surprise us. It is doubtless derived from the sea, partly through the medium of the birds themselves, and partly from the evaporation of the salt spray continually driven upon the coasts by the wind. It is variable in quantity, as we should expect from a knowledge of its origin, ranging in samples of genuine guano from 1 to 5 per cent. Although common salt has been shown* to possess a certain power of absorbing ammonia, yet this is but transient, and the efficacy of guano cannot be said to depend in any extent upon the sea salt present in it. The knowledge of its amount is of great importance, since the guano is not unfrequently adulterated with salt.

Water.—Obviously the larger the amount of water present in guano, the smaller will be the proportion of valuable constituents in a given weight. Genuine guano contains on an average from 10 to about 20 per cent. of water. Many of the salts in guano are likewise deliquescent, so that it has a tendency to become moist by exposure to the air; and this tendency to absorb moisture, is an element of value in the manure, especially in dry seasons.

Calculation of the money value of guano from the results of analyses.—In a most important and interesting paper "On the value of artificial manures,"† Mr. Way

* A. B. Northcott, on the Function of Salt in Agriculture, Phil. Mag. x. 170.

† Agricultural Journal, xvi. 503.

arrives at certain money values for ammonia, phosphoric acid, and the various constituents of guano and other manures, by a comparison with the cost of these several compounds in their ordinary commercial sale. These numbers will be found most valuable to the agriculturist in drawing his own conclusions respecting the value of a guano or other manure from the results of analysis furnished to him by the chemist. They are as follows:—

Ammonia	-	-	-	-	-	-	-	£	56	per ton.
Potash	-	-	-	-	-	-	-	31	"	
Phosphate of lime (insoluble)	-	-	-	-	-	-	-	7	"	
Phosphate of lime (soluble)	-	-	-	-	-	-	-	33	"	
Organic matter	-	-	-	-	-	-	-	1	"	

and the following example of their application may prove useful.

Calculation of the money value of guano, as deduced from the cost of its several constituents in their commercial sale, applied to the mean composition of Peruvian guano deduced by Mr. Way from 78 analyses:—

100 tons contain		£		£
Ammonia	-	-	16.5 at 56 per ton	970
Organic matter	-	-	32.0 " 1 "	32
Potash	-	-	3.5 " 31 "	108
Insoluble phosphate of lime	-	-	23.0 " 7 "	161
Soluble phosphate of lime	-	-	7.0 " 32 "	224

Value of 100 tons - £1,475

Or per ton - £14 13 0

Hence it is obvious that whilst guano was selling at 11/ per ton, it was more economical and convenient to employ it than to make an artificial mixture of its chemical constituents; but now that the price has risen to about 14/ per ton, it becomes a question whether it will not be possible to produce an artificial compound having equal value as a manure which will compete in price with the guano.

Impurities and adulterations.—In consequence of the high price of guano the great demand for it, and the ease with which the unwary farmer may be imposed upon, guano is adulterated with various substances, and to a great extent. Impostors even have been practised by selling as genuine guano artificial mixtures, made to look so much like guano that the farmer would scarcely detect it. The writer recollects examining a guano which contained 50 per cent. of sand, and no less than 25 per cent. of sea salt; and Dr. Ure gives the following analysis of an article sent to him, which had been offered to the public by advertisement as Peruvian guano which contained—

Common salt	-	-	-	-	-	-	-	32.0
Sand	-	-	-	-	-	-	-	23.0
Sulphate of iron	-	-	-	-	-	-	-	5.2
Phosphate of lime	-	-	-	-	-	-	-	4.0
Organic matter (from bad guano to give it smell)	-	-	-	-	-	-	-	23.3
Moisture	-	-	-	-	-	-	-	7.5
								100.0

In fact so numerous and various are the tricks played with guano, that unless a sample is submitted to a skilful chemist for analysis before purchase, we would strongly recommend the agriculturist to purchase of no one but dealers of unquestionable honour.

Professor Johnston observes.—"Four vessels recently sailed hence for guano stations, ballasted with gypsum, or plaster of Paris. This substance is intended for admixture with guano, and will enable the parties to deliver from the vessel, a nice looking and light coloured article. The favourite material for adulterating guano at the present moment, is amber, which is brought from Anglesen in large quantities. The rate of admixture is, we are informed, about 15 cwts. of amber to about 5 cwts. of Peruvian guano, from which an excellent looking article, called African guano, is manufactured."

Analysis of Guano.

The following is Dr. Ure's method for the complete analysis of guano:—

1. In every case I determine, first of all, the specific gravity of the guano; which I

take by means of spirits of turpentine, with a peculiar instrument contrived to render the process easy and precise. If it exceeds 1.75 in density, water being 1.0, it must contain sandy impurities, or has an excess of earthy phosphates, and a defect of animal matter.

2. Triturate and digest 200 grains of it with distilled water, filter, dry the insoluble matter, and weigh it.

3. The above solution, diffused in 2000 gr. measure, is examined as to its specific gravity, and then with test paper, to see whether it be acid or alkaline.

4. One half of this solution is distilled along with slaked lime in a matrass connected with a small quadruple globe condenser, containing distilled water, and immersed in a basin of the same. As the condensing apparatus terminates in a water-trap, no part of the ammonia can be lost; and it is all afterwards estimated by a peculiar meter, whose indications make manifest one hundredth part of a grain.

5. The other half of the solution is mixed with some nitric acid, and divided into three equal portions.

a, the first portion, is treated with nitrate of barytes, and the resulting sulphate of barytes is collected, ignited, and weighed.

b, the second portion, is treated with nitrate of silver, and the resulting chloride of silver ignited and weighed.

c, the third portion, has a certain measure of a definite solution of ferric nitrate mixed with it, and then ammonia in excess. From the weight of the precipitated sulphate of iron after ignition, the known amount of oxide used being deducted, the quantity of phosphoric acid in the soluble portion of the guano becomes known.

d, the three above portions are now mixed, freed by a few drops of dilute sulphuric and hydrochloric acids from any barytes and silver left in them, and then tested by nitrate of lime for oxalate of ammonia. The quantity of oxalate of lime obtained determines that point.

6. The last liquor filtered, being freed from any secondary particles of lime by oxalate of ammonia, is evaporated to dryness and ignited, to obtain the fixed alkaline matter. This being weighed, is then dissolved in a little water, neutralised with acid, and treated with soda-chloride of platinum. From the quantity of potash-chloride of platinum, which precipitates, after being filtered, dried, and weighed, the amount of potash present is deduced; the rest is soda. These bases may be assigned to the sulphuric, hydrochloric, and phosphoric acids, in proportions corresponding to their respective affinities.

7. The proportion of organic matter in the above solution of guano, is determined directly by evaporating a certain portion of it to dryness, and igniting. The loss of weight, minus the ammonia and oxalic acid, represents the amount of organic matter.

8. A second portion of a solution of the guano is evaporated to dryness by a gentle steam heat, weighed, inclosed in a stout well-closed phial along with alcohol of 0.85, and heated to 212°. After cooling, the alcoholic solution is decanted or filtered clear, evaporated to dryness by a gentle heat, and weighed. This is urea, which may be tested by its conversion into carbonate of ammonia, when heated in a test tube or small retort. In this way I have obtained from Bolivian guano 5 per cent. of urea; a certain proof of its entire soundness.

9. *Analysis of the insoluble matter.*—One third of it is digested with bent in abundance of borax-water, containing 1/2 of the salt, filtered, and the filter dried by a steam heat. The loss of weight indicates the amount of uric acid, which is verified by supersaturating the filtrate with acetic or hydrochloric acid, thus precipitating the uric acid, throwing it upon a filter, drying, and weighing it. This weight should nearly agree with the above loss of weight, the small difference being due to soluble organic matter, sometimes called gelatin and ulmic acid. The uric acid is evidenced, 1, by its specific gravity, which I find to be only 1.25, as also that of the urate of ammonia; 2, by its affording fine purple murexide when heated in a capsule along with nitric acid, and then exposed to the vapour of ammonia from a feather held over it; 3, by its dissipation when heated, without emitting an empyreumatic odour.

10. Another third of the solid matter is distilled along with half its weight of slaked lime, and 10 times its weight of water, in the apparatus already described, and the ammonia obtained from it estimated.

11. The remaining third having been ignited, is digested with a gentle heat in weak hydrochloric acid, and the undissolved silica and alumina washed on a filter, dried, and weighed. To the hydrochloric solution, dilute sulphuric acid is added, and the mixture is heated till all the hydrochloric acid be expelled, with the greater part of the water. Alcohol of 0.850 is now poured upon the watery residuum, and the whole, after being well stirred, is thrown upon a filter. The phosphoric acid passes through, as also the magnesia in union with sulphuric acid. The sulphate of lime, which is quite insoluble in spirits of wine, being washed with them, is dried, ignited, and weighed. From the

weight of sulphate of lime, the quantity of phosphate of that earth that was present becomes known.

12. Ammonia in excess is now added to the filtrate, which throws down the granular phosphate of ammonia and magnesia. After washing and drying this powder at a heat of 150° , its weight denotes the quantity of that compound in the guano.

13. To the filtered liquor (of 12), if a little ammonia be added, and then muriate of magnesia be slowly dropped in, phosphate of ammonia and magnesia will precipitate, from the amount of which the quantity of phosphoric acid may be estimated.

14. The proportion of oxalate of lime is determined by igniting the washed residuum (of 9), and placing it in an apparatus for estimating the quantity of carbonic acid given off in dissolving carbonate of lime. I have rarely obtained more than $\frac{1}{2}$ gr. of carbonic acid from the insoluble residuum of 100 gr. of good guano, and that corresponds to less than $1\frac{1}{2}$ per cent. of oxalate of lime in the guano. Sometimes no effervescence at all is to be perceived in treating the washed residuum with acid after ignition.

15. The carbonate of ammonia in guano is readily determined by filtering the solution of it in cold water, and neutralising the ammonia with a test or alkalimetric acid.

16. Besides the above series of operations, the following researches must be made to complete our knowledge of guano. The insoluble residuum (of 10), which has been deprived by two successive operations of its uric acid and ammonia, may contain animal organic matter. It is to be therefore well dried, mixed with 5 times its weight of the usual mixture of hydrate of soda and quicklime, and subjected to gentle ignition in a glass or iron tube closed at one end, and connected at the other with an ammonia-condensing apparatus. The amount of ammonia being estimated by a proper ammonia-water represents the quantity of azote, allowing 14 of this element for 17 of ammonia, being the potential ammonia corresponding to the undefined animal matter. In a sample of Peruvian guano I obtained 5 per cent. of ammonia from this source.

17. The whole quantity of ammonia producible from guano is to be determined by gently igniting 25 gr. of it well dried, and mixed with 10 times its weight of the mixture of hydrate of soda and quicklime (2 parts of the latter to 1 of the former). The ammonia disengaged is condensed and measured, as described above.

18. The ready formed ammonia in all cases determined by distilling a mixture of 100 gr. of it with 50 gr. of slaked lime, condensing the disengaged ammonia, and estimating it exactly by the meter.

19. The relation of the combustible and volatile to the incombustible and fixed constituents of guano, is determined by igniting 100 gr. of it in a passed platinum capsule. The loss of weight denotes the amount of combustible and volatile matter, including the moisture, which is known from previous experiments.

20. The insoluble matter is digested in hot water, thrown upon a filter, dried, and weighed. The loss of weight is due to the fixed alkaline salts, which, after concentrating their solutions, are investigated by appropriate tests: 1. nitrate of baryta for the sulphates; 2. nitrate of silver for the chlorides and sulphates; and 3. soda-lime for platinum, for distinguishing the potash from the soda salts.

21. The insoluble matter (of 20) is digested with heat in dilute nitric or hydrochloric acid, and the whole thrown upon a filter. The silica which remains on the filter is washed, ignited, and weighed. The lime, magnesia, and phosphoric acid may be determined as already pointed out.

If, however, the remarks made in an earlier part of this article be correct, it is altogether unnecessary, in order to ascertain the commercial value of a sample of guano, to perform so elaborate a series of operations as that described above.

The following points are all that are required to be investigated:—

The amount of water; organic matter; nitrogen; proportion of ash; analysis of the ash as to phosphoric acid and alkalies—potash and common salt; sand.

1. *Water*.—The most delicate and troublesome operation, is perhaps the determination of the amount of water. If the substance be dried in the water-oven, as is the usual practice, at 212° F., a very large quantity of ammonia is expelled: so that it becomes necessary to desiccate by protracted exposure under a bell glass, over a vessel of sulphuric acid. Even in this manner, the error is not entirely eliminated, and Mr. Way suggests treating the specimen in a shallow platinum dish, with a few drops of hydrochloric acid, which is allowed to soak through the whole: he states, that it may then be dried at 212° F., without loss.

2. *Organic matter*. The proportion of organic matter is determined in the usual way, by burning it off in an open platinum crucible, until nothing is left but the white or brownish white ash, which is then weighed.

3. *Determination of nitrogen*.—This is best performed by Will and Varrentrapp's process, which will be found described under the head of NITROGEN.

4. *Phosphoric acid*.—The phosphoric acid in the ash of the guano is determined by converting into perphosphate of iron, and then separating as ammonio-magnesia

phosphate, in the same way as has been described under the head of *ANIMAL PLANTS*. In fact, under this head will be found the general method for the complete analysis of the ashes of organic bodies, which, if it be thought desirable, may be carried out, *in extenso*, in the case of the ash of guano.

5. *Alkalies*.—This is, however, scarcely necessary, so long as the alkalies are determined to ascertain the amount of the valuable alkali potash, and the extent of contamination with common salt.

6. *Sand*.—The quantity of sand is determined by treating a portion of the dried guano with hydrochloric acid and water, till nothing more is dissolved, then igniting and weighing the residue.

Statistics of the guano trade of Peru.—We extract the following from an article lately published in the official journal at Lima:—The exportation of guano began in 1841, under the contract with the house of Messrs. Quiros, Allier, and Co. Up to the end of 1856, the exportation from the Cincha Islands has been 1,967,079 tons, of which 1,626,405 tons were sold, and 23,873 were lost at sea. The stock in hand of the company was 316,789 tons. The gross proceeds of all these sales came to \$100,263,518; the charges amounted to \$61,008,881, leaving net proceeds, \$39,254,637; or at £1 per \$5—£7,850,927. In the year 1857 the exportation amounted to 472,065 tons, which, added to 316,789 tons, left on hand in the previous year, gives 789,754 tons; of these 504,549 tons were sold, and 19,156 were lost at sea, leaving 466,009 tons. The net profit this year was \$12,538,016, or at \$5 per £1—£2,507,603. In the first six months of the present year the exportation has been 160,580 tons, which, added to those in the hands of the consignees at the closing of 1857, or 466,009 tons, gives 633,589 tons. One of the most grievous losses that the government has had to suffer in their exportation of guano has resulted from losses occasioned in the loading of the vessels. The government estimates at 16 per cent. of the guano exported the losses in putting on board, or by guano thrown overboard. To avoid this serious loss, which amounts to several hundreds of dollars, the government has now erected a wharf, where vessels of any tonnage come alongside to load, and by a railway the guano is brought on board the ships from the deposits. Besides this, in order that the captains of vessels should not go to sea with their cargoes of guano in an unseaworthy state, all vessels after receiving their cargoes, come now to Callao to undergo a proper survey. Thus the sea risks are likely to be greatly lessened. By a decree of the 5th of October, 1856, the house of Messrs. Anthony Gibbs and Son, of London, was requested to take charge of the guano sales in Spain, hitherto confided to Messrs. O. de Murriek and Co., of the same city, on a commission of five and a half per cent.; but the former house have given proof of the interest they take in the welfare of Peru, and of all those depending on the revenues of that country, by only accepting and charging four and a half per cent., affording by this item only to the republic a considerable increase in the proceeds of the sale of the guano in Spain, the government has issued a decree of thanks in favour of Messrs. A. Gibbs and Son for their liberality, and besides for the steps they have taken to effect a considerable saving in the warehouse rent and other charges on the guano introduced into Spain. The change of agents in the United States has also caused considerable saving in the commission and charges. The President promises to lay before the Congress the result of the investigation of the inspectors sent to Europe and the United States, which will prove highly interesting.

The stock of guano up to the end of 1857 appears to have been 633,589 tons, at £12 per ton, representing a capital of £7,627,000. This must involve a large amount of interest, to which add warehouse rent, and it will be found that there is great expense involved in keeping it, to say nothing of the deterioration of the quality.

Guano imported, 1857:—

	Tons.	Computed real value.
France - - - - -	1,538	£17,023

GUANINE, CHINOP. An organic base found by Unger in guano. Guano contains about 6 per cent.

GUAVA. This fruit is a native of the two Indies and the Brazil. There are two well known varieties, the *Indica pomifera*, or apple-fruited guava; and the *P. pyriformis*, the pear-fruited variety. The pulpy fruits of these trees make with sugar excellent preserves. Imported as Guava jelly.

GUINEA PEPPER. Another name for the Grains of Paradise.

GUM (*Gomme*, Fr.; *Gummi*, *Pflanzenacklein*, Germ.) is the name of a peptizable vegetable product, which forms with water a stinky solution, but is insoluble in alcohol, ether, and oils; it is converted by strong sulphuric acid into oxalic and mucic acids.

There are six varieties of gum: 1, gum arabic; 2, gum senegal; 3, gum of the cherry and other stone fruit trees; 4, gum tragacanth; 5, gum of Bassora; 6, the gum of seeds and roots. The first five spontaneously flow from the branches and trunks of their trees, and sometimes from the fruits in the form of a mucilage which dries and hardens in the air. The sixth kind is extracted by boiling water. In commerce, under the name of gum, very different substances are confounded; thus we have *gum elemi* and *gum copal*, which are true resins; and *gum ammoniacum*, which is a gum resin; and *gum elastic* (caoutchouc), which is a peculiar body, differing from either.

Gum arabic and gum senegal consist almost wholly of the purest gum called *arabine* by the French chemists; our native fruit trees contain some *ceresine*, along with arabine; the gum of Bassora and gum tragacanth consist of arabine and *bassorine*.

Gum arabic, flows from the *Acacia arabica* and the *Acacia vera*, which grow upon the banks of the Nile and in Arabia. It occurs in commerce in the form of small pieces, rounded upon one side and hollow upon the other. It is transparent, without smell, brittle, easy to pulverise, sometimes colourless, sometimes with a yellow or brownish tint. It may be bleached by exposure to the air and the sunbeams, at the temperature of boiling water. Its specific gravity is 1.353. Moistened gum arabic reddens litmus paper, owing to the presence of a little supermalate of lime, which may be removed by boiling alcohol; it shows also traces of the chlorides of potassium and calcium, and the acetate of potash. 100 parts of good gum contain 70.00 of arabine, 17.60 of water, with a few per cents. of saline and earthy matters. Gum arabic is used in medicine, as also to give lustre to crapes and other silk stuffs.

Gum senegal, is collected by the negroes during the month of November, from the *Acacia senegal*, a tree 18 or 20 feet high. It comes to us in pieces about the size of a partridge's egg, but sometimes larger, with a hollow centre. Its specific gravity is 1.436. It consists of 81.10 arabine; 16.10 water; and from 2 to 3 of saline matters. The chemical properties and uses of this gum are the same as those of gum arabic. It is much employed in calico printing.

Cherry-tree gum, consists of 92.10 arabine; 34.90 ceresine; 12 water; and 1 saline matter.

Gum tragacanth, is gathered about the end of June, from the *Astragalus tragacanth* of Crete and the surrounding islands. It has the appearance of twisted ribbons; is white or reddish; nearly opaque, and a little ductile. It is difficult to pulverise without heating the mortar. Its specific gravity is 1.384. When plunged in water, it dissolves in part, swells considerably, and forms a very thick mucilage. 100 parts of it consist of 53.30 arabine; 33.30 bassorine and starch; 11.0 water; and from 2 to 3 parts of saline matters. It is employed in calico printing, and by shoemakers.

Gum of Bassora; see **BASSORINE**.

Gum of seeds, as linseed, consists of 52.70 arabine; 24.9 of an insoluble matter; 10.5 water; and 7.11 saline matter. Neither bassorine nor ceresine seems to be present in seeds and roots. For *British Gum*, see **DEXTRINE**.

GUM ELASTIC. See **CAOUTCHOUC**.

GUM LAC. See **LAC**.

GUM RESINS. (*Gomme-résines*, Fr.; *Schleimharze*, Germ.) When incisions are made in the stems, branches, and roots of certain plants, a milky juice exudes, which gradually hardens in the air; and appears to be formed of resin and essential oil, held suspended in water charged with gum, and sometimes with other vegetable matters, such as caoutchouc, bassorine, starch, wax, and several saline matters. The said concrete juice is called a *gum-resin*; an improper name, as it gives a false idea of the nature of the substance. They are all solid; heavier than water; in general opaque and brittle; may have an acrid taste, and a strong smell; their colour is very variable. They are partially soluble in water, and also in alcohol; and the solution in the former liquid seldom becomes transparent. Almost all the gum resins are medi-

cial substances, and little employed in the arts and manufactures. The following is a list of them—assafoetida; gum arabic; bdellium; copal; galbanum; gamboge; myrrh; olibanum or frankincense; opoponax; and scammony. Such of these are employed in the arts or manufactures are described in the work under their proper names.

GUM-WOOD. *Eucalyptus piperita*, or blue gum tree of New South Wales. The wood is sent over in large logs and packs; the colour of dark Spanish mahogany, with a blue and sometimes a greyish cast.

GUN BARRELS. See FIRE ARMS.

GUN COTTON. (Syn. *Pyroxylon*; *Pulverin*, Fr.) In 1833 M. Braconnot discovered that starch, by the action of monohydrated nitric acid, became converted into a peculiar substance which dissolved in excess of the acid, and was reprecipitated in a granular state on the addition of water. This substance, known as xylodine, when washed and dried, was found to explode on contact of a light, and even if heated to 356°. It also exploded if subjected to a smart blow. The subsequent researches of M. Pelouze indicated this singular body to be starch, $C_{12}H_{22}O_{11}$, in which one equivalent of hydrogen is replaced by peroxide of nitrogen, or hyponitric acid. The formula of xylodine would consequently be $C_{12}H_{21}NO_5$. On the supposition of the

being the correct formula, 100 parts of starch should yield 127.7 of xylodine, and M. Pelouze obtained from 125 to 150. About thirty years subsequently to the discovery of xylodine, M. Schonbein announced his discovery of gun cotton. Cloppertmann distinctly saw the analogy between the two substances, for while xylodine appears to be derived from starch by the substitution of one equivalent of hyponitric acid for one of hydrogen, gun cotton is derived from cellulose ($C_{12}H_{22}O_{11}$, isomeric with starch) by the substitution of two or three equivalents of hyponitric acid for the same number of equivalents of hydrogen.

Preparation.—Gun cotton can be prepared in several ways. The most simple consists in immersing, for a few seconds, well carded cotton in a mixture of equal parts by volume of oil of vitriol of the specific gravity 1.815, and nitric acid of the specific gravity 1.500. The cotton when well saturated is to be removed, and, after being pressed to expel as much as possible of the excess of adhering acid, well washed in clean cold water. As soon as the water no longer reddens litmus paper, the washing may be considered sufficient. The gun cotton thus prepared is cautiously dried at a constant temperature of 112°. It is only to dry in about 1 lb. The cotton prepared by this means explodes well, but does not always dissolve easily in ether. If, consequently, it is desired to prepare a very soluble cotton for photographic collodion, the following process may be employed, in which, instead of nitric acid, dry nitre is used.

4½ ounces pure dry nitre in fine powder.

20 grains (dram measure) sulphuric acid, sp. gr. 1.845.

120 grains of well carded cotton.

The cotton is to be well pulled out and immersed in the mixture of the nitre and sulphuric acid. The contact with the acid, &c., is to be increased by stirring and pulling out the cotton with two glass rods. As soon as perfect saturation is effected, which, with good management, will be in about one minute, the cotton is to be thrown into a large pan of water and well rinsed. The vessel is to be continued under a tap until litmus paper is no longer reddened. The cotton is to be squeezed in the folds of a clean towel and exposed (after being again well pulled out) to a gentle heat to dry. It is curious that the most soluble cotton is often the least explosive, although there is reason to believe that the most soluble cotton is that which nearest approaches in constitution to tri-nitro cellulose.

M. Schonbein recommends a mixture of one measure of nitric acid with three measures of sulphuric acid as the best bath for the cotton. The liquid is to be allowed to cool previous to its immersion. He also saturates the cotton with nitrate of potash, by immersing it in a solution of that salt before drying. Cotton prepared in this manner is not adapted for photographic purposes, but it is highly explosive and therefore well fitted for blasting rocks.

The true constitution of gun cotton is by no means well established. It appears to be very liable to differ in composition according to the method of preparation. According to M. Wöhler it is essential, in order to obtain a cotton both fulminating and soluble in ether, to operate upon the mixture of nitre and sulphuric acid before the temperature (which rises on the ingredients being mingled) has fallen. If cooling has taken place previous to the immersion of the cotton, the resulting pyroxiline is fulminating, but insoluble in ether.

The analyses of M. M. Donato and Monard, and also of M. Wöhler, agree best with bi-nitro cellulose, while those of Gladstone, Vankerschell, and Reuter, Schmidt and

Heckler and Pelouze are more in accordance with a tri-nitro cellulose. To add to the difficulty of forming a conclusion on the subject, M. Pelligot's analyses agree best with the expression $\left\{ \begin{matrix} 1^{m} 11^{n} \\ (NO_2)^3 \end{matrix} \right\} O^{12}$ which is that of bi-nitro glucose.

According to M. Hechampt xyloidine and pyroxiline are acted on by protacetat. of iron, the original substance being regenerated. Thus xyloidine affects starch, and pyroxiline cotton. The regenerated cotton was analysed with the following result:—

Experiment		Calculation	
Carbon	- 43.33	$C^7 = 72$	44.44
Hydrogen	- 6.31	$H^{10} = 10$	6.17
Oxygen	- 50.34	$O^8 = 80$	49.39
100.00		163	100.00

Hechampt (and others) regard gun cotton as containing nitric acid. The former supports his views with numerous experiments, but there are several disturbing influences preventing the products of the decomposition of gun cotton by alkalis, &c. being regarded as sufficiently known to enable us to express a decided opinion as to its true constitution. It may be mentioned in evidence of this that during the action of caustic potash upon gun cotton, M. Hechampt observed sugar to be produced. The latter chemist in common with many others doubts the formula which we, following M. Gerhardt, have provisionally adopted for cellulose; he moreover formulates the latter substance and its nitro-derivatives thus:—

Explosive substances analogous to gun cotton may be prepared from many organic bodies of the cellulose kind, by immersing them in the same bath as for gun cotton. Among these may be mentioned paper, tow, sawdust, and calico.

When collodion is wanted for an application to cut surfaces, and the cotton is with difficulty soluble in alcoholic ether, a solution may easily be obtained if the cotton be first moistened with acetic ether and the alcoholic ether be afterwards added.

Several of the nitro-derivatives of starch and cellulose undergo spontaneous decomposition when kept for some time in stoppered bottles (*Glutoline*)—C. G. W.

GUNNERY. Under the heads of **ARTILLERY** and **FIREARMS**, we have included nearly every point with which it appears necessary to deal in a work of this description. It is convenient, however, to say a few words in this place of Sir William Armstrong's gun. Instead of being cast like ordinary cannon—or formed of several longitudinal pieces like the Whitworth cannon—or of a hoop or wire-bound tube, as proposed by Captain Blakely, Mr. Mallet, and others: the new gun is formed of an internal steel tube, bound over with strips of rolled iron, laid on spirally, somewhat after the fashion of small-arm barrels, the alternate strips being laid in opposite directions, so that the joints may cross each other, or, in other words, so as to “break joint.” This system of construction is, of course, expensive, but it gives great strength with a very small quantity of metal. The internal steel tube is rifled in a very peculiar manner. Instead of having two, three, or four grooves, like ordinary rifled guns—or being formed with an oval bore like that employed by Mr. Lancaster, or with a polygonal bore, as in the Whitworth system—it has a very large number of small grooves close to each other, no less than 40, we believe, in a gun of 2½ inches bore. The shot or shell Mr. Armstrong usually makes of cast-iron, of about three diameters in length, and covers it entirely over with thin lead, so that it may readily conform itself to the rifled interior of the bore when forced forward by the explosion of the charge. Provision for loading the gun at the breech is made by cutting a slot near the breech end down from the upper side into the bore, of a sufficient length to admit the elongated projectile and the charge of powder, and of a breadth slightly greater than the diameter of the bore. The bore itself is also slightly enlarged where it opens into the space formed by cutting out the slot, in order that the projectile and powder, after being lowered into the slot, may be easily pressed forward by hand or other means into the bore. In order to close the space formed by the slot after the gun is charged, a movable breech-piece is formed to fit into it, and is furnished with two handles, by means of which it may be lifted out or dropped into its place as required. This breech-piece has fitted to its front face a facet of copper, a portion of which projects slightly, so as to form a disc which, when the breech-piece is forced a little forward, will enter the bore behind the charge, and by its expansion, at the moment of explosion prevent all escape of gas. The slight

forcing forward of the breech-piece is effected by means of a strong screw passing in through the extreme breech end of the gun, and passing against the rear end of the breech-piece. This screw is turned by a hand lever. The fore end of the breech-piece is bored out at the centre, the bore extending through the copper disc, and into the bore is placed at the time of loading a small discharging cartridge. The "touch-hole," or hole for the detonating plug, is formed in the breech-piece, passing down from its upper side into its bore; so that when the piece is to be discharged the detonating cap or plug is struck, the small discharging cartridge is thereby fired, and its fire is instantaneously communicated to the main cartridge in the bore of the gun itself. With his shells Mr. Armstrong uses a percussion fuse of his invention for causing the shell to burst on striking an object, in case the striking takes place before the time-fuse has operated. In a cylindrical case within the shell Mr. Armstrong fixes a weight or striker, by means of a pin passing through it and the sides of the case. This pin is cut or broken by the shock which the projectile receives in the gun at the instance of firing, and the striker being thus liberated recoils to the rear end of the case, and there remains until the velocity of the shell is checked by coming into contact with some object. When this takes place, the striker, not participating in the retardation of the shell, advances in the case, and causes a patch of detonating composition to be carried suddenly against a fixed point, which fires the composition and ignites the burning charge in the shell.

Experiments have shown that a 32-pounder gun, constructed upon Mr. Armstrong's system, has a greater range and fires with greater accuracy than any gun at present in use in the navy, and yet, while the former weighs but 26 cwt., the present weighs no less than 95 cwt. We may therefore at once reduce the weight of our naval guns by nearly three-fourths, without impairing their range or aim. This would enormously increase the facility of handling them, and therefore leave us free to greatly reduce the number of men employed to work them. Again, with the breech-loading arm it would probably be found possible to get rid of the running out and in of the gun while in action, by counteracting the recoil in some suitable way; and for this reason, also the number of men required to work them might be very much below the present staff. Again, both the bore and the thickness of the metal of the gun being greatly reduced, the external diameter of the gun will be so small that very small ports only would be necessary, and this would add materially to the safety of the gunners, especially in close action. Another advantage might be gained in the use of certain guns, particularly the bow-chase guns, on board ship. It is always a matter of great difficulty to give such a form to the ship that the muzzles of these may, when the guns are run out, project sufficiently far to carry the fire of the explosion clear of the vessel. With the long, slight Armstrong gun this difficulty would not be experienced. See *SHELLS*.

GUNNY CLOTH or HAGS. The coarse sacking made in India, which is used for wrapping rice, spices, &c. The Bengal gunny cloth is made of the fibre of a species of *Cereus*, while that of Bombay and Madras is manufactured from different kinds of sunn fibre, the *Crotalaria juncea* — *Simmonds*.

GUNPOWDER. The discovery of gunpowder has been claimed for Roger Bacon and Schwarz. The ground for this appears to be no more than this. In their writings the earliest recorded mention of the discovery is made in any European language. Roger Bacon, unquestionably antecedent to his German rival, was born 1214 and died 1292; and his work, "*De Nollitate Magis*," appears to have been written about 1270, while Kircher's account gives 1354 as the date of the discovery by Schwarz. It appears, however, that an Arabic manuscript exists in the collection of the Bodleian which unmistakably describes gunpowder and its properties, the date of which is anterior to 1250 — *Mallet*.

This well known composition is employed for charging the numerous varieties of fire arms. Its use depends upon the fact that, at the moment of ignition, violent deflagration takes place, accompanied by the evolution of a large volume of gas. It is evident that if the explosion occurs in a limited space, a vast pressure accumulates and becomes a propulsive force. The gas produced by the explosion of good gunpowder occupies nearly 900 times the volume of the powder itself; but, owing to the high temperature, the space occupied by the gas at the moment of formation, is probably nearly 2700 times greater than the volume of the powder. One of the most popular errors regarding the propulsive force of explosive substances, arises from the extremely vague meaning generally attached to the words strong, powerful, and other equivalent terms. It is this which leads so many to imagine the possibility of attaining marvellously long ranges by means of the various illuminating substances known to chemists. The latter are unfit for use in firearms, owing to a variety of circumstances. One of them is the extreme rapidity of their explosion. The whole mass appears to be converted into gas at once, whereas in gunpowder the ignition proceeds from

particle to particle. The action of fulminates is also too local; if a portion of any of the more violently explosive substances be fired on a piece of metal, the latter will be perforated or depressed exactly at the spot occupied by the substance, and if it be attempted to use it to charge firearms, they will be destroyed, and yet, in all probability the bullet not projected. Moreover, it is impossible to use fulminates successfully for charging shells, because the latter, instead of being blown into pieces of moderate size, capable of inflicting large wounds and throwing down buildings, become converted into fragments so small as to be far less destructive. The escape of the Emperor of the French, from a recent attempt at his assassination, was probably owing to this circumstance.

It has been found that no composition fulfils so many requisites for charging firearms as a mixture, in due proportions, of sulphur, nitre, and charcoal. It is this composition which, in the form of small grains, more or less polished, constitutes gunpowder. The latter should possess several properties which, although sometimes tending in opposite directions, are not entirely incompatible, and may therefore be nearly attained in practice. Some of the principal of these are the following:—

1. The proportions should be so adjusted that the combustion may be complete, and little residue be left after explosion.
2. The powder should be as little hygrometric as possible.
3. It should be sufficiently, but not too explosive.
4. It should be hard and dense enough to bear carriage without breakage of the grains.

Too great a proportion of carbon and sulphur will cause rapid fouling of the gun, and the explosive force will be less than it should be; too small a proportion of sulphur will render the powder too hygrometric. The presence of soda or chloride of potassium in the nitre will lead to the same fault. The powder must be sufficiently stamped, or it will not possess the fourth requisite.

The history of gunpowder may be conveniently studied under the following heads:—

- Preparation of the ingredients.
- Mixture and granulation.
- Modes of estimating projectile force.
- Analysis of gunpowder.

PREPARATION OF THE INGREDIENTS.

Preparation of the nitre.—The nitre employed for powder is always in a state of almost absolute purity, especially as regards the presence of the chlorides of potassium or sodium. The crude nitre of commerce contains several impurities, among which are found nitrates of soda and lime, chlorides of potassium and sodium, and sulphates of potash and soda. They are all removed by crystallisation. The principal impurity is common salt. The process of purification is founded on the fact that, the latter substance is almost equally soluble in hot or cold water, whereas nitre is far more soluble in hot than in cold water. The following is the French mode of refining saltpetre:—1200 kilogrammes are gently heated with 600 litres of water in a copper boiler. The solution is constantly stirred and skimmed, and more nitre is added, until the total quantity is 3000 kilogrammes. As soon as the whole is added, and it is presumed that all the nitre is dissolved, the common salt is removed from the bottom of the boiler. The solution is now to be clarified with glue. For this purpose 400 litres of water are added by small portions, and then 1 kilogramme of the glue dissolved in hot water. The scum, which soon rises, is removed, and the fluid is boiled until clear. The whole is then allowed to cool to about 104°, and the solution of nitre is carefully decanted from the layer of common salt into the crystallising vessel. The latter is a large shallow pan with sloping sides. The fluid is constantly stirred as it cools, in order that the crystals formed may be very small, this is done in order to facilitate the washing process, and also because the fine powdery crystals are well adapted for admixture with the other ingredients. When the crystallising solution is cold the nitre is removed to boxes containing false bottoms, pierced with holes. The aperture in the bottom of the box (below the false bottom) being closed, a saturated solution of pure nitre is poured on the crystals to dissolve out the chloride of sodium. Being already saturated, it is evident it cannot dissolve any of the nitre. After remaining two hours in contact with the nitre, the solution is allowed to run off, and when the dripping has almost entirely ceased, the process of washing is repeated, substituting pure water for the solution of nitre. The product is dried at a gentle heat, being constantly stirred to enable it to retain the pulverulent form. The power (above alluded to) possessed by a saturated solution of nitre, of dissolving other salts has been taken advantage of in one of the processes for analysing saltpetre. Some manufacturers fine the nitre after it has been purified by crystallisation, this process has several disadvantages, among others that of necessitating machinery to reduce it again to a pulverulent state.

Preparation of the sulphur.—Sulphur may be purified for the gunpowder maker by two processes. In the first the crude sulphur is fused in an iron pot, so contrived that the fire does not play directly on the bottom, but only round its sides. The lighter impurities are to be removed by skimming, while the heavier sink to the bottom. The temperature should not be allowed to rise much above 200° , for it then becomes bluish, and at 280° it is so thick as to prevent the impurities from being removed.

Sulphur may be more readily and economically purified by distillation. The apparatus for the purpose is extremely simple in principle; but the process requires care, and is not entirely free from danger. As it is not intended to obtain the sulphur in the state of flowers, the apparatus for condensation is not required to be kept cool; in fact, the still is purposely placed so near to the chamber of condensation, that the sulphur may be received in the fluid state. There are several points which must be attended to in the construction of an apparatus for the distillation of sulphur; they are as follows:—1. The crude sulphur must be capable of being introduced, and the refined product removed easily, without air being, at the same time, permitted to enter the still or condenser. 2. Free means of egress for the heated air must be provided. 3. The contrivance for the latter purpose must not allow fresh air to return. 4. The process must be continuous. The still and condenser employed in France for the purification of crude sulphur fulfils all these conditions. The still is in the form of a very well-necked tubulated retort, made of cast iron. It is set in brickwork over a furnace, and opens into a square brick chamber surmounted by a dome. The latter has a rather short chimney over it, containing a valve opening upwards to permit escape of the heated air, but not allowing anything to return. Over what may be termed the tubulature of the retort or still, is placed an iron pot with a tube communicating with it. The pot is heated by the same fire that works the still. The crude sulphur is placed in the pot where it melts, and by raising a plug, which closes the tubulature, may be made to enter the still. The pipe forming the tubulature rises a short distance above the bottom of the iron supply pot. This is in order that any heavy mechanical impurities may sink to the bottom, and not enter the still, and unnecessarily clog it. If the pot be always kept full of melted sulphur, and the latter is permitted to enter by raising the plug, it is evident that no air will find its way into either the retort or condenser. It is exceedingly important that this should be the case, because violent explosions are liable to occur if the highly heated vapour of sulphur comes in contact with an oxidising medium, such as atmospheric air, which would convert it into sulphurous acid. The melted sulphur which collects on the floor of the chamber is allowed to flow out when desired, by means of an iron plug attached to a rod of the same metal. The sulphur is not allowed to run out entirely, so as to permit air to enter, for the reason stated above. The loss occurring during the purification is owing partly to oxidation, resulting in the formation of sulphurous acid, and partly to the fixed impurities contained in the crude material. See also the article *SULPHUR*.

Preparation of the charcoal.—Of the three ingredients of gunpowder, the most important is generally considered to be the charcoal. Unfortunately the woods which are best adapted for the production of pyroligneous acid, are not fitted for the manufacture of gunpowder: the charcoal must, therefore, be prepared specially. The following are the essential properties of good charcoal for powder:—1. It should be light and porous. 2. It should yield little ashes. 3. It should contain little moisture. The woods yielding good powder charcoals are black alder, poplar, spindle tree, black dogwood, and chestnut. Hemp stalks are said to yield good charcoal for gunpowder. The operation of preparing the charcoal naturally divides itself into three processes. 1. The selection of the wood. 2. Preparation of the wood previous to carbonisation. 3. The carbonisation.

In selecting the wood care is to be taken to avoid the old branches, as the charcoal made from them would yield too much ashes. The bark is to be rejected for the same reason. The wood is to be cut into pieces from $4\frac{1}{2}$ feet to 6 feet long. If the branches used are more than $\frac{1}{2}$ of an inch in diameter they are to be split. If the wood be too large, great difficulty will be found in uniformly charring it.

There are two methods employed in the charring of wood for gunpowder. In one, the operation is conducted in pits; but the process more commonly resorted to is distillation in cylindrical iron retorts. There are certain advantages in the pit process, but they are more than counterbalanced by the convenience and economy of distillation. The stills used are about 6 feet long, and 2 feet 9 inches in diameter. The ends of the cylinders are closed by iron plates, pierced to admit tubes of the same metal. Some of the latter are for the introduction during the carbonisation of sticks of wood, which are capable of being removed to indicate the stage of the decomposition, while another communicates with the condenser. The more freely the

volatile matters are allowed to escape the better the quality of the resulting charcoal. If care be not taken in this respect, especially as the distillation reaches its close, the tarry matters become decomposed, and a hard coating of carbon is deposited on the charcoal, which greatly lowers its quality. The process of burning in pits is considered to yield a superior coal, owing to the facility with which the gases and vapours fly off.

The degree to which the burning or distillation is carried, materially influences the nature of the resulting powder. If the operation be arrested before the charcoal becomes quite black, so that it may retain a dark-brownish hue, the powder will be more explosive than it would be if it were pushed until the charcoal had attained a deep black colour. When it has been found that no more volatile products are being given off, the fire is damped, and in a few hours the contents of the cylinders are transferred to well closed iron boxes to cool.

MIXTURE AND GRANULATION.

A very considerable number of methods have been employed at various times, for effecting that thorough incorporation of the ingredients necessary for the production of a good powder. The oldest method consists in stamping the materials in wooden mortars. The pestles are square shafts of wood ending in brass beaters. The mortars are of wood, and so shaped that any of the composition which may be forced upwards by the blows of the stampers, falls back to the bottom. In order to prevent fracturing of the mortars, a piece of wood of the toughest kind should be set in on the spot where the pestle falls. The pestles are raised by means of coggs fixed on a shaft, driven by a water wheel or steam engine.

One of the many methods adopted to mix the nitre, sulphur, and charcoal, is by means of drums containing metallic balls; but this arrangement is inferior to that where edge stones are employed. This last is superior to all others, the product being not only very dense and, therefore, capable of enduring, without becoming pulverulent, the motion unavoidable in carrying it about; but it is also thoroughly incorporated. It is, of course, essential that the stones, and the bed on which they work, should not strike fire during work. To secure this, they are sometimes made of calcareous stone, and sometimes of cast iron. Previous to being subjected to the action of the mill, the ingredients must be pulverised and mixed. The pulverisation may conveniently be effected in wooden drums, containing metallic balls. The pulverised materials, after being sifted or bolted, and weighed out in the proper proportions, are to be inserted in a mixing drum, containing on its inside pieces of wood projecting inwards, so that, as it revolves, complete admixture gradually takes place. The product of the last operation is now ready to be laid on the bed of the mill. During the grinding, the cake is kept moist by the addition, at proper intervals, of enough water to make it cohere. As the stones revolve, a scraper causes the material to take such a position that it cannot escape their action. The cake produced by the action of the stones is ready for graining or corning. For this purpose the cake is subjected to powerful pressure, by means of a hydraulic press. The mass is then broken up and transferred to a species of sieve of skin or metal pierced with holes. A wooden flail is placed on the fragments, and the sieves are violently agitated by machinery. By this means the grains and dust produced by the operation fall through the holes in the skin or metal discs, and are afterwards separated by sifting. Sometimes the machinery is so arranged that the graining and separation of the meal powder is effected at one operation. The meal powder is reworked, so as to convert it into grains. The next operation to which the powder is subjected is glazing. Its object is to render it less liable to injury, by absorption of moisture or disintegration during its carriage from place to place. The glazing is effected by causing the grained powder to rotate for some time in a wooden drum or cylinder, containing rods of wood running from end to end. The grains as they rub against each other and against the wooden ribs, have their angles and asperities rubbed off, and at the same time the surface becomes harder and polished. It is finally dried by exposure to a stream of air, heated by means of steam.

A vast number of experiments have been made, at various times, to discover the proportions of nitre, sulphur, and charcoal best adapted for the production of gunpowder. It has been found, as might have been anticipated, that no general rule can be given, no admixture can be made which shall fulfil every requirement. Those powders which contain the largest quantities of charcoal are, it is true, as powerful as others in projectile force; but they have the disadvantage of attracting more humidity from the air. It is very singular that all nations appear to have found, by trial, the proportions most generally useful for ordinary purposes, and it is worthy of remark, that they all approximate to the percentages required by the very simple formula.

$\text{K.O., NO}^3 = 8 + 3\text{C}$. In fact, the Prussian powder approaches so closely the theoretical numbers, that they fall within the limits of the errors of analysis, thus:—

Prussian powder.		Theoretical proportions.	
Nitre	- 75.0	K.O., NO^3	93 or 1 equivalent 74.8
Sulphur	- 11.3	S	- 16 " " 11.9
Charcoal	- 13.5	O	- 18 or 3 equivalents 13.3
	100		100.0

When a powder constituted as above is fired, the decomposition is probably as follows (represented in symbols):—

That is to say, the explosion of one equivalent of powder results in the formation of three equivalents of carbonic acid, one of nitrogen and one of sulphide of potassium. It is evident that these theoretical relations are not *absolutely* the true expression of the phenomena; because, in the first place, gunpowder is merely a mechanical mixture, and not a definite chemical compound; and, in the next, the charcoal is represented by the symbol C as if it were pure carbon, whereas, in fact, even the purest and best made charcoals contain variable amounts of hydrogen, ash, and oxygen. The hydrogen is partly converted into water and partly into hydrosulphuric acid (sulphuretted hydrogen).

The following are the proportions of the ingredients used in various countries.

Table of the Composition of various Gunpowders.

	Nitre.	Sulphur.	Charcoal.
English war powder	75	10	15
" sporting ditto	77	9	14
French war powder	75	12.5	12.5
" sporting ditto	76.5	9.0	13.5
" blasting ditto	62	20	18
" " ditto (another kind)	63	30	15
United States war powder	75	12.5	12.5
Prussian war powder	75	11.5	13.5
Russian " " " " "	75.8	12.6	13.6
Austrian " " " " "	75	10	15
Spanish " " " " "	70.5	12.7	10.8
Swedish " " " " "	75	16	9
Chinese " " " " "	75.7	14.4	9.9

Blasting powders contain less nitre than others, the combustion is therefore less perfect, and if used for artillery or small arms, not only is the piece very soon rendered foul, but the ball is projected to a much less distance than is required in practice. In France, where a heavy tax is laid on sporting powders, this difference of composition prevents the cheap blasting powder from being used in fowling pieces.

MODES OF ESTIMATING THE PROJECTILE FORCE OF GUNPOWDER.

The usual mode of determining the propulsive force of powder is by ascertaining the distance to which it can throw a ball of known weight. The instrument used in this country for this purpose consists of an 8-inch mortar charged with 2 ounces of powder, the balls being in each case of the same size and weight. The French use for the purpose an iron mortar, elevated at an angle of 45° . The mortar is 7.5 inches in diameter. The ball is of bronze, and is only 0.067 inches smaller than the bore of the gun; the windage is, consequently, very small. The charge of powder being 37 ounces, and the weight of the ball 65 lbs., the latter should be thrown not less than 437.5 yards.

The force of powder may also be estimated by means of an instrument, called a *pendulum gun*. It consists of a gun barrel hung at the lower end of a pendulum, so arranged that the amount of angular deviation caused by the recoil may be measured; the balls may also be fired into a cup suspended to a similar pendulum. The data obtained serve to enable the rapidity of motion of the ball, at the moment of discharge, to be calculated by means of formulae contrived for the purpose.

ON THE ANALYSIS OF GUNPOWDER.

Several methods have been given by various chemists for the analysis of gunpowder: the following, on the whole, appears the most effective:—The percentage of water is, in the first place, to be determined by drying *in vacuo* over sulphuric acid, until no more diminution of weight occurs. The dried powder, or a fresh quantity, is then to be washed on a filter with boiling water, until nothing more is dissolved out. The residuum is to be dried below 212° and weighed; the loss is the nitre. If preferred, the solution of the nitre may be evaporated to dryness, and the residue weighed. The mixture of charcoal and sulphur is then to be digested in a stoppered flask, with bisulphide of carbon; this will dissolve out the sulphur and leave the charcoal. The loss of weight of the dry mixture of sulphur and charcoal will enable the percentages of sulphur and charcoal to be calculated. If it be desired to know the quality of the charcoal, a combustion of it may be made with a mixture of chromate of lead and bichromate of potash. Ordinary charcoal contains from 69 to 74 of carbon, 3.9 to 5.5 hydrogen, 0.3 to 3.0 per cent. ashes. It has been attempted to dissolve out the sulphur with sulphate of soda or caustic potash; but these methods involve several sources of error.

Good gunpowder should not lose more than 1 per cent. of moisture on drying. It should not leave alkaline globules, when exploded on a clean metallic plate. The specific gravity of a good powder should not be less than 1.735; it is sometimes as high as 1.840. The denser the powder the better it endures transportation. As the density cannot be taken in water, owing to the solubility of the nitre, turpentine or benzole must be substituted, a correction being made for the difference in density of the fluid medium.—C. G. W.

GUTTA PERCHA. Although the trees yielding this substance abound in the forests of the Indian Archipelago, the first notice taken of it appears to have been by Dr. W. Montgomerie, in a letter to the Bengal Medical Board, in the beginning of 1843, wherein he recommends the substance as likely to prove useful for some surgical purposes, and supposes it to belong to the fig tribe. In April, 1843, the substance was taken to Europe by Dr. D'Almeida, who presented it to the Royal Society of Arts of London, but it did not at first attract much attention, as the Society simply acknowledged the receipt of the gift; whereas, its value becoming known, they awarded a gold medal to Dr. W. Montgomerie.

The gutta percha tree, or gutta ulman, as it ought more properly to be called, according to Mr. Oxley, belongs to the natural family *Sapotææ*, but differs much from all described genera, having alliance with both *Achras* and *Bassia*, but differing in some essentials from both. It is the *Maniltra gutta* of Hooker, and is described in the London Journal of Botany, 1848, where it is figured, and in Pereira's *Materna Medica*.

The tree is of a large size, from 60 to 70 feet in height, and from 2 to 3 feet in diameter. Its general appearance resembles the gourd *Durio*, or well known *Boorin*, so much so as to strike the most superficial observer. The under surface of the leaf, however, is of a more reddish and decided brown than in the *durio*, and the shape is somewhat different.

Only a short time ago the gutta percha tree was tolerably abundant on the island of Singapore; but already all the large timber has been felled, and few, if any, other than small plants, are now to be found. The range of its growth, however, appears to be considerable, it being found all up the Malayan Peninsula, as far as Penang. The tree is also found in Borneo, and, there is little doubt, is to be found in most of the islands adjacent.

The localities it particularly likes are the alluvial tracts along the foot of hills, where it flourishes luxuriantly, forming, in many spots, the principal portion of the jungle. But, notwithstanding the indigenous character of the tree, its apparent abundance and wide-spread diffusion, the gutta will soon become a very scarce article, if some more provident means be not adopted in its collection than those at present in use by the Malays and Chinese.

Montgomerie says "a magnificent tree of 50, or more probably 100 years' growth, is cut down, the bark stripped off and the milky juice collected and poured into a trough formed by the hollow stem of the plantain leaf; it quickly coagulates on exposure to the air; but from one tree I am told not more than 20lbs. or 30lbs. are procured."

The mode in which the natives obtain the gutta is by cutting down the trees of full growth, and ringing the bark at distances of about 12 to 18 inches apart, and placing a cocoa-nut shell, spathe of a palm, or such like receptacle, under the fallen trunk, to receive the milky sap that immediately exudes upon every fresh incision. This sap is collected in bamboo, taken to their houses, and boiled, in order to drive off

the watery particles and sap unite it to the consistence it finally assumes. Although the process of boiling appears necessary when the gutta is collected in large quantities, if a tree be freshly wounded, a small quantity allowed to exude, and it be collected and moulded in the hand, it will consolidate perfectly in a few minutes, and have all the appearance of the prepared article.

When it is quite pure the colour is of a greyish white; but, as brought to market, it is more ordinarily found of a reddish hue, arising from chips of bark that fall into the sap in the act of making the incision, and which yield their colour to it. Besides these accidental chips there is a great deal of intentional adulteration by sand and other materials. Some specimens brought to market do not contain much less than $\frac{1}{2}$ lb. of impurities: and even in the purest specimens, one pound of the substance yielded, on being cleansed, one ounce of impurities. Fortunately, it is not difficult to detect or clean the gutta of foreign matter, it being only necessary to boil it in water until well softened, roll out the substance into thin sheets, and then pick out all impurities, which is easily done, as the gutta does not adhere to anything, and all foreign matter is merely entangled in its fibres, not incorporated in its substance. The quantity of gutta percha obtained from each tree varies from 5 to 25 cwt., so that, taking the average at 10 cwt., which is a tolerably liberal one, it will require the destruction of ten trees to produce one cwt. How much better would it, therefore, be to adopt the method of tapping the tree, practised by the Harnese in obtaining the caoutchouc from the *Ficus elastica* (viz. to make oblique incisions in the bark, placing bamboos to receive the sap which runs out freely). True, they would not at first get so much from a single tree, but the ultimate gain would be incalculable, particularly as the tree seems to be one of slow growth; by no means so rapid as the *Ficus elastica*.

Properties of the Gutta percha.—This substance when fresh and pure, is of a dirty white colour, and of a greasy feel, with a peculiar leathery smell. It is not affected by boiling alcohol, but dissolves readily in boiling spirits of turpentine, also in naphtha and coal-tar. A good cement for lining bottles and other purposes is formed by boiling together equal parts of gutta and coal-tar and resin. When required for use, it can always be made plastic by putting the pot containing it over the fire for a few minutes. The gutta percha itself is highly inflammable; a strip cut off takes light, and burns with a bright flame, emitting sparks, and dropping a black residuum in the manner of sealing wax, which in its combustion it very much resembles. But the great peculiarity of this substance, and that which makes it so eminently useful for many purposes, is the effect of boiling water upon it. When immersed for a few minutes in water above 150° Fahr. it becomes soft and plastic, so as to be capable of being moulded to any required shape or form, which it retains upon cooling. If a strip of it be cut off and plunged into boiling water, it contracts in size both in length and breadth.

It is this plasticity when plunged into boiling water that has allowed of its being applied to so many useful purposes, and which first induced some Malays to fabricate it into whips, which were brought into Singapore, and led to its further notice. The natives subsequently extended their manufactures to buckets, basins, awnings, shoes, trunks, vessels for cooling wines, and several other domestic uses. Its easy plasticity and power of retaining any shape given to it when cool, at once pointed it out as suitable for the manufacture of bougies; and accordingly Dr. W. Montgomerie, availed himself of this, made several of the above instruments, and recommended the use of it to the Bengal Medical Board. It also answers very well for the tubes of syringes, which are always getting out of order in hot climates, when made of caoutchouc.

Mr. T. Oxley, surgeon, Prince of Wales Island and Malacca, whose remarks are of much value from his acquaintance with the production of which he writes, says:—

"I observed in the *Mechanics' Magazine* for March, 1847, a notice of several patents taken out for the working of this article by Mr. Charles Hancock, in which an elaborate process is described for cleaning the gutta, as also mention of its having a disagreeable acid smell. The gutta, when pure, is certainly slightly acid, that is, it will cause a very slight effervescence when put into a solution of soda, but is unaffected by liquor potassæ. The smell, although peculiar, is neither strong nor unpleasant, so that the article experimented upon must have been exceedingly impure, and possibly derived a large portion of its acidity from the admixture and fermentation of other vegetable substances. Again; it appears to me that, if the gutta be pure, the very elaborate process described as being necessary for cleaning it, is superfluous. The gutta can be obtained here in a perfectly pure state by simply boiling it in hot water until well softened, and then rolling it out into thin sheets, when all foreign matter can be easily removed. I would recommend that the manufacturers at home should offer a higher price for the article if previously strained through

cloth at the time of being collected, when they will receive the gutta in a state that will save them a vast deal more in trouble and expense than the trifling addition necessary to the original prime cost."

In February, 1847, Mr. Charles Hancock obtained a patent for improvements in the manufacture of gutta percha. In the first place, for the construction of a slicing machine, consisting of a circular iron plate, formed with three radial slots, in which knives are fixed in a similar manner to the irons of an ordinary plane or spoke shave; the shaft which carries the plate is caused to rotate by steam or other power. The lumps of gutta percha drop against the knives, by which they are cut into slices, of a degree of thickness corresponding to the projection given to the knives. These slices are then soaked in a vessel of hot water till they become pliable. Instead of a circular revolving cutter, a vertical cutter or chopper may be used; curved knives may be had recourse to for refractory lumps. The softened slices are next subjected to the action of breakers or rollers with serrated blades, which are mounted transversely over the tank. In front of each breaker there is a pair of fluted feeding rollers; and the pieces of gutta percha are passed to the rollers of the first breaker. There is an inclined endless web mounted upon two rollers, the front one of which is numbered in the water, and the other is situated opposite the space between the feeding rollers of the second breaker. There is a second inclined web placed before the third breaker. There is also a mincing cylinder with radial blades working partly in the water. The feeding-rollers, and the carrying-rollers of the endless webs, are made to revolve in a forward direction, while the breakers, the mincing cylinder, and the agitator, are made to revolve in the opposite direction. The breakers and mincing cylinder should revolve at the rate of from 600 to 800 revolutions per minute, but the feeding rollers and endless webs need not move faster than about one-sixth of that rate. Thus, the substance is reduced to fragments and washed in the water, the heavy impurities falling to the bottom of the tanks, and the light purer matter floating. The water should be used cold. When the gutta percha has a fetid smell, it is treated with carbonate of soda or chloride of lime. The same apparatus may be used for purifying caoutchouc.

Mr. Hancock combined sulphur with gutta percha in the following manner:—He found that if a minute portion of sulphur be used along with a sulphide the best result is obtained; the proper proportions being 6 parts of sulphide of antimony, or hydrosulphide of lime, and 1 part of sulphur to 46 parts of gutta percha. When these materials have been mixed, the compound is put into a boiler and heated under pressure to a temperature of from 260° to 300° F. and it is to be left in this state for a period varying from half an hour to two hours, according to the thickness of the materials. He prefers, for effecting the union of the sulphurous constituent, the following method to the masticating machine. 1st. He subjects the purified gutta percha to the combined action of steam and the fumes of orpiment and sulphur mixed in the proportions stated, in a metal chamber, provided with a steam-tight cover secured by screw-bolts. There is also a steam boiler connected therewith, and when the heat in it is raised to about 290° Fahr., a fire is lighted beneath the pot containing the sulphurising materials. But the gutta percha, &c., should be heated with the steam before it is sulphurised. In from half an hour to two hours the sulphurising is finished. Or, the gutta percha may be rubbed strongly over with the sulphurous mixture and then heated, either dry or with the aid of steam, or it may be coated in the form of a paste.

Another of Mr. Hancock's inventions is to expose the gutta percha to the dentoxyde of azote, or chloride of zinc, concentrated and boiling hot, and then washing with an alkaline solution or mere water. Gutta percha thus treated by the action of nitrous gas, as it is evolved from nitric acid and copper, iron, or zinc, becomes exceedingly smooth, and of a lustre approaching to metallic; the same effect is produced upon common unsulphurised caoutchouc. Gutta percha is thus also freed from all stickiness; and if sulphurised it acquires under this treatment the downy softness of velvet. Chloride of zinc and nitrous gas remove the smell of vulcanised caoutchouc in a great measure, especially if it be afterwards washed.

Another invention is that of masticating gutta percha in the proportion of 6 parts with 1 of chloride of zinc; which compound may be afterwards sulphurised. A further modification consists in producing a spongy gutta percha for stuffing sofas, &c. 45 parts of it is moistened with oil of turpentine, coal naphtha, bisulphide of carbon, or other proper solvent, 6 parts of hydrosulphide of lime, sulphide of antimony, or other analogous sulphide, 10 parts of carbonate of ammonia, carbonate of lime, or other substance that is either volatile or capable of yielding a volatile product, and 1 part of sulphur. Mr. Hancock mixes these materials together in a masticator, and then subjects them to a high degree of heat, observing the same conditions which are stated in the former description, except only that the heat may be pushed with advantage several degrees higher, say from 260° to 300°.

Various articles are manufactured of ordinary gutta percha, such as slings and double texture waterproof fabrics, boots, gaiters, belts, ha-layers, trousers and other straps, capes, life-preservers, tubes, knapsacks, caps, cups, and other vessels of capacity, hammer claws, cotton spinning rollers, backs of carls for carding wool, pumilio hammers, paper holders, springs, trusses, &c. By taking the gutta percha after it has been sulphurised, and brushing it with a solution of resin in benzine, and placing it in a chamber heated to from 75° to 100° Fahr., and afterwards pressing it by the means usually employed by the japanners, it acquires the lustre of japanned ware.

Mr. Hancock has also contrived a machine for cutting gutta percha into strips or riband, threads, or cord of any required shape. It consists of two grooved rollers of iron or steel, mounted in a suitable framework. The grooves of each roller are semi-circular, and the projecting divisions between the grooves are made with knife edges, so as to divide readily any sheet or mass of gutta percha presented to them. The upper roller is flanged at both ends, and the upper roller is made to fit inside of these flanges, in order to keep the cutting edges from shifting or being damaged. To cut thin sheets of gutta percha with this machine into strips or riband, the material is passed through it in a cold state, and only the cutting edges are brought into operation. To make round cord or thread by means of it, either a sheet of gutta percha of a thickness equal to the diameter of the holes formed by the grooves, and at a temperature of 200° Fahr. (produced by supplying it from a feeding-chamber heated to that degree) is passed through the machine, and the threads or cords are received in a tank of cold water, from which they are led away to be wound on reels or drums; or the gutta percha is employed in a plastic state, and passed under a gauge before it enters the machine. If it be desired to produce a cord of a semicircular form in the transverse section, a plane roller is substituted for the larger grooved roller; or should cord of a square, triangular, or hexangular, or any other form be required, the two rollers must be shaped to suit.

Gutta Percha Tubes.—A series of interesting experiments have been made at the Birmingham Waterworks, relative to the strength of Gutta Percha Tubing, with a view to its applicability for the conveyance of water. The experiments were made (under the direction of Henry Rose, Esq., engineer), upon tubes $\frac{1}{2}$ of an inch diameter, and one eighth, of gutta percha. These were attached to the iron main, and subjected for two months to a pressure of 200 feet head of water, without being in the slightest degree deteriorated. In order to ascertain if possible the maximum strength of the tubes, they were connected with the Water Company's hydraulic proving pump, the regular load of which is 350 lbs. on the square inch. At this point the tubes were unaffected, and the pump was worked up to 337 lbs., but to the astonishment of every one the tubes still remained perfect. It was then proposed to work the pump up to 500 lbs., but it was found that the lever of the valve would not bear this weight. The utmost power of the hydraulic pump could not break the tubes.

The gutta percha being somewhat elastic, allowed the tubes to become slightly expanded by the extraordinary pressure which was applied, but on its withdrawal they resumed their former size.

This tubing is such an extraordinary conductor of sound, that its value, not only to deaf persons, but to the public generally, will speedily be appreciated. It has already been fitted up in dwelling houses, in lieu of bells;—as speaking tubes for giving and receiving messages in mines, railway stations, prisons, workhouses, hotels, and all large establishments, it is invaluable.

Properties of common Gutta Percha.—The gutta percha, purified for manufacturing purposes, is of a reddish-brown colour; it readily becomes electrical by friction and is a bad conductor of both electricity and heat. At the ordinary temperature of our climate, say from 32° to 77°, it possesses about as much tenacity as thick leather, with rather less flexibility; it softens and becomes sensibly doughy towards 120°, although still very tough. Its ductility is such, at a temperature of from 110° to 211°, that it is readily extended into thin sheets, or drawn into threads or tubes; its flexibility and ductility diminish as the temperature becomes lower. It does not possess at any temperature the peculiar elastic extensibility which characterises caoutchouc. Exposed for an hour to a temperature of 142°, its flexibility is slightly diminished.

In its various forms, gutta percha possesses a peculiar porosity, as may be shown in the following manner:—A drop of its solution in sulphuret of carbon is to be placed on a glass slip; the spontaneous evaporation soon reduces this solution to a whitish plate; if it be then examined with the microscope, the numerous cavities with which it is pierced may be distinctly perceived. These cavities may be enlarged still more visible by means of a drop of water; the liquid gradually imbibes itself, the mass appears more opaque, and by means of the microscope the cavities are seen to be enlarged.

Similar results are obtained, by keeping thin transparent laminae, obtained by the evaporation, by heat, of a solution of gutta percha immersed in water for a considerable time.

The preceding observations lead us to think, that this substance retaining, in consequence of its porosity, a great many minute particles of air, owes to this circumstance its appearance of possessing a less density than that of water, namely 0.679. In fact, on stretching gutta percha under strong pressure, and immediately cutting the strips thus produced into very small pieces under water, the greater part of the fragments fall to the bottom of the vessel—some immediately, others after absorbing a certain quantity of water. The same result is also obtained by keeping very thin leaves of gutta percha, prepared by different methods, immersed for a month in water deprived of air: their pores becoming gradually filled with the liquid, they become heavier than the water, and then ceased to float. Gutta percha is also heavier in proportion to the length of time it has been exposed to the air, particularly in thin leaves.

The porous structure of gutta percha becomes changed into a fibrous texture when it is drawn out so as to double its length: then retaining but little extensibility, it supports, without breaking, the action of a force equal to double that required for its elongation in the first instance.

Common gutta percha resists cold water, damp, and also the various influences which excite fermentation; but it can be softened, and experience a sort of superficial doughy fusion by the action of the solar rays in summer.

It is not attacked by alkaline solutions, even when caustic and concentrated; ammonia, saline solutions, water containing carbonic acid, the various vegetable and mineral acids, do not act upon it; the weaker alcoholic liquors (wines, beer, &c.) do not touch it; and even brandy scarcely dissolves a trace of it. Olive oil does not appear to attack gutta percha when cold; when hot, it dissolves a small portion of it, which is again precipitated on cooling.

Sulphuric acid with one equiv. of water colours it brown, and disintegrates it with a sensible evolution of sulphurous acid.

Muriatic acid, in its saturated solution in water at a temperature of 68° F., attacks gutta percha slowly, and gives it a more or less deep brown colour, at length rendering it brittle.

Monohydrated nitric acid attacks it rapidly, with effervescence and an abundant evolution of fumes of hyponitrous acid; the substance is decomposed, and coloured of a brownish-orange red; it becomes doughy, and afterwards solidifies by degrees and remains friable.

In the cold, and even by heat, only a part of the gutta percha (0.15 to 0.22) is dissolved by anhydrous alcohol or ether. Benzine and spirits of turpentine dissolve it partially when cold, but nearly completely if aided by heat. Sulphide of carbon and chloroform dissolve gutta percha when cold; the solutions may be filtered beneath a bell-glass to prevent evaporation; the filter retains the foreign matters of a reddish-brown colour, whilst the solution passes perfectly clear, and almost colourless. The filtered liquid, exposed to the air in a sancer, allows the solvent to escape, and deposits the white gutta percha in a plate of greater or less thickness, which shrinks gradually in proportion to the evaporation of the liquid.

Except the colour, which has disappeared, the gutta percha then offers the characters and properties mentioned above as belonging to the commercial substance. Submitted to a gradually raised temperature, it softens and melts, and may be made to boil without acquiring a sensible colour; the transparent fluid gives abundant vapours, which are condensable into a nearly colourless oily liquid. The portions last distilled have a brownish-orange colour, and a thin layer of carbonaceous deposit remains adherent to the sides of the vessel.

Analysis.—We have said above that alcohol and ether can dissolve only a portion of gutta percha; this is because that substance consists, in fact, of three proximate principles, the separation of which has required very delicate observation, although they are very clearly distinguished by several of their properties.

When gutta percha in thin leaves is brought into contact, in a close vessel, with 15 to 20 vols. of cold anhydrous alcohol, and the temperature raised slowly by means of the water-bath to the point of ebullition (172° F.), and kept at this point during several hours, the liquid, if filtered whilst boiling and left in a closed flask, will, at the end of from 12 to 36 hours, begin to deposit on the sides of the vessel and on the surface of the solution white opaline granules, distant from one another, but some of them in groups; their size will gradually increase for some days. These granules, carefully examined under the microscope, will be found to have the form of spherules truncated by the sides of the vessel. Their surface is either smooth, or bristling with very small transparent, elongated, lamellar crystals. Some superficial fissures appear to indicate

that these spherules are formed of a sort of transparent yellow kernel covered with a white pellicle.

Perhaps no other example is known of this singular crystalline structure. In fact, cold anhydrous alcohol dissolves the whole of the yellow spheroidal substance, whilst the superficial pellicle, in the interior of which the alcohol has substituted itself for the solid globule, appears whiter and less transparent.

The alcoholic solution, which has been for some days depositing this complex spheroidal crystallization, can again take up by heat a portion of the two proximate principles remaining in the substance, allowing a fresh quantity to crystallise on cooling. The extraction is completed by retaining the boiling alcohol several times upon the gutta percha until it no longer dissolves anything.

The solid substance which has resisted the action of the solvent, possesses, with some modifications, the principal properties of crude gutta percha; we shall here call it *pure gutta*. As to the two other organic principles, one is a *yellow resin*, which is much more soluble in cold alcohol than the other, the *white crystalline resin*.

By taking advantage of these different degrees of solubility, we are enabled with time and patience to effect the complete purification of these three principles. The separation may also be effected by treating finely-divided gutta percha with cold ether, which dissolves the mixture of the two resins more abundantly than alcohol; they are afterwards separated from one another by the same treatment already described for alcohol.

The tendency of the white resin to form itself into radiated groups is manifested in a rather remarkable circumstance, which it is easy to reproduce. Narrow ribbons cut from a thin leaf of ordinary gutta percha are to be placed in a tube, and immersed in anhydrous alcohol. The tube is then closed, and left for twenty or thirty days, when a few whitish points appear here and there on the ribbons, and afterwards on the sides of the tube. These points, which become gradually larger, are formed of crystalline tufts of the white resin. Thus this proximate principle is separated directly, and in the cold, even when the atmospheric temperature is gradually rising, for instance during the spring or early summer.

The crystalline white resin, when completely purified by washings with alcohol, and then redissolved in anhydrous alcohol, is deposited by slow spontaneous evaporation in the air, in radiated crystals, forming sometimes symmetrical tufts arranged in stars, and then presenting the appearance of a sort of efflorescence.

Distinctive characters and properties of the three proximate principles which constitute common Gutta Percha.—The most abundant of these three principles, forming at least from 75 to 83 per cent. of the whole mass, is the pure gutta, which presents the principal properties of the commercial substance; it is white, transparent at a temperature of 212° F., when all its parts are melted together; opaque or semi-transparent when cold, from its then acquiring a structure which causes the interposition of air, or of a liquid possessing a different refraction from its own. This structure appears still more distinct than in the natural substance containing all three principles.

In thin sheets, and at a temperature of 50° to 68° F., it is supple, tough, extensible but not very elastic. At 112° F., it softens and turns back upon itself, and becomes more and more adhesive and translucent in proportion to the elevation of temperature, undergoing a sort of doughy fusion, which becomes more distinct towards 212° to 270° . Heated beyond this point, it melts, boils, and distils, furnishing a pyrogenous oil and carbonated gases.

Soubeyran believes the composition of perfectly pure gutta percha to be $C^{11}H^{10}$ corresponding to 67.8 carbon, and 12.2 hydrogen. Faraday found caoutchouc to be 87.2 carbon, 12.8 hydrogen; hence their chemical composition is identical.

Pure gutta, like the other two proximate principles, is quickly rendered electrical by friction, and is a bad conductor of heat; it generally floats on water, but sinks to the bottom as soon as its pores are filled with this liquid. It is insoluble in alcohol and ether, almost completely insoluble in benzine at 32° F.; it is soluble at 77° , and becomes more and more so in proportion as the temperature is raised. The saturated solution at 86° forms itself into a semi-transparent mass when cooled below 32° ; alcohol precipitates the pure gutta from its solution in benzine.

At 32° , spirits of turpentine dissolves very little gutta, whilst it disintegrates and dissolves it readily when hot.

Chloroform and sulphide of carbon dissolve the gutta percha in the cold.

After the extraction by means of ether of the two resins interposed in the thin leaves of white gutta percha, leaving the last portion of ether with which they were impregnated to evaporate in the open air, these leaves, enclosed in a flask, experienced, after remaining there for two months at a temperature of from 68° to 82° F., an alteration which appeared to depend on their porosity, the action of the air, and

perhaps the ether retained in their pores. However it be, these leaves had then acquired new properties: they were brittle; exhaled a very distinct sharp odour; brought into contact with an excess of anhydrous ether, they were partially dissolved; the soluble portion, obtained by the evaporation of the ether and desiccation at 194° F., was glutinous and translucent; it became opaque and hard by cooling down to 14° F.

Sulphide of carbon, renewed three times in six days, and evaporated each time after two days' contact, left as residue a white flexible leaf. The portion not dissolved, swelled and transparent, did not appear to undergo any change when left in sulphide of carbon for ten days.

This kind of spontaneous transformation would perhaps become complete if more prolonged; its study will require much time; it will perhaps put us in the way of ascertaining the causes of certain changes observed in some small objects formed of gutta percha. It has already been ascertained, that thin leaves, exposed for eight consecutive days to the action of the sun in moist air, were discoloured, and that their substance had become in great part soluble in ether.

Monohydrated sulphuric acid disintegrates, and communicates a brown colour to the pure gutta, with evolution of sulphurous acid; after eight days' contact, the deep brown liquid, on dilution with water, becomes turbid, and furnishes a brown flocculent precipitate. Nitric acid, with a single equivalent of water, attacks the pure gutta with a lively effervescence, and the evolution of orange vapours of hyponitrous acid. Muriatic acid, in its saturated solution, slowly attacks the thin leaves of gutta, giving them a deep brown colour; at the end of eight days it becomes friable. The reaction of muretiatic acid establishes an additional distinctive character between this proximate principle and the two others.

M. Payen has carefully examined the chemical and physical peculiarities of the three principles which he has discovered in gutta percha. These have, however, no interest for the manufacturer, and we refer the chemical student to M. Payen's Memoir.

The juice of Modilar has been proposed as a substitute for gutta percha, but we are not aware that it has in any manufacture taken its place. Dr. Falconer describes a new kind of gutta percha, which grows in the most southern British possession of the Merguin Islands, Indian Ocean.

If a solution of gutta percha in chloroform be mixed with 3 parts of ether, and exposed for some time to a temperature below 15° , the gutta percha is precipitated as a white powder, forming when washed and dried a soft white mass. On spreading this solution on a plate of glass, a skin is formed, resembling kid-glove leather, which becomes transparent on the application of heat. These films are beautifully white, if carefully prepared, and they have been employed in the manufacture of the finest kinds of artificial flowers.

In 1848, Dr. Faraday drew the attention of experimentalists to the highly insulating power of gutta percha, which not only possesses this property under ordinary circumstances, but likewise retains it under atmospheric conditions which would make the surface of glass a good conductor. This has led to its almost universal adoption as the insulator for the wires of the electrical telegraph. When buried in the earth, unless it is attacked by insects, or by a fungus, it retains its high insulatory power, and we have every reason for believing that gutta percha does not undergo a change when immersed in sea water. It has, however, been found, that when it has been exposed to the intense sunshine of India, it undergoes a remarkable change: oxygen is absorbed, the gutta percha loses its coherence, and at the same time its power of insulation.

The quantity of gutta percha imported in 1857 was —

T. J. P.

GYPSUM. This natural production, which in its varieties is known as *sulphate of lime*, *alabaster*, *selenite*, *satın spar*, *gyps*, and *plaster of Paris*, has a composition of, sulphuric acid, 46.51; lime, 32.56; water, 20.93.

The *anhydrite* from Derby is a mineral like gypsum, but, as its name indicates, containing no water; its composition being, lime, 41.9; sulphuric acid, 58.8; this is also called *muriacite* and *tripe-stone*. It absorbs moisture and changes to gypsum. When gypsum is carefully burnt it loses its water of composition, and forms the well-known *plaster of Paris*.

The transparent varieties of gypsum are called *selenite*; its fine massive varieties are *alabaster*, and its fibrous kinds *satın spar*. There is another variety in small scales of a pearly lustre, known as *schaumkalk*. See ALABASTER.

H.

HACKLE. A flax comb. See **FLAX**.

HADE. A miner's term, used in Derbyshire and some of the northern counties, signifying the inclination or deviation from the vertical of any mineral vein or lode. *Hadings* signify that some parts of the vein incline, while others are vertical.

HEMATINONE. A kind of glass used by the ancients for making ornamental vessels, mosaics, &c. It is described by Pliny, and has been found pretty abundantly in the excavations of Pompeii. This glass is of a beautiful red colour. It contains no tin or any other colouring matter except copper. All attempts of the moderns to imitate the antique *hematones* have hitherto failed; the nearest approach is supposed to be the Italian *porporino*, which, however, differs from it in most respects.

HAIR (*Cheveu*, *Crin*, Fr.; *Haar*, Germ.) is of all animal products the one least liable to spontaneous change. It can be dissolved in water only at a temperature somewhat above 230° F., in a Papin's gester, but it appears to be partially decomposed by this heat, since some sulphuretted hydrogen is disengaged. By dry distillation, hair gives off sulphuretted gases, while the residuum contains sulphate of lime, common salt, much silica, with some oxide of iron and manganese. It is a remarkable fact that fair hair affords magnesia, instead of these latter two oxides. Horse-hair yields about 12 per cent. of phosphate of lime.

We have no recent analysis of hair. Vauquelin found nine different substances in black hair; in red hair, a red oil instead of a greenish-black one.

Hairs are tubular, their cavities being filled with a fat oil, having the same colour with themselves. Hair plunged in chlorine gas, is immediately decomposed and converted into a viscid mass; but when immersed in weak aqueous chlorine, it undergoes no change, except a little bleaching.

Living hairs are rendered black by applying to them for a short time a paste made by mixing libarge, slaked lime, and bicarbonate of potash, in various proportions, according to the shade of colour desired. The ordinary mode of dyeing human hair, is first to saturate the hair with the sulphide of potassium in solution; then, when this has been well absorbed and is partially dry, a solution of nitrate of silver is to be applied. By varying the proportions of the sulphide, and the strength of the silver solution, almost any tone of colour, from a brown to a black, can be produced.

The salts of silver, mercury, lead, bismuth, as well as their oxides, blacken hair, or make it of a dark violet, by the formation, most probably, of metallic sulphurets (*sulphides*).

Hair as an object of manufactures is of two kinds, the *curly* and the *straight*. The former, which is short, is spun into a cord, and boiled in this state, to give it the tortuous springy form. The hairs of rabbits and hares are prepared for the hat-maker by a process called *secretage*, so as to render them fit for felt. The skins with the hair still upon them are laid upon a table, and with a brush, made from the bristle of the wild boar, a solution of nitrate of mercury is applied many times in succession, till every part of the fur be equally touched, and till about two-thirds of the length of the hairs be moistened. The skins are then placed together to complete the impregnation, and put into a stove-room. In drying there is a retraction of the hairs, and the required curling is produced. The long straight hair is woven into cloth for sleeves, and also for ornamental purposes, as in the damask-hair cloth of chair bottoms. For this purpose the hair may be dyed in the following way:—

Forty pounds of tail hair, about 26 inches long, are steeped in lime water during twelve hours. Then a bath is made with a decoction of 20 pounds of logwood, kept boiling for three hours, after which time the fire is withdrawn from the boiler, and ten ounces of copperas are introduced, stirred about, and the hair is immersed, having been washed from the lime in river water. The hair should remain in this coloring bath for 24 hours, when the operation will be finished. Hair used for weaving is obtained principally from South America and from Russia. All the black and grey hair is dyed for the manufacture of black hair-cloth for covering furniture. White only can be dyed so as to produce what are called fancy colours, and great care is required in the process, which however, when well managed, produces good permanent colour.

The quality of hair-cloth, as well as the brilliancy and permanency of the colours, depend in a great degree on the nature of the warp, which may be either of cotton, linen, or worsted. Coloured hair-cloth, which is made at Worcester, Sheffield, and Paris, has been much used for fitting up the principal cabins of steam vessels, for covering sofas and chairs, and for railway carriages.

The looms for weaving hair differ from the common ones, only in the templet and the shuttle. Two templets of iron must be used to keep the stuff equally but lightly stretched. These templets, of which one is represented in *fig. 936*, are constructed in the shape of flat pincers; the jaws, *c c*, being furnished with teeth inside. A screw, *x*, binds the jaws together, and hinders the selvage from going inwards. Upon the side cross beam of the loom, seen in section at *t*, a bolt is fixed which carries a nut *r* at its end, into which a screwed iron rod *u* enters, on one of whose ends is the handle *n*. The other extremity of the screw *x* is adapted by a washer and pin to the back of the pincers at the point *u*, so that by turning the handle to the right or the left, we draw

onwards or push backwards the pincers and the stuff at pleasure. The warp of the web is made of black linen yarn. The weft is of hair, and it is thrown with a long hooked shuttle, or a long rod, having a catch hook at its end. The length of this shuttle is about 3 feet; its breadth half an inch, and its thickness one sixth. It is made of box-wood. The reed is of polished steel; the thread warps are conducted through it in the usual way. The workman passes this shuttle between the hairs of the warp with one hand, when the shed or shuttle way is opened by the tressles; a child placed on one side of the loom presents a hair to the weaver near the selvage, who catches it with the hook of his shuttle, and by drawing it out passes it through the warp. The hairs are placed in a bundle on the side where the child stands, in a chest filled with water to keep them moist, for otherwise they would not have the suppleness requisite to form a web. Each time that a hair is thrown across, the batten is driven home twice. The warp is dressed with paste in the usual way. The hair-cloth, after it is woven, is hot calendered to give it lustre. In the Great Exhibition of 1861, J. Bardolfsky (Russia) exhibited a collection of bowls, diables, plates, &c., formed of the hair of the rabbit, hare, and other animals, which were felted and afterwards varnished. They had the appearance of paper maché, and were very light.

In 1867 we imported —

HAIR BRUSHES, or PENCILS, for artists.

The *hair brushes* are manufactured with coarse hair, as that of the swine, the wild boar, the dog, &c. and these are usually attached, by binding with cord or by securing them with a piece of tin plate, to a wooden handle.

The *hair pencils* are composed of very fine hairs, as those of the sable, the miniver, the martlet, the badger, and the polecat. These are usually mounted in a quill, but sometimes they are secured as in the former case with tinned iron.

The most essential quality of a good pencil is to form a fine point, so that all the hairs without exception may be united when they are moistened by laying them upon the tongue, or drawing them through the lips. When hairs present the form of an elongated cone in a pencil, their point only can be used. The whole difficulty consists, after the hairs are cleaned, in arranging them together so that all their points may lie in the same horizontal plane. We must wash the tails of the animals whose hairs are to be used, by scouring them in a solution of alum till they be quite free from grease, and then steeping them for 24 hours in luke-warm water. We next squeeze out the water by pressing them strongly from the root to the tip, in order to lay the hairs as smooth as possible. They are to be combed in the longitudinal direction, with a very fine-toothed comb, and finally wrapped up in fine linen, and dried. When perfectly dry, the hairs are seized with pincers, cut across close to the skin, and arranged in separate heaps, according to their respective lengths.

Each of these little heaps is placed separately, one after the other, in small tin pans with flat bottoms, with the tips of the hair upwards. On striking the bottom of the pan slightly upon a table, the hairs get arranged parallel to each other, and their delicate points rise more or less according to their lengths. The longer ones are to be picked out and made into so many separate parcels, whereby each parcel may be composed of equally long hairs. The perfection of the pencil depends upon this equality; the tapering point being produced simply by the attenuation of the tips.

A pinch of one of these parcels is then taken, of a thickness corresponding to the intended size of the pencil; it is set in a little tin pan, with its tips undermost, and

is shaken by striking the pan on the table as before. The root end of the hairs being tied by the fisherman's or seaman's knot, with a fine thread, it is taken out of the pan, and then hooped with stronger thread or twine; the knots being drawn very tight by means of two little sticks. The distance from the tips at which these ligatures are placed, is of course relative to the nature of the hair, and the desired length of the pencil. The base of the pencil must be trimmed flat with a pair of scissors.

Nothing now remains to be done but to mount the pencils in quill or tin-plate tubes, as above described. The quills are those of swans, geese, ducks, lapwings, plovers, or larks, according to the size of the pencil. They are steeped during 24 hours in water, to swell and soften them, and to prevent the chance of their splitting when the hair brush is pressed into them. The brush of hair is introduced by its tips into the large end of the cut quill, having previously drawn them to a point with the lips, when it is pushed forwards with a wire of the same diameter, till it comes out at the other and narrower end of the quill.

The smaller the pencils, the finer ought the hairs to be. In this respect, the manufacture requires much delicacy of taste and experience.

HALIOTIS, the sea ear shell. A genus of molluscous animals belonging to the class Gastropoda. These shells possessing a fine pearly are extensively used in the ornamentation of papier maché articles, and mother-of-pearl ornaments.

HALOGENE, is a term employed by Berzelius to designate those substances which form compounds of a saline nature by their union with metals; such are chlorine, iodine, bromine, fluorine, and cyanogen; the salts thus formed being called *haloid salts*, from their resemblance to common salt (NaCl). (See, sea salt, and also, form). Since the discovery of the compound halogens, Cyanogen, some chemists have been led to view all salts as under the type of haloid salts; assuming in the different acids certain compound halogens, as in sulphuric acid the halogene (SO^4); in nitric acid the halogene (NO^4) &c.; which in combination with hydrogen form the acids; the different salts being formed by the displacement of the hydrogen by the metal, as follows: sulphuric acid (H_2SO^4), sulphate of potash (K_2SO^4), nitric acid (HNO^4), nitrate of soda (NaNO^4), &c.—H. K. R.

HANDSPIKE. A strong wooden bar, used as a lever to move the windlass and capstan in heaving the anchor, or raising any heavy weights aboard ship. The handle is round, smooth, and somewhat taper. The other end is squared to fit the holes in the head of the capstan or the barrel of the windlass.

HARDENING. The processes by which metals are rendered harder than they are when they first leave the hands of the workman.

Some metals are hardened by hammering or rolling; but care is required not to carry this too far, as brittleness may be induced. Sudden cooling is had recourse to with some metals. Pure hammered iron appears after annealing to be equally soft, whether suddenly or slowly cooled; some of the impure kinds of malleable iron harden by immersion. Steel, however, receives by sudden cooling that extreme degree of hardness combined with tenacity, which places it so incalculably beyond every other material for the manufacture of cutting tools.

In hardening and tempering steel there are three things to be considered, namely, the means of heating the objects to redness, the means of cooling the same, and the means of applying the heat for *tempering*, or "letting them down." It is not possible in this work to enter into the manipulatory details of hardening steel for various purposes; the most valuable information on this subject is given in Holzapfel's work on *Turning and Mechanical Manipulation*.

Steel pens are hardened by being heated in large quantities in iron trays within a furnace, and then plunged in an oily mixture; generally, they are likewise tempered in oil, or a composition, the boiling point of which is the same as the temperature suited to "letting them down."

Saws and springs are hardened in various compositions of oil, suet, wax, and other ingredients, "which however lose their hardening property after a few weeks' constant use." Steel plates are hardened occasionally by allowing water to fall on them when hot. See **TRANSFER ENGRAVING**.

Case hardening is the process by which wrought iron is first converted exteriorly into steel, and is subsequently hardened to that particular depth, leaving the central parts in their original condition of soft and fibrous iron. The principal agents used for case hardening are animal matters, as the hoofs, horns, bones, and skins of animals. The prussiate of potash, which is a compound of carbon and nitrogen, is also employed for case hardening. In principle it is the same as the animal substances. The iron is heated in the open fire to a dull red, and the prussiate is either sprinkled upon it or rubbed on in the lump; it is returned to the fire for a few minutes, and immersed in water. In the volume of Lardner's "Cyclopædia," on *Iron and Steel*, edited by Robert Hunt, the subjects of hardening and tempering are treated in a practical manner.

HARDNESS. (*Dureté*, Fr.; *Härte*, *Festigkeit*, Germ.) A hard body will scratch one that is softer than itself. This method of determining the hardness of minerals is employed by mineralogists. A good steel file is also used for trying the respective hardness of minerals.

Mohs introduced a scale of hardness, which shows the gradual increase in hardness through 10 minerals.

1. *Talc*; common laminated light green variety.
2. *Gypsum*; crystallised variety.
3. *Calcite*; transparent variety.
4. *Fluor spar*; crystalline variety.
5. *Apatite*; transparent variety.
6. *Feldspar* (orthoclase); white cleavable variety.
7. *Quartz*; transparent.
8. *Topaz*; ditto.
9. *Sapphire*; cleavable varieties.
10. *Diamond*.

The following table, compiled by Dr. Ure for the early editions of his dictionary, will still be found very useful as representing, relatively, the hardness of the mineral named, although the numbers which express the degree of hardness do not agree with the scale of Mohs.

		100

HAT MANUFACTURE. (*L'art de Chapelier*, Fr.; *Hutmacherkunst*, Germ.) Hat is the name of a covering for the head worn by both sexes, but principally by men.

As the art of making hats does not involve the description of any curious machinery, or any interesting processes, we shall not enter into very minute details upon the subject. It will be sufficient to convey to the reader a general idea of the methods employed in this manufacture.

The materials used in making stiff hats are the furs of hares and rabbits freed from the long hair, together with wool and beaver. The beaver is reserved for the finer

hats. The fur is first laid upon a hurdle made of wood or wire, with longitudinal openings, and the operator, by means of an instrument called the bow, (which is a piece of elastic ash, six or seven feet long, with a catgut stretched between its two extremities, and made to vibrate by a bowstick,) causes the vibrating string to strike and play upon the fur, so as to scatter the fibres in all directions, while the dust and filth descend through the grills of the hurdle.

After the fur is thus driven by the bow from one end of the hurdle to the other, it forms a mass called a *bat*, which is only half the quantity sufficient for a hat. The bat or *capade* thus formed is rendered compact by pressing it down with the *hardening skin* (a piece of half-tanned leather), and the union of the fibres is increased by covering them with a cloth, while the workman presses them together repeatedly with his hands. The cloth being taken off, a piece of paper, with its corners doubled in, so as to give it a triangular outline, is laid above the bat. The opposite edges of the hat are then folded over the paper, and being brought together and pressed again with the hands, they form a conical cap. This cap is next laid upon another bat, ready hardened, so that the joined edges of the first bat rest upon the new one. This new bat is folded over the other, and its edges joined by pressure as before; so that the joining of the first conical cap is opposite to that of the second. This compound hat is now wrought with the hands for a considerable time upon the hurdle between folds of linen cloth, being occasionally sprinkled with clear water, till the hat is *browned*, or rendered tolerably firm.

The cap is now taken to a wooden receiver, like a very flat mill-hopper, consisting of eight wooden planks, sloping gently to the centre, which contains a kettle filled with

932

water acidulated with sulphuric acid. The technical name of this vessel is the *battery*. It consists of a kettle *A*, fig. 932; and of the planks, *a, c*, which are sloping planes, usually eight in number, one being allotted to each workman. The half of each plank next the kettle is made of lead, the upper half of mahogany. In this liquor the hat is occasionally dipped, and wrought by the hands, or sometimes with a roller, upon the sloping planks. It is thus felled or thickened during four or five hours; the knots or hard substances are picked out by the workman, and fresh felt is added by means of a wet brush to those parts that require it. The beaver is applied at the end of this operation. In the manufacture of beaver hats, the grounds of beer are added to the liquor in the kettle.

Steeping, or thickening the thin spots, seen by looking through the body, is performed by daubing on additional stuff with successive applications of the hot acidulous liquor from a brush dipped into the kettle, until the body be sufficiently shrunk and made uniform. After drying, it is stiffened with varnish composition rubbed in with a brush; the inside surface being more copiously imbued with it than the outer; while the brim is peculiarly charged with the stiffening.

When once more dried, the body is ready to be *covered*, which is done at the *battery*. The first cover of beaver or napping, which has been previously *bowed*, is stretched equally over the body, and patted on with a brush moistened with the hot liquor, until it gets incorporated; the cut ends towards the root, being the points which spontaneously intrude. The body is now put into a coarse hair cloth, then dipped and rolled in the hot liquor, until the root ends of the beaver are thoroughly worked in. This is technically called *rolling off*, or *roughing*. A strip for the brim, round the edge of the inside, is treated in the same way; whereby everything is ready for the second cover (of beaver), which is incorporated in like manner; the finishing, &c. being continued, till a uniform, close, and well-felted hood is formed.

The hat is now ready to receive its proper shape. For this purpose the workman turns up the edge or brim to the depth of about $1\frac{1}{2}$ inch, and then returns the point of the cone back again through the axis of the cap, so as to produce another inner fold of the same depth. A third fold is produced by returning the point of the cone, and so on till the point resembles a flat circular piece having a number of concentric folds. In this state it is laid upon the plank, and wetted with the liquor. The workman pulls out the point with his fingers, and presses it down with his hand, turning it at the same time round on its centre upon the plank, till a flat portion, equal to the crown of the hat, is rubbed out. The flat crown is now placed upon a block, and, by pressing a string called a *roundel*, down the sides of the block, he forces the parts adja-

cent to the crown, to assume a cylindrical figure. The brim now appears like a puckered appendage round the cylindrical cone; but the proper figure is next given to it, by working and rubbing it. The body is rendered waterproof and stiff by being imbedded with a varnish composed of shellac, sandarach, mastic, and other resins dissolved in alcohol or naphtha.

The hat being dried, its nap is raised or loosened with a wire brush or card, and sometimes it is previously pounced or rubbed with pumice, to take off the coarser parts and afterwards rubbed over with seal skin. The hat is now tied with pack-thread upon its block, and is afterwards dyed.

The dyed hats are now removed to the stiffening shop. Bees grounds are next applied on the inside of the crown, for the purpose of preventing the glue from coming through; and when the bees grounds are dried, glue (gum Senegal is sometimes used), a little thinner than that used by carpenters, is laid with a brush on the inside of the crown, and the lower surface of the brim.

The hat is then softened by exposure to steam, on the steaming basin, and is brushed and ironed till it receives the proper gloss. It is lastly cut round at the brim by a knife fixed at the end of a gauge, which rests against the crown. The brim, however, is not cut entirely through, but is torn off so as to leave an edging of beaver round the external rim of the hat. The crown being tied up in a gauze paper, which is neatly ironed down, is then ready for the last operations of lining and binding.

The furs and wools of which hats are manufactured contain in their early stage of preparation, *hemp* and *hair*, which must be removed in order to produce a material for the better description of hats. This separation is effected by a sort of winnowing machine, which wafts away the finer and lighter parts of the furs and wools from the coarser.

The annexed figures represent Mr. Ollerenshaw's machine, generally employed for ironing hats. Fig. 938 is the frame-work or standard upon which three of these

lathes are mounted, as A, B, C. The lathe A is intended to be employed when the crown of the hat is to be ironed. The lathe B, when the flat top, and the upper side of the brim is ironed, and lathe C, when its under side is ironed; motion being given to the whole by means of a band passing from any first mover (as a steam-engine, water-wheel, &c.) to the drum on the main shaft a a. From this drum a strap passes over the rigger b, which actuates the axle of the lathe A. On to this lathe a sort of chuck is screwed, and to the chuck the block c is made fast by screws, bolts, or pins. This block is represented in section, in order to show the manner in which it is made, of several pieces held fast by the centre wedge-piece, as seen at fig. 939.

The hat-block being made to turn round with the chuck, at the rate of about twenty turns per minute, but in the opposite direction to the revolution of an ordinary turning lathe, the workman applies his hot iron to the surface of the hat, and thereby smooths it, giving a beautiful glossy appearance to the beaver; he then applies a plush cushion, and rubs round the surface of the hat while it is still revolving. The hat, with its block, is now removed to the lathe B, where it is placed upon the chuck d, and made to turn in a horizontal direction, at the rate of about twenty revolutions per minute, for the purpose of ironing the flat-top of the crown. This lathe B moves upon an upright shaft e, and is actuated by a twisted band passing from the main shaft round the rigger f. In order to iron the upper surface of the brim, the block c is removed from

the lathe, and taken out of the hat, when the block *fig. 940* is mounted upon the chuck *d*, and made to turn under the hand of the workman, as before.

The hat is now to be removed to the lathe *c*, where it is introduced in an inverted position, between the arms *g g* supporting the rim *A A*, the top surface of which is shown at *fig. 941*. The spindle *i* of the lathe turns by similar means to the last, but slower; only ten turns per minute will be sufficient. The workman now smooths the under side of the brim, by drawing the iron across it, that is from the centre outwards. The hat is then carefully examined, and all the burs and coarse hairs picked out, after which the smoothing process is performed as before, and the dressing of the hat is complete. This description of the manufacture of the beaver hat has been retained, though it is now but little practised, the silk hat having taken its place.

Silk hats, for several years after they were manufactured, were liable to two objections; first, the body or shell over which the silk covering is laid, was, from its hardness, apt to hurt the head; second, the edge of the crown being much exposed to blows, the silk nap soon got abraded, so as to lay bare the cotton foundation, which is not capable of taking so fine a black dye as the silk; whence the hat assumed a shabby appearance. Messrs. Mayhew and White, of London, proposed to remedy these defects, by making the hat body of stuff or wool, and relieving the stiffness of the inner part round the brim, by attaching a coating of beaver upon the under side of the brim, so as to render the hat pliable. Round the edge of the tip or crown, a quantity of what is called stop wool is to be attached by the ordinary operation of bowing, which will render the edge soft and elastic. The hat is to be afterwards dyed of a good black colour, both outside and inside; and being then properly stiffened and blocked, is ready for the covering of silk.

The plush employed for covering silk hats, is a raised nap or pile woven usually upon a cotton foundation; and the cotton, being incapable of receiving the same brilliant black dye as the silk, renders the hat apt to turn brown whenever the silk nap is partially worn off. To counteract this evil, the foundation of the plush is now frequently made entirely of silk. To these two improvements, now pretty generally introduced, the present excellence of the silk hats may be ascribed.

Fig. 942 is a side view of the carding engine, employed in preparing the silk for

hats, with a horizontal plan or view of the lower part of the carding machine, showing the operative parts of the winding apparatus, as connected to the carding engine. The doffer cylinder is covered with fillets of wire cards, such as are usually employed in carding engines, and these fillets are divided into two, three, or more spaces extending round the periphery of the cylinder, the object of which division is to separate the sliver into two, three, or more breadths, which are to be conducted to and wound upon distinct blocks, for making so many separate hats or caps.

The principal cylinder of the carding engine, is made to revolve by a rigger upon its axle, actuated by a band from any first move as usual, and the subordinate rollers or cylinders belonging to the carding engine, are all turned by pulleys, and bands, and gear, as in the ordinary construction.

The wool or other material is supplied to the feeding cloth, and carried through the engine to the doffer cylinder, as in other carding engines; the doffer comb is actuated by a revolving crank in the common way, and by means of it the slivers are taken from the doffer cylinder, and thence received on to the surfaces of the blocks *c c*. These blocks, of which two only are shown to prevent confusion, are mounted upon axles, supported by suitable bearings, in a carriage *ff*, and are made to revolve by means of a band *g g*, leading from a pulley on the axle of a conical drum beneath. The band *g* passes over a pulley *h*, affixed to the axle of one of the blocks, while another pulley *i*, upon the same axle, gives motion, by means of a band, to as many other blocks as are adapted to the machine.

As it is necessary in winding the slivers on to the blocks, to cross them in different directions, and also to pass the sliver over the hemispherical ends of the blocks, in order that the wool or other material may be uniformly spread over the surface in forming the cap or hood for the shell or foundation of the intended hat, the carriage *ff*, with the blocks, is made to traverse to and fro in lateral directions upon rollers at each end.

This alternating motion of the carriage is caused by a horizontal lever *ll* (seen in the horizontal view *fig. 943*), moving upon a fulcrum *pio* at *m*, which lever is attached to the carriage at one extremity *n*, and at the other end has a weighted cord which draws the axle of this lever against a cam wheel *a*. This cam is made to revolve by means of a band and pulley, which turns the shaft and endless screw *q*, and this endless screw, taking into a toothed wheel *r*, on the axle of the cam *a*, causes the cam to revolve, the periphery of which cam running against a friction roller on the side of the lever *l*, causes the lever to vibrate, and the carriage *ff*, attached to it, to traverse to and fro upon the supporting rollers, as described. By these means the slivers are laid in oblique directions (varying as the carriage traverses) over the surface of the blocks.

The blocks being conically formed, or of other irregular figures, it is necessary, in order to wind the slivers with uniform tension, to vary their speed according to the diameter of that part of the block which is receiving the sliver. This is effected by giving different velocities to the pulley on the axle of the conical drum *s*, corresponding with *c*. There is a similar conical drum *t*, placed in a reverse position in the lower part of the frame, which is actuated by a band from any convenient part of the machine passing over a pulley *u*, upon the axle of *t*. From the drum *t*, to the drum *s*, there is a band *v*, which is made to slide along the drums by the guidance of two rollers at the end of the lever *l*.

It will now be seen that when the larger diameter of the cam wheel *a* forces the lever outwards, the band *v* will be guided on to the smaller part of the conical drum *t*, and the larger part of *s*, consequently the drum *s* will at this time receive its slowest motion, and the band *g* will turn the blocks slower also; the reverse end of the lever *l*, having by the same movement slid the carriage into that position which causes the slivers to wind upon the larger diameter of the blocks.

When the smaller diameter of the cam is acting against the side of the lever, the weighted cord draws the end of the lever to the opposite side, and the band *v* will be guided on to the larger part of the cone *t*, and the smaller part of the cone *s*; consequently, the quicker movement of the band *g* will now cause the blocks *c c* to revolve with a corresponding speed. The carriage *ff* will also be moved upon its rollers to the reverse side, and the sliver of wool or other material be now wound upon the smaller parts and ends of the blocks, at which time the quicker rotation of the blocks is required. It may be here observed, that the cam wheel *a* should be differently formed according to the different shaped blocks employed, so as to produce the requisite movements of the lever and carriage suited thereto.

It only remains to state that there are two heavy conical rollers *w w*, bearing upon the peripheries of the blocks *c c*, which turn loosely upon their axles by the friction of contact, for the purpose of pressing the slivers of wool or other material on the blocks as it comes from the doffer cylinder of the carding engine, and when the blocks have been coated with a sufficient quantity of the sliver, the smaller end of the pressing rollers is to be raised, while the cap is withdrawn from the block. The process being continued as before, the formations of other bodies or caps is effected in the manner above described.

After the caps or bodies of hats, &c. are formed in the above described machine, they are folded in wet cloths, and placed upon heated plates, where they are rolled under pressure, for the purpose of being hardened. *Fig. 938* represents the front of three

furnaces *a a a*, the tops of which are covered with iron plates *b b b*. Upon these plates, which are heated by the furnace below, or by steam, the bodies wrapped in the wet cloths *c c c*, are placed, and pressed upon by the flaps or covers *d d d*, sliding upon guide rods, to which flaps a traversing motion is given, by means of chains attached to an alternating bar *e e*. This bar is moved by a rotary crank *f*, which has its motion by pulleys from any actuating power. When any one of the flaps is turned up to remove the bodies from beneath, the chains hang loosely, and the flap remains stationary.

These caps or hat bodies, after having been hardened in the manner above described, may be felted in the usual way by hand, or they are felted in a felting mill by the usual process employed for making cloths, except that the hat bodies are occasionally taken out of the felting mill, and passed between rollers, for the purpose of rendering the felt more perfect.

Mr. Carey, of Hartford, obtained a patent in October, 1834, for an invention of certain machinery to be employed in the manufacture of hats, which is ingenious and well adapted to be worthy of notice in this place. It consists in the adaptation of a system of rollers, forming a machine, by means of which the operation of roughing or planing of hats,

may be performed; that is, the beaver or other fur may be made to attach itself, and work into the felt or hat body without the necessity of the ordinary manual operations.

The accompanying drawings represent the machine in several views, for the purpose of showing the construction of all its parts. Fig. 944 is a front elevation of the machine; fig. 945 is a side elevation of the same; fig. 946 is a longitudinal section of the machine; and fig. 947 is a transverse section; the similar letters indicating the same parts in all the figures.

Upon a brick or other suitable base, a furnace or fireplace *a*, is made, having a descending flue *b*, for the purpose of carrying away the smoke. A pan or shallow vessel *c c*, formed of lead, is placed over the furnace; which vessel is intended to contain a sour liquor, as a solution of vitriolic acid and water. On the edge of this pan is erected a wooden casing *d d d*, which encloses three shafts, leaving the fourth open for the purpose of obtaining access to the working apparatus within. A series of what may be termed lantern rollers, *e e e*, is mounted on axles turning in the side casings; and another series of similar lantern rollers, *f f f*, is in like manner mounted above. These lantern rollers are made to revolve by means of bevel pinions, fixed on the ends of their axles, which are turned by similar bevel wheels on the

lateral shafts *g*, and *h*, driven by a winch, *i*, and gear, as shown in figs. 944 and 945.

Having prepared the bodies of the hats, and laid upon their surfaces the usual coatings of beaver, or other fur, when so prepared they are to be placed between hair

944

945

946

cloths, and these hair cloths folded within a canvas or other suitable wrapper. Three or more hats being thus enclosed in each wrapper, the packages are severally put into bags or pockets in an endless band of sackcloth, or other suitable material, which endless band is extended over the lantern rollers in the machine.

In the first instance, for the purpose of merely attaching the furs to the felts (which is called *slacking*, when performed by hand), Mr. Carey prefers to pass the endless band *AAA*, with the covered hat bodies, over the upper series *fff*, of the lantern rollers, in order to avoid the inconvenience of disturbing the fur, which might occur from subjecting them to immersion in the solution contained in the pan, before the fur had become attached to the bodies.

After this operation of *slacking* has been effected, he distends the endless band *AAA*, over the lower series of lantern rollers *ccc*, and round a carrier roller *l*, as shown in fig. 246; and having withdrawn the hat bodies for the purpose of examining them, and changing their folds, he packs them again in a similar way in flannel, or other suitable cloths, and introduces them into the pockets or bags of the endless bands, as before.

On putting the machinery in rotatory motion in the way described, the hats will be carried along through the apparatus, and subjected to the scalding solution in the pan, as also to the pressure, and to a tortuous action between the ribs of the lantern rollers, as they revolve, which will cause the ends of the fur to work into the felted bodies of the hats, and by that means permanently to attach the nap to the body; an operation which when performed by hand, is called *rolling off*.

A varnish made by dissolving shellac, mastic, sandarac, and other resins in alcohol, or the naphtha of wood vinegar, is generally employed as the stiffening and water-proof ingredient of hat bodies. A solution of caoutchouc is often applied to whalebone and horse-hair hat bodies.

The following recipe has been prescribed as a good composition for stiffening hats: four parts of shellac, one part of mastic, one half of a part of turpentine, dissolved in five parts of alcohol, by agitation and subsequent repose, without the aid of heat. This stiffening varnish should be applied quickly to the body or foundation with a soft oblong brush, in a dry and rather warm workshop; the hat being previously fitted with its table turned outwards upon a block. The body must be immediately afterwards taken off, to prevent adhesion.

Another method of proceeding is, first to dissolve the gums by agitation in twice the due quantity of spirits, whether of wood or wine, and then, after complete solution, draw off one half the spirit in a still, so as to bring the stiffening in a proper consistency. No sediment subsequently appears on diluting this solution, however much it may be done.

Both the spirit and alkali stiffenings for hats made by the following two recipes, have been tried by some of the first houses in the trade, and have been much approved of:—

Spirit Stiffening.

- 7 pounds of orange shellac.
- 2 pounds of gum sandarac.
- 4 ounces of gum mastic
- Half a pound of amber resin.
- 1 pint of solution of copal.
- 1 gallon of spirit of wine or wood naphtha.

The shellac, sandarac, mastic, resin, are dissolved in the spirit, and the solution of copal is added last.

Alkali Stiffening.

- 7 pounds of common black shellac.
- 1 pound of amber resin.
- 4 ounces of gum thus.
- 4 ounces of gum mastic
- 6 ounces of borax.
- Half a pint of solution of copal.

The borax is first dissolved in a little warm water (say 1 gallon); this alkaline liquor is now put into a copper pan (heated by steam), together with the shellac, resin, thus, and mastic, and allowed to boil for some time, more warm water being added occasionally until it is of a proper consistence.

Hat-Dyeing.—The ordinary bath for dyeing hats employed by the London manufacturers consists, for 12 dozen, of—

- 144 pounds of logwood;
- 12 pounds of green sulphate of iron, or copperas;
- 7½ pounds of verdigris.

The copper is usually made of a semi-cylindrical shape, and should be surrounded with an iron jacket or case, into which steam may be admitted, so as to raise the temperature of the interior bath to 180° F., but no higher, otherwise the heat is apt to affect the stiffening varnish, called the gum, with which the body of the hat has been impregnated. The ker-wood having been introduced and digested for some time, the copperas and verdigris are added in successive quantities, and in the above proportions, along with every successive two or three dozens of hats, suspended upon the dyeing machine. Each set of hats, after being exposed to the bath with occasional stirrings during 40 minutes, is taken off the pegs, and laid out upon the ground to be more completely blackened by the peroxidisation of the iron with the atmospheric oxygen. In 3 or 4 hours the dyeing is completed. When fully dyed, the hats are well washed in running water.

Mr. Buffum states that there are four principal objects accomplished by his patent invention for dyeing hats:—

1. In the operation;
2. The production of a better colour;
3. The prevention of any of the damages to which hats are liable in the dyeing;
4. The accomplishment of the dyeing process in a much shorter time than by the usual methods, and consequently lessening the injurious effects of the dye-bath upon the texture of the hat.

Fig. 945 shows one method of constructing the apparatus. *a a* is a semi-cylindrical

shaped copper vessel, with flat ends, in which the dyeing process is carried on. *b b b* is a wheel with several circular rims mounted upon arms, which revolve upon an axle. In the face of these rims a number of pegs or blocks are set at nearly equal distances apart, upon each of which pegs or blocks it is intended to place a hat, and as the wheel revolves, to pass it into and out of the dyeing liquor in the vat or copper. This wheel may be kept revolving with a very slow motion, either by gear connecting its axle, *c*, with any moving power, or it may be turned round by hand, at intervals of ten minutes; whereby the hats hung upon the pegs will be alternately immersed for the space of two minutes in the dyeing liquor, and then for the same space exposed to the atmospheric air. In this way, the process of dyeing, it is supposed, may be greatly facilitated and improved, as the occasional transition from the dye vat into the air, and from the air again into the bath, will enable the oxygen of the atmosphere to strike the dye more perfectly and expeditiously into the materials of which the hat is composed, than by a continued immersion in the bath for a much longer time.

A variation in the mode of performing this process is suggested, and the apparatus *fig. 949* is proposed to be employed. *a a* is a square vat or vessel containing the dyeing liquor; *b b* is a frame or rack having a number of pegs placed in it for hanging the hats upon, which are about to be dyed, in a manner similar to the wheel above described. This frame or rack is suspended by cords from a crane, and may in that way be lowered down with the hats into the vat, or drawn up and exposed in the air; changes which may be made every 10 or 20 minutes.

Mr. William Hodge's patent improvements in hat dyeing, partly founded upon an invention of Mr. Bowler, consist, first in causing every alternate frame to which the suspenders or blocks are to be attached, to slide in and out of grooves, for the purpose of more easily removing the said suspenders when required. *Fig. 950*, represents the improved dyeing frame, consisting of two circular rims, *a a*, which are connected together at top and bottom, by three fixed perpendicular bars or the frame-work *b b b*. Two other perpendicular frames, *c c*, similar to the former, slide in grooves, *d d d*,

fixed to the upper and lower rims. These grooves have anti-friction rollers in them for the purpose of making the frames *c c*, to slide in and out more freely. The suspenders or substitutes for blocks, by these means, may be more easily got at by drawing out the frames *c c*, about half way, when the suspenders, which are attached to the frames with the hats upon them, may be easily reached, and either removed or altered in position; and when it is done on one side, the sliding-frame may be brought out on the other, and the remaining quantity of "suspenders" undergo the same operation.

The patentee remarks, that it is well known to all hat dyers, that after the hats have been in the dyeing liquor some time, they ought to be taken out and exposed to the action of the atmospheric air, when they are again immersed in the copper, that part of the hat which was uppermost in the first immersion, being placed downwards in the second.

This is done for the purpose of obtaining an uniform and regular dye. The patentee's mode of carrying this operation into effect, is shown in the figure: *c c* are pivots for the dyeing-frame to turn upon, which is supported by the arms *f*, from a crane above. The whole apparatus may be raised up or lowered into the copper by means of the crane or other mechanism. When the dyeing-frame is raised out of the copper, the whole of the suspenders or blocks are reversed, by turning the apparatus over upon the pivots *c c*, and thus the whole surfaces of the hats are equally acted upon by the dyeing material.

It should be observed, that when the dyeing-frame is raised up out of the copper, it should be tilted on one side, so as to make all the liquor run out of the hats, as also to cause the rims of the hats to hang down, and not stick to the body of the hat, or leave a bad place or uneven dye upon it. The second improvement described by the patentee, is the construction of "suspenders," to be substituted instead of the ordinary blocks.

These "suspenders" are composed of thin plates of copper, bent into the required form, that is, nearly resembling that of a hat block, and made in such a manner as to be capable of contraction and expansion to suit different sized hats, and keep them distended, which may be altered by the workman at pleasure, when it is required to place the hats upon them, or remove them therefrom. The dyeing-frame at *fig. 950*, is shown with only two of these "suspenders," in order to prevent confusion. One of these suspenders is represented detached at *fig. 951*, which exhibits a side view; and *fig. 952*, a front view of the same. It will be seen by reference to the figure, that the suspenders consist of two distinct parts, which may be enlarged or collapsed by a variety of means, and which means may be suggested by any competent mechanic. The two parts of the suspenders are proposed to be connected together by arms *g g*, and at the junction of these arms a key is connected for turning them round when required. It will be seen on reference to the front view, *fig. 952*, that the "suspenders" or substitutes for blocks are open at the top or crown part of the hat; this is for the purpose of allowing the dyeing liquor to penetrate.

From the mixture of copperas and verdigris employed in the hat dye, a vast quantity of an obnoxious muddy precipitate results, amounting to no less than 25 per cent. of the weight of the copperas. This iron mud forms a deposit upon the hats, which not only corrodes the fine filaments of the beaver, but causes both them and the felt stuff to turn speedily of a rusty brown. There is no process in the whole circle of our manufactures so barbarous as that of dyeing stuff hats. No ray of chemical science seems hitherto to have penetrated the dark recesses of their dye shops. Some hatters have tried to remove this corrosive brown ochre by a bath of dilute sulphuric acid, and then counteract the evil effect of the acid upon the black dye by an alkaline bath; but with a most unhappy effect. Hats so treated are most deceptive and

unpleasant as they turn of a dirty brown hue when exposed for a few weeks to air.

The annual value of the hats manufactured at present in the United Kingdom is estimated at £1,000,000, sterling. The quantity exported in 1927, was 149,246 dozens, valued at 292,128*l*.

HAWTHORN (*Egnaea Hiemale*, Fr.; *Wieschen*, Germ.) (*Crataegus argentea*, Linn.) This shrub has a hard whitish wood, but as it is small and difficult to work it is not much used.

HAYESSINE. A borax of lime, which is found abundantly on the western coast of America, so called from its discoverer. It has been introduced for use in our glass manufacture, and is used by our potters. See BORAX.

HAZEL (*Hæstler*, Fr.; *Häsel*, Germ.) The *Corulus avellana*, a small underwood, used a little in tannery and for the manufacture of toys.

HAZEL. A north of England term for a hard grit.

HAZEL MOULD. The name given in Hampshire to a light loamy soil.

HEARTH (*Foyer*, Fr.; *Herd*, Germ.) is the flat or hollow space in a smelting furnace upon which the ore and flux are subjected to the influence of flame. See COPPER, IRON, METALLURGY, &c.

HEARTHSTONE. A soft stone employed for whitening door steps, &c. An enormous quantity of hearthstones are brought to London from the quarries at Godstone.

HEAT. The Force or Principle upon which the conditions, relatively, of solid, fluid, and æreiform states depend. That which produces the sensation of warmth.

The discussion of the habitudes of heat with the different kinds of matter belongs to physico-chemical science, and will be treated of in *Ure's Dictionary of Chemistry*. It will suffice in this place, to state succinctly those laws which have, more directly, a bearing on any of our manufacturing processes.

Heat and motive power are mutually convertible, and heat requires for its production, and produces by its disappearance, motive power in the proportion of 772 foot-pounds for each Fahrenheit unit of heat. — Rankine.

This unit of heat has been established by Dr. Joule to be the amount of heat required to raise the temperature of one pound of liquid water by one degree of Fahrenheit. A falling weight, or any other mode of motion, produces a definite quantity of heat according to this law.

If the total actual heat of a homogeneous and uniformly hot substance be conceived to be divided into any numbers of equal parts, the effect of those parts in causing work to be performed will be equal. — Rankine.

Or in other words, of a given equivalent of heat, from whatever source produced, the work which it can effect is always an equal and constant quantity.

Heat may be produced by friction, as we see in the development of it, powerfully, in the axles of railway carriages insufficiently lubricated. By the attrition of two pieces of wood ignition can be obtained.

Heat is developed in the mixture of bodies of different densities, such as spirits of wine and water, or sulphuric acid and water, there being a diminution of volume in each case.

Heat is produced by many conditions of chemical combination, in numerous cases so energetically as to produce intense combustion and even explosion.

Heat is obtained by combustion for our ordinary manufacturing processes, and domestic uses. This is a chemical union of one body with another, as carbon with oxygen; but to effect this, an excitant appears necessary or a continually increasing excitement of the energy upon which heat depends, as, the application of flame in one case and the phenomena of spontaneous combustion in another.

Electricity by its disturbing power, develops heat, and this all important force is also rendered manifest by the processes of vitality (vital or nervous force).

Dr. Joule has clearly shown, that whatever may be the source of heat, a certain fixed elevation of temperature is produced by a given amount of mechanical, chemical, electrical, or vital disturbance, and that the mechanical value of the cause producing the heat is exactly represented by the mechanical effect obtained.

For a full discussion of this important point, see the *Memoirs of Joule*, of Thompson, and of Rankine, in the *Philosophical Transactions of London and Edinburgh*. The applications of heat will be found under the proper heads. See also **SPONTANEOUS STATE**.

HEAT-REGULATOR, or THERMOSTAT. The name given by M. Bonnemain to an ingenious apparatus for regulating the temperature of his incubating stove rooms. See INCUBATION, ARTIFICIAL, for the manner of applying the Heat-Regulator.

The construction of the regulator is founded upon the unequal dilatation of different metals by the same degree of heat. A rod of iron *r*, fig. 253, is tapped at its lower

end in to a brass nut *y*, enclosed in a lead-l box or tube, terminated above by a brass collet *z*. This tube is plunged into the water of the boiler, a neck of the boiler being more than the iron for a like degree of temperature, and the rod *z* and with the tube being less easily warmed, whenever the heat rises to the desired point, the elongation of the tube puts the collet *z* in contact with the heel, *a*, of the bent lever *a, b, d*; thence the slightest increase of heat lengthens the tube anew, and the collet lifting the heel of the lever, depresses the other end *d* through a much greater space, on account of the relative lengths of its legs. This movement operates near the axis of a balance-bar *e*, sinks one end of this, and thereby increases the extent of the movement, which is transmitted directly to the iron skewer *v*. This pushing down a swing register diminishes or cuts off the access of air to the fire-place. The combustion is thereby obstructed, and the temperature falling by degrees, the tube shrinks and disengages the heel of the lever. The counterpoise *g*, fixed to the balance beam *e*, raises the other extremity of this beam by raising the end *d* of this lever as much as is necessary to make the heel bear upon the collet of the tube. The swing register acted upon by this means, presents a greater section to the passage of the air; whence the combustion is increased. To counterbalance the effect of atmospheric changes, the iron stem which supports the regulator is terminated by a dial disc, round the shaft of the needle above *h*, *fig. 954*; on turning this needle, the stem below it turns, as well as a screw at its under end, which raises or lowers the leaden tube. In the first case the heel falls, and opens the swing register, whence a higher temperature is required to shut it, by the expansion of the tube. We may thus obtain a regularly higher temperature. If, on the contrary, we raise the tube by turning the needle in the other direction, the register presents a smaller opening, and shuts at a lower temperature; in this case we obtain a regularly lower temperature. It is therefore easy, says M. Bonnemain, to determine *a priori* the degree of temperature to be given to the water circulating in the stove pipes. In order to facilitate the regulation of the apparatus, he graduated the disc dial, and inserted upon its top and bottom, the words Strong and Weak heat.

Thermostat, is the name of an apparatus for regulating temperature, in vaporization, distillations, heating baths or bathhouses, and ventilating apartments, &c. for which I obtained a patent in the year 1831. It operates upon the physical principle, that when two thin metallic bars of different expansibilities are riveted or soldered face to face together, any change of temperature in them will cause a sensible movement of flexure in the compound bar, to one side or other; which movement may be made to operate, by the intervention of levers, &c., in any desired degree, upon valves, stopcocks, stove-registers, air-ventilators, &c., so as to regulate the temperature of the media in which the said compound bars are placed. Two long rulers, one of steel, and one of hard hammered brass, riveted together, answer very well; the object being not simply to indicate, but to control or modify temperature. The following diagrams will illustrate a few out of the numerous applications of this instrument:

Fig. 953, a, b, is a simple thermostatic bar, consisting of two or more bars or rulers of differently expansible solids (of which, in certain cases, wood may be one); these bars or rulers are firmly riveted or soldered together, face to face. One end of the compound bar is fixed by bolts at *a*, to the interior of the containing cistern, boiler, or apartment, *a, l = b*, whereof the temperature has to be regulated, and the other end of the compound bar at *b*, is left free to move down towards *c*, by the flexure which will take place when its temperature is raised.

The end *b*, is connected by a link, *b, d*, with a lever *d, e*, which is moved by the flexure into the dotted position *b, g*, causing the turning-valve, air-ventilator, or register, *e, n*, to revolve with a corresponding angular motion, whereby the lever will raise the equipped slide-damper *h, f*, which is suspended by a link from the end *e*, of the lever *e, d*, into the position *h, k*. Thus a hot-house or a water-bath may have its temperature regulated by the contemporaneous admission of warm, and discharge of cold air, or water.

Fig. 954, *a b c* is a thermostatic hoop, immersed horizontally beneath the surface of the water bath of a still. The hoop is fixed at *a*, and the two ends *b c*, are connected by two links *b d, c d*, with a straight sliding rod *d h*, to which the hoop will give an

endwise motion, when its temperature is altered; *e*, is an adjusting screw-nut on the rod *d h*, for setting the lever *f g*, which is fixed on the axis of the turning valve or cock *f*, at any desired position, so that the valve may be opened or shut at any desired temperature, corresponding to the widening of the points *b, c*, and the consequent retraction of the point *d*, towards the circumference *a b c* of the hoop. *y h*, is an are graduated by a thermometer, after the screw-piece *e* has been adjusted. Through a hole at *h*, the guide rod passes; *i*, is the cold-water cistern; *s f A*, the pipe to admit cold water; *l*, the overflow pipe, at which the excess of hot water runs off.

Fig. 955 shows a pair of thermostatic bars, bolted fast together at the ends *a*. The free ends *b, c*, are of unequal length, so as to act by the cross links *d, f*, on the stopcock *e*. The links are jointed to the handle of the turning plug of the cock, on opposite sides of its centre; whereby that plug will be turned round in proportion to the widening

of the points *b, c*. *h g* is the pipe communicating with the cistern.

Suppose that for certain purposes in pharmacy, dyeing, or any other chemical art, a water-bath is required to be maintained steadily at a temperature of 120° F. let the combined thermostatic bars, hinged together at *e, f*, Fig. 958, be placed in the bath

between the outer and inner vessels *a, b, c, d*, being bolted fast to the inner vessel at *g*; and have their sliding rod *h*, connected by a link with a lever fixed upon the turning plug of the stopcock *k*, which introduces cold water from a cistern *m*, through a pipe *m, r, a*, into the bottom part of the bath. The length of the link must be so adjusted that the flexure of the bars, when they are at a temperature of 150° , will open the said stopcock, and admit cold water to pass into the bottom of the bath through the pipe *r n*, whereby hot water will be displaced at the top of the bath through an open overflow-pipe at *q*. An oil bath may be regulated on the same plan; the hot oil overflowing from *q*,

into a refrigeratory worm, from which it may be restored to the cistern *m*. When a water bath is heated by the distribution of a tortuous steam pipe through it, as *u o p*, it will be necessary to connect the link of the thermostatic bars with the lever of the turning plug of the steam-cock, or of the throttle valve *i*, in order that the bars, by their flexure, may shut or open the steam passage more or less, according as the temperature of the water in the bath shall tend more or less to deviate from the pitch to which the apparatus has been adjusted. The water of the condensed steam will pass off from the sloping winding-pipe *u o p*, through the sloping orifice *p*. A saline acid or alkaline bath has a boiling temperature proportional to its degree of concentration, and may therefore have its heat regulated by immersing a thermostat in it and connecting the working part of the instrument with a stopcock *i*, which will admit water to dilute the bath whenever by evaporation it has become concentrated, and has acquired a higher boiling point. The space for the bath, between the outer and inner pans, should communicate by one pipe with the water cistern *m*, and by another pipe with a safety cistern *r*, into which the bath may be allowed to overflow during any sudden excess of ebullition.

Fig. 961 is a thermostatic apparatus, composed of three pairs of bars *d d d*, which are represented in a state of flexure by heat; but they become nearly straight

and parallel when cold. $a b c$ is a guide rod, fixed at one end by an adjusting screw e , in the strong frame $f e$, having deep guide grooves at the sides. $f g$, is the working-rod, which moves endways when the bars $d d$ operate by heat or cold. A square register-plate $h g$, may be affixed to the rod $f g$, so as to be moved backwards and forwards thereby, according to the variations of temperature, or the rod $f g$, may cause the circular turning air-register, i , to revolve by rack and wheel work, or by a chain and pulley. The register plate $h g$, or turning register i , is situated at the ceiling or upper part of the chamber, and serves to let out hot-air. k , is a pulley, over which a cord runs to raise or lower a hot-air register l , which may be situated near the floor of the apartment or hot-house, to admit hot air into the room. c is a milled head, for adjusting the thermostat, by means of the screw at e , in order that it may regulate the temperature to any degree.

Fig. 962 represents a chimney, furnished with a pyrostat, $a b c$, acting by the links h, d, e, c , on a damper $f h g$. The more expansible metal is in the present example supposed to be on the outside. The plane of the damper-plate will, in this case, be turned more directly into the passage of the draught through the chimney by increase of temperature.

Fig. 960 represents a circular turning register, such as is used for a stove, or stove-grate, or for ventilating apartments; it is furnished with a series of spiral thermostatic bars, each bar being fixed fast at the circumference of the circle b, c , of the fixed plate of the air-register; and all the bars act in concert at the centre a of the turning part of the register; by their ends being inserted between the teeth of a small pinion, or by being jointed to the central part of the turning plate by small pins.

Fig. 959 represents another arrangement of my thermostatic apparatus applied to a circular turning register, like the preceding, for ventilating apartments. Two pairs of compound bars are applied so as to act in concert, by means of the links a, c, h, e , on the opposite ends of a short lever which is fixed on the central part of the turning plate of the air-register. The two pairs of compound bars $a b$, are fastened to the circumference of the fixed plate of the turning register, by two sliding rods $a d, b e$, which are furnished with adjusting screws. Their motion or flexure is transmitted by the links $a c$ and $b e$, to the turning plate, about its centre, for the purpose of shutting or opening the ventilating sectorial apertures, more or less, according to the temperature of the air which surrounds the thermostatic turning register. By adjusting the screws $a d$, and $b e$, the turning register is made to close all its apertures at any desired degree of temperature; but whenever the air is above that temperature, the flexure of the compound bars will open the apertures.

HEAVE, a miner's term, expressing the dislocation of a lode. See FAULT.

HEAVY-SPAR, SULPHATE OF BARYTES, or CAWK* (Spoth pearly, Fr.; Schwerspath, Germ.), is an abundant mineral, which accompanies veins of lead, silver, mercury, &c., but is often found, also, in large masses. Its colour is usually white, or flesh coloured. It varies from translucent to opaque. It belongs to the trimetric system, but it occurs in many crystalline forms, of which the cleavage is a right rhombohedral prism. It is met with also of a fibrous, radiated, and granular structure. Its sp. gr. varies from 4.1 to 4.7, $H = 2.5$ to 3.5. It has a strong lustre, between the fatty and the vitreous, sometimes pearly. It melts at 35° Wedgw. into a white opaque enamel. Its constituents are 65.67 baryta, and 34.33 sulphuric acid; but it is sometimes rendered impure by oxide of iron, silica, carbonate of lime and alumina, and commonly by sulphate of strontian. It is not acted upon by acids; decrepitates before the blow-pipe; and is difficultly fusible, or only on the edges. In the inner flame is reduced to a sulphuret, and the globule when moistened smells slightly hyposulphuric. It is decomposed by calcination in contact with charcoal at a white heat, into sulphuret of baryta; from which all the baryta salts may be readily formed. Its chief employment in commerce is for adulterating white lead; a purpose which it

* The term Cawk has been applied to the opaque massive variety, of an earthy appearance, and dirty-white colour, which is found in Derbyshire and Staffordshire.

readily serves on account of its density. Its presence here is easily detected by dilute nitric acid, which dissolves the carbonate of lead, and leaves the heavy spar. It is also a useful ingredient in some kinds of pottery, and glass.

In 1856 the following quantities were raised (*Hunt's Mineral Statistics*):—

			Tons.	Cwt.
Alston Moor - - -	Carbonate - - -	443	16	
Northumberland, <i>Fallockfield</i>	do - - -	1045	15

Lake of Arran - - -	do - - -	550	0	

HECKLE (*Scrut*, Fr.; *Hechel*, Germ.) is an implement for drawing the filaments of flax, and laying them in parallel sticks or threads. See FLAX.

HELIOGRAPHY was the name given by M. Niepce to his process for obtaining, through the agency of the solar rays upon plates of metal or glass covered with resins, the impression of external objects. The process has been employed of late years in preparing lithographic stones, and steel or copper plates, for receiving photographic impressions, which might be subsequently printed from. The name heliography is a far more appropriate one than photography; but the latter has become too permanently fixed in our language to leave any hope of war returning to the former. See PHOTOGRAPHY.

HELIOTROPE is a variety of Jasper, mixed with chlorite, green earth, and diallage; occasionally marked with blood red points; whence its vulgar name of blood-stone.

HEMATINE is the name given by its discoverer Chevreul to a crystalline substance, of a pale pink colour, and brilliant lustre when viewed in a lens, which he extracted from logwood, the *Hæmaturylin Compochinum* of botanists. It is, in fact, the characteristic principle of this dye wood. To procure hematine, digest during a few hours ground logwood in water heated to a temperature of about 150° Fahr.; filter the liquor, evaporate it to dryness by a steam bath, and put the extract in alcohol of 0.85 for a day. Then filter anew, and after having inspissated the alcoholic solution by evaporation, pour into it a little water, evaporate gently again, and then leave it to itself in a cool place. In this way numerous crystals of hematine will be obtained, which may be purified by washing with alcohol and drying.

When subjected to dry distillation in a retort, hematine affords all the usual products of vegetable bodies, along with a little ammonia; which proves the presence of azote. Boiling water dissolves it abundantly, and assumes an orange-red colour, which passes into yellow by cooling, but becomes red again with heat. Sulphurous acid destroys the colour of solution of hematine. Potash and ammonia convert into a dark purple-red tint the pale solution of hematine; when these alkalies are added in large quantity, they make the colour violet blue, then brown-red, and lastly brown-yellow. By this time the hematine has become decomposed, and cannot be restored to its pristine state by neutralising the alkalies with acids.

The waters of baryta, strontia, and lime exercise an analogous power of decomposition; but they eventually precipitate the changed colouring matter.

A red solution of hematine subjected to a current of sulphuretted hydrogen becomes yellow; but it resumes its original hue when the sulphuretted hydrogen is removed by a little potash.

The protoxide of lead, the protoxide of tin, the hydrate of peroxide of iron, the hydrate of oxides of copper and nickel, oxide of bismuth, combine with hematine, and colour it blue with more or less of a violet cast.

Hematine precipitates glue from its solution in reddish flocks. This substance has not hitherto been employed in its pure state; but as it constitutes the active principle of logwood, it enters as an ingredient into all the colours made with that dye stuff.

These colours are principally violet and black. Chevreul has proposed hematine as an excellent test of acidity.

HEMATITE (*Fer Oligiste*, Fr.; *Rotheisenstein*, Germ.) is a native reddish-brown peroxide of iron. This term was applied to this ore of iron by the ancients, on account of the red colour of its powder, from *æps* blood.

This species includes *specular iron* and the *old red iron ore* (see IRON, SPECULAR; MICACEOUS). "The varieties of a sub-metallic or non-metallic lustre were included under the names of *red hematite*, *fibrous red iron*, or of *soft and earthy red ochre*, and when consisting of slightly coherent scales, *scaly red iron* or *red iron froth*" (Dana). Dana also includes, most injudiciously as it appears, *red dirt* or *red chalk*, and *jaspery clay iron ore*, with some others, among the hematites.

* This is manufactured at Liverpool, Wigan, and Walspool.

The hematite proper occurs in a remarkable manner at Whitehaven and at Ulverstone. The following analysis of the Whitehaven ore of Cleator Moor by Mr. A. Dick, shows its peculiar character:—

Peroxide of iron	-	-	-	-	-	95.16
Protoxide of manganese	-	-	-	-	-	0.24
Lime	-	-	-	-	-	0.07
Phosphoric acid	-	-	-	-	-	trace
Sulphuric acid	-	-	-	-	-	trace
Bisulphide of iron	-	-	-	-	-	5.68
Insoluble residue	-	-	-	-	-	101.15
Iron, total amount	-	-	-	-	-	66.60

The following analysis of the Ulverstone ore is by the same chemist:—

<i>Gillman Ore.</i>						
Peroxide of iron	-	-	-	-	-	86.50
Protoxide of manganese	-	-	-	-	-	0.54
Lime	-	-	-	-	-	2.77
Magnesia	-	-	-	-	-	1.46
Carbonic acid	-	-	-	-	-	2.96
Phosphoric acid	-	-	-	-	-	trace
Sulphuric acid	-	-	-	-	-	0.11
Insoluble residue	-	-	-	-	-	6.55
	-	-	-	-	-	100.88
Iron, total amount	-	-	-	-	-	60.55

Another ore, that of Lindale Moor, near Ulverstone, was analysed by Mr. J. Spiller.

Peroxide of iron	-	-	-	-	-	94.23
Protoxide of manganese	-	-	-	-	-	0.23
Alumina	-	-	-	-	-	0.51
Lime	-	-	-	-	-	0.05
Magnesia	-	-	-	-	-	trace
Phosphoric acid	-	-	-	-	-	minute trace
Sulphuric acid	-	-	-	-	-	0.09
Bisulphide of iron	-	-	-	-	-	0.03
Water, hygroscopic	-	-	-	-	-	0.39
" combined	-	-	-	-	-	0.17
Insoluble residue	-	-	-	-	-	5.14
	-	-	-	-	-	100.88
Iron, total amount	-	-	-	-	-	65.98

In 1857 Whitehaven district produced of hematite, 323,512 tons; and in 1856, 348,636 tons; and the Lancashire or Ulverstone district, 592,390 tons in 1857, and 438,546 in 1856.

A small quantity of the Ulverstone ore is smelted with charcoal at some furnaces in the district, and the following quantities of this ore were used at the furnaces near Whitehaven:—

Cleator Moor furnaces	-	-	-	-	-	47,311
Harrington	-	-	-	-	-	3,000
Lenton	-	-	-	-	-	6,200
	-	-	-	-	-	56,511

All the remainder was sent into the other great iron-making districts for mixing with the argillaceous carbonates, and other ores of iron. See IRON.

HEMATOSIN. The red colouring matter of blood, which is sold in a dry state for making Prussian blue.

HEMLOCK SPRUCE. The *Abies Canadensis*, the wood of which has been used for railway sleepers, and is employed for laths.

HEMP. (*Chanvre*, Fr.; *Hanf*, Germ.) A plant (*Cannabis sativa*), a native of India, but has been long introduced into Europe, and cultivated extensively in Italy, and in Russia and Poland; a small quantity has been cultivated in Suffolk, in Lincolnshire, and in Ireland.

Hemp is assorted, into *clean hemp*, *out-shot hemp*, *half clean hemp*, and *hemp cordilla*. According to McCulloch, a bundle of clean hemp from Russia weighs 35 to 65 pounds; of out shot, from 48 to 53 pounds; of half clean, 40 to 45 pounds; the pool being equal to 36 lbs. avoirdupois.

Manilla Hemp is the produce of the wild banana. *Musa sapientum*. "It is known," says Mr. Crum, "in his history of the Eastern Archipelago, to our traders and navigators under the name of Manilla rope, and is equally applicable to cables and to standing or running rigging."

Stann and Jute are two varieties of hemp. Hemp is used in the manufacture of huckaback for towels and common tablecloths, and of the low priced cloth worn by agricultural laborers. The largest consumption of this material is in the manufacture of sail cloth and cordage.

Our imports of hemp were as follows in 1857:—

	Hemp dressed.	Hemp undressed.	Cables of hemp.	Jute.
	Cents.	Cents.	Cents.	Cents.
Russia . . .	29,747	348,246	5,864	
Prussia . . .		10,248		
Austrian Italy . .	4,043	22,005	2,771	
Philippine Islands .		52,861		
British East Indies .	1,774	45,526		538,438
United States . .		42,254		80,215
Hanse Towns . .			2,045	
Holland . . .			2,837	
Spain . . .			1,681	
Other parts . .	1,024	18,680	701	7,140
	37,288	739,935	14,973	618,583

HEMP SEED. (*Chenop.* Fr.; *Hanfseed* Germ.) The seed of the hemp; it is used for crushing, for its oil, or as food for birds.

In 1857 we imported 4,727 quarters of hemp seed, the computed real value of which was 10,636*l*.

HENBANE. The *Hyoscyamus niger*. Henbane is a plant used in medicine, from which modern chemistry has extracted a new crystalline vegetable principle called *hyoscyamine*, which is very poisonous, and when applied in solution to the eye, determines a remarkable dilatation of the pupil; no *belladonna* also does.

HELENA. The herb used for dyeing the nails in the East. See **ATRENSA**.

HEPAR, which signifies liver in Latin, was a name given by the older chemists to some of the compounds of sulphur.

HEPATIC AIR. Sulphuretted hydrogen gas.

HERMETICAL SEAL, is an expression derived from Hermes, who was said to be the parent of Egyptian chemistry. It is used to designate the perfect closure of a hollow vessel, by the cementing or melting of the lips of its orifice; as in the case of a glass thermometer, or matras.

HERNANDIA OVIGERA. Hernant seeds, some of which are imported from India for tanning.

HESSONITE, or *Picconite*. The name given by Hany to cinnamon stone.

HICKORY. The *Juglans alba*; white walnut, a native of America. It is used for making handspikes, and other classic tools.

The bark has been recommended by Dr. Hanroft as a yellow dye.

HIDE. (*Pecu.* Fr.; *Haut*, Germ.) The strong skin of an ox, horse, or other large animal. The lists of imports below will show to what an extent a trade in the skins of animals is carried on with this country. We receive hides largely from Russia and the north of Europe. From America there are also large quantities brought to this country.

The following table shows the number of salted and dry hides which were exported from Bahia in the five years ending September, 1855.

	Number of hides.	Price salted.	Price dry.
		per hide.	per hide.
1850—51 . . .	90,040	3 <i>½</i> d.	4 <i>½</i> d.
1851—52 . . .	93,484	3 <i>½</i> d.	3 <i>½</i> d.
1852—53 . . .	108,783	3 <i>½</i> d.	4 <i>½</i> d.
1853—54 . . .	128,675	4 <i>½</i> d.	5 <i>½</i> d.
1854—55 . . .	134,231	5 <i>½</i> d.	6 <i>½</i> d.

From the Dominican Republic (Puerto Plata) the number of hides exported was in 1854, 12,314, and in 1855, 10,526; they went chiefly to the United States.

From Equator (Guayaquil), during 1855, there were exported principally for the Lima market, 26,246, valued at 10,482*l* 1*s* 8*d*.

From Guatemala, 20,991 hides were exported in 1855.

From Salvador, 24,235, valued at 27,347 dollars, in 1855.

HIPPONASTANUM. The common horse-chestnut.

HIPPOPOTAMUS TEETH. See **IVORY.**

HOG'S LARD, or *Arundo*, the latter name derived from the use to which it was put by the ancients, i. e. to grease the axle of a wheel. It is obtained from all the hog tribe (*Sus scrofa*). Hog's lard is largely used in the manufacture of ointments, pomatum, &c. Its proximate analysis gives, according to Braconnot:—

Stearine and margarine, 38; Elaine, 62.

The stearine is separated and used in the manufacture of candles, and the Elaine sold under the name of Lard Oil. The ultimate analysis of lard gives—

Carbon, 79.2; hydrogen, 11.1; oxygen, 9.7.

HOLLAND. A linen fabric, which is sold when outbleached as *brown holland*, and which is used when bleached for finer purposes. See **LINEN.**

HOLLANDS. A grain spirit manufactured in Holland.

HOLLY. (*Le Hour*, Fr.; *Stechpalme*, Germ.) *The Ilex aquifolium* of LINNÆUS, a British plant. Its leaves yield a yellow colouring matter similar to that obtained from wheat. The wood is as white as ivory, very hard and fine grained, and susceptible of a high polish; it is employed for many purposes.

HOMOLOGOUS. A term used in organic chemistry to denote that substances differ by the constant increment C^{H}_2 . Thus, in the great series of acids commencing with the formic and extending up to the fatty acids, each homologue contains C^{H}_2 more than the one before, and C^{H}_2 less than the one following, thus:—

Formic acid	-	-	$\text{C}^{\text{H}}_2\text{O}^2$	Propionic acid	-	-	$\text{C}^{\text{H}}_4\text{O}^2$
Acetic acid	-	-	$\text{C}^{\text{H}}_4\text{O}^2$	Butyric acid	-	-	$\text{C}^{\text{H}}_6\text{O}^2$ &c.—C. G. W.

HONDURAS MAHOGANY.—See **MAHOGANY.**

HONES AND HONE SLATES. These are slaty stones which are used in straight pieces for sharpening tools after they have been ground on revolving grindstones. The more important varieties are the following:—

The Norway Razor stone which is the coarsest variety of the hone slates, is imported in large quantities from Norway. In Charnwood Forest, near Monot Sorrel, in Leicestershire, particularly from the Whittle Hill quarry, are obtained the *Charnley Forest Stone*, said to be one of the best substitutes for the Turkey oilstone, and it is much in request by joiners and others. *Ayr stone*, *Snake stone*, and *Scotch stone*, are used especially for polishing copper plates. The *Welsh oilstone* is almost in equal repute with the Charnley Forest stone; it is obtained from the vicinity of Llyn Idwall, near Snowdon, and hence it is sometimes called *Idwall stone*. From Snowdon is also obtained the *cutter's green stone*. The *Devonshire oilstones*, obtained near Tavistock, which were introduced by Mr. John Taylor, are of excellent quality, but the supply of them being irregular they have fallen into disuse.

The German razor hone has been long celebrated. It is obtained from the slate mountains in the neighbourhood of Ratisbau, where it occurs in the form of a yellow vein running through the blue slate, varying in thickness from 1 to 15 inches. When quarried it is sawn into thin slabs, and these are generally cemented to slices of slate which serve as a support. Sometimes, however, the yellow and the blue slate are cut out naturally combined. There are several other hone stones, which, however, require no particular notice.

The Turkey oilstone is said to surpass in its way every other known substance, and it possesses in an eminent degree the property of abrading the hardest steel; it is, at the same time, of so compact and close a nature as to resist the pressure necessary for sharpening a graver, or any instrument of that description. There are white and black varieties of the Turkey oilstone, the black being the hardest, and it is imported in somewhat larger pieces than the white; they are found in the interior of Asia Minor and are brought down to Smyrna for sale.

HONEY (*Mel*, Fr.; *Honig*, Germ.) is a sweet viscid liquor, secreted in the nectaries of flowers, collected by the working bees, and deposited by them in the waxy cells of their combs. Virgin honey is that which is collected from a hive, the bees of which have never swarmed, the common honey is obtained from the older hives. The former, which is considered the best, is whitish or pale yellow, of a granular texture, a fragrant smell, and a sweet slightly pungent taste; the latter is darker coloured, thicker, and

not so agreeable either in taste or smell. Honey would seem to be simply collected by the bees, for it consists of merely the vegetable products; such as the sugars of grape, gum, and manna; along with mucilage, extractive matter, a little wax, and acid.

Narbonne honey, the flavour of which is so much admired, owes its peculiarity to the flowers on which the bees feed.

Treasury honey has been long celebrated for its intoxicating qualities. The description given in Xenophon's *Retreat of the Ten Thousand* is well known. Many examples of poisonous honey are on record.

HONEY COMB. The waxen cells of the bee. See **WAX**.

HONEY-STONE (*Mellite*, Fr.; *Hinagstein*, Germ.) is a mineral of a yellowish or reddish colour, and a resinous aspect, crystallising in octahedrons with a square base; specific gravity 1.76. It is harder than gypsum, but not so hard as calc-spar; it is deeply scratched by a steel point; very brittle; absorbs water by calcination; blackens, then burns at the flame of the blowpipe, and leaves a white residuum which becomes blue when it is calcined, after having been moistened with a drop of nitrate of cobalt. It is a mellate of alumina, and consists of

	Kilopoth	Water.
Mellitic acid - - - - -	46	44.4
Alumina - - - - -	16	14.5
Water - - - - -	81	41.1
	100	100.0

The honey-stone, like amber, belongs to the geological formation of lignite. It has been hitherto found only at Artern in Thuringia; at Leusnitz, near Bala in Bohemia; and near Walchow in Moravia.

HOP (*Houblon*, Fr.; *Hopsen*, Germ.) is the name of a well-known plant of the natural family of *Urticæ*, and of the *Dereis pentandria* of Linnaeus. The female flowers, placed upon different plants from the male, grow in ovoid cones formed of oval leafy scales, concave, imbricated, containing each at the base an ovary furnished with tubular open styles, and sharp pointed stigmata. The fruit of the hop is a small rounded seed, slightly compressed, brownish coloured, enveloped in a scaly calyx, thin, but solid, which contains, spread at its base, a granular yellow substance, appearing to the eye like a fine dust, but in the microscope they seem to be round, yellow, transparent, grains; deeper coloured, the older the fruit. This secretion which constitutes the useful portion of the hop, has been examined in succession by Lye, Planche, Payen, and Chevallier. A pretty full account of the results of their researches in treating of the hop is given in the article **BEER**.

Number of Acres under the Cultivation of Hops in England.

that of goats and sheep, from its being whiter and more transparent than the horn of any other animals. When horn is wanted in sheets or plates, it must be steeped in water, in order to separate the pith from the kernel, for about fifteen days in summer, and a month in winter; and after it is soaked, it must be taken out by one end, well shaken and rubbed in order to get off the pith; after which it must be put for half an hour into boiling water, then taken out, and the surface sawed even lengthways; it must again be put into the boiling water to soften it, so as to render it capable of separating; then, with the help of a small iron chisel, it can be divided into sheets or leaves. The thick pieces will form three leaves, those which are thin will form only two, whilst young horn, which is only one quarter of an inch thick, will form only one. These plates or leaves must again be put into boiling water, and when they are sufficiently soft, they must be scraped with a sharp cutting instrument, to render those parts that are thick even and uniform; they must be put once more into the boiling water, and finally carried to the press.

At the bottom of the press employed, there must be a strong block, in which is formed a cavity, of nine inches square, and of a proportionate depth, the sheets of horn are to be laid within this cavity, in the following manner: at the bottom, first a sheet of hot iron, upon this a sheet of horn, next again a sheet of hot iron, and so on, taking care to place at the top a plate of iron even with the last. The press must then be screwed down tight.

There is a more expeditious process, at least in part, for reducing the horn into sheets, when it is wanted very even. After having sawed it with a very fine and sharp saw, the pieces must be put into a copper made on purpose, and there boiled until sufficiently soft, so as to be able to be split with pincers; the sheets of horn must then be put in the press where they are to be placed in a strong vice, the chips of which are of iron and larger than the sheets of horn, and the vice must be screwed as quick and tight as possible; let them cool in the press or vice, or it is as well to plunge the whole into cold water. The last mode is preferable, because the horn does not shrink in cooling. Now draw out the leaves of horn, and introduce other horn to undergo the same process. The horn so enlarged in pressing, is to be submitted to the action of the saw, which ought to be set in an iron frame, if the horn is wanted to be cut with advantage, in sheets of any desired thickness, which cannot be done without adopting this mode. The thin sheets thus produced must be kept constantly very warm between plates of hot iron to preserve their softness; every leaf being loaded with a weight heavy enough to prevent its warping. To join the edges of three pieces of horn together, it is necessary to provide strong iron moulds suited to the shape of the article wanted, and to place the pieces in contact with copper-plates or with polished metal surfaces against them; when this is done, the whole is to be put into a vice and screwed up tight, then plunged into boiling water, and after some time it is to be removed from thence and immersed in cold water. The edges of the horn will be thus made to cement together and become perfectly united.

To complete the polish of the horn, the surface must be rubbed with the sublimate of bismuth by the palm of the hand. The process is short, and has this advantage, that it makes the horn dry promptly.

When it is wished to spot the horn in imitation of tortoise shell, metallic solutions must be employed as follows:—To spot it red, a solution of gold in aqua regia must be employed; to spot it black, a solution of silver in nitric acid must be used; and for brown, a hot solution of mercury in nitric acid. The right side of the horn must be impregnated with these solutions, and they will assume the colours intended. The brown spots can be produced on the horn by means of a paste made of red lead, with a solution of potash, which must be put in patches on the horn, and subjected some time to the action of heat. The darkness of the brown shades depends upon the quantity of potash used in the paste, and the length of time the mixture lies on the horn. A decoction of Brazil wood, or a solution of indigo, in sulphuric acid, or a decoction of saffron and Barbary wood may also be used. After having employed these materials, the horn may be left for half a day in a strong solution of vinegar and alum.

In France, Holland, and Austria, the comb-maker and horn-turners use the clippings of horn—which are of a whitish yellow—and tortoise-shell skins, out of which they make auff-boxes, powder horns, and many curious and handsome things. They first soften the horn and shell in boiling water, so as to be able to submit them to the press in iron moulds, and by means of heat they form them into one mass. The degree of heat necessary to join the horn clippings must be stronger than that for shell skins, and it can only be found out by experience. The heat must not, however, be too great, for fear of scorching the horn or shell. Considerable care is required in these operations, not to touch the horn with the fingers, or with any greasy body, because the grease will prevent the perfect joining. Wooden instruments should be used to move them, while they are at the fire, and for carrying them to the moulds.

In making a ring of horn for bell-pulls, &c., the required piece is to be first cut out

in the flat of the proper dimensions, and nearly in the shape of a knee-blade, it is then pressed in a pair of dies to give it within the desired pattern, but previous to this process, the two pieces of horn and the dies are to be heated, the pieces of horn so to be introduced between the dies, opened in a vice, and when cold, the impression or pattern will be fixed upon the horn. One particular condition, however, is to be observed in the construction of the dies, for forming a ring. They are to be so formed that the open ends of the horn—above piece of horn, after being properly shaped, have at one end a notch and at the other a convex of a dovetailed form, corresponding to each other; and the second operation in forming this ring is to heat the horn, and press it in another pair of dies, which shall bring its open ends together, and cause the dovetailed joints to be locked fast together, which completes the ring, and gives it the appearance of the junction.

In forming the handles of table knives and forks, or other things which require to be made of two pieces, each of the two pieces or arms of the handle is formed in a particular pair of dies; the one piece is made with a counter-sunk groove along one edge, and the other piece with corresponding leaves or projecting edges. When these two pieces are formed, by first being cut out of the flat horn, then pressed in the dies in a heated state, for the purpose of giving the pattern, the two pieces are again heated and put together, the leaves or edges of the one piece dropping into the counter-sunk grooves of the other piece, and being introduced between a second pair of heated dies, the joints are pressed together and the two pieces formed into one handle.

In making the knobs for drawers which have metal stems or pins to fasten them to the furniture, the face of the knob is to be first made in a die, as above described, and then the back part of the knob with a hole in it; a metal disc plate of iron is next provided, in which the metal stem or screw pin is fixed, and the stem being passed through the aperture in the back piece, and the two, that is, the back and front pieces of horn put together, they are then heated and pressed in dies as above described; the sides of the back piece falling into the counter-sunk groove of the front piece, while by the heat they are perfectly cemented together.

Mr. J. James has contrived a method of opening up the horns of cattle, by which he avoids the risk of scorching or frizzling, which is apt to happen in heating them over an open fire. He takes a solid block of iron pierced with a conical hole, which is fitted with a conical iron plug, heats them in a stove to the temperature of melting lead, and having previously cut up the horn lengthwise on one side with a saw, he inserts its narrow end into the hole, and drives the plug into it with a mallet. By the heat of the iron, the horn gets so softened in the course of about a minute, as to bear flattening out in the usual way.

HORNBEAM. The *Carpinus betulus*, sometimes called the yoke-elm. It is a stringy and tough wood which grows in some parts of Europe, and which is imported from America. It is used by millwrights for the cogs of wheels, also for skittles, and for mallets.

HORN SILVER, or LUNA CORNEA. Fused chloride of silver. Both these names were given by the alchemists to this preparation. It is found native. See SILVER, ORPIMENT.

HORNSTONE. A variety of quartz, resembling flint, but more brittle, and, breaking with a more splintery fracture. It sometimes occurs imbedded in limestone. See CHLINT.

HORSE CHESTNUT. (*Marronnier D'Inde*, Fr.; *Conus Rusticus*, Germ.) The wood of this well known tree is used by the Turnbridge turner. It is only employed for some large varnished works.

HORSE POWER, in steam engines, is estimated by Mr. Watt at 32,000 pounds avoirdupois lifted one foot high per minute, for one horse. M. D'Arbuthnot, from an examination of the work done by horses in the whims, or gigs (*marches à mâtres*), for raising ore from the mines at Freyberg, the horses being of average size and strength, has concluded that the useful effect of a horse yoked during eight hours, by two ridings of four hours each, in a manege or mill course, may be estimated at 40 kilogranmes raised one foot per second; which is nearly 16,440 pounds raised one foot per minute; being very nearly one half of Mr. Watt's liberal estimates for the horse power of his steam engines.

Frederick William Simms, M. Inst. C. E., adopted some peculiar conditions of work on which he was engaged to determine the value of horse power. He had to make a tunnel for the South Eastern Railway. This tunnel was driven in the middle bed of the lower green-sand, between which and the surface of the ground is interposed only the upper bed of the same stratum; but in sinking the eleven shafts for the work, it was found that at the level of the top of the tunnel, the ground assumed the character of a quicksand, saturated with water, in such quantity that it could not be reduced by manual labour. Under these circumstances horse gins were erected for drawing the water by barrels, containing one hundred gallons each, weighing when full about 1210 lbs.

The engineer's intention was, to draw simultaneously from the shafts, in the direction of the tunnel, an equal quantity to carry off the water; but the earth, which was covered with fine particles of blue clay, was so filled with water as to become a mass of fluid mud, so that exertions were therefore necessary to overcome the water, without erecting pumps. At first this was accomplished by making each horse work for 12 hours and then for 8 hours per day, allowing one hour for feed and rest; as the water increased it became necessary to work night and day, and the time of each horse's working was reduced generally to 6 hours, and sometimes to 3 hours. As all the horses were hired at the rate of seven shillings per day, the engineer, who had the direction of the works, ordered a daily register to be kept of the actual work done by each horse, for the double purpose of ascertaining whether they all performed their duty, and also hoping to collect a body of facts relative to horse power which might be useful hereafter.

Mr. Simms gives as a proposition, "that the proper estimate of horse power would be that which measures the weight that a horse would draw up out of a well, the animal acting by a horizontal line of traction turned into the vertical direction by a simple pulley, whose friction should be reduced as much as possible." He states that the manner in which the work was performed, necessarily approached very nearly to these conditions; and after giving the principal dimensions of the horse gins, he analyses each set of experiments, and by taking the mean of those, against which no objections could be urged, he arrives at the following results:—

The power of a horse for 8 hours = 25,412 lbs. raised 1 foot high in one minute.
 do. do. 6 = 31,760 do.
 do. do. 4½ = 27,046 do.
 do. do. 3 = 22,943 do.

Of these results, he thinks the experiments for 6 hours and for 3 hours alone should be adopted as practical guides, all the others being in some degree objectionable.

As a means of comparison, the following table of estimates of horse power is given:—

Name.	Pounds raised 1 foot high in a minute.	Hours of work	Authority.
Boulton and Watt - -	32,000	8	Robinson's Mech. Phil. ii. 143. Tredgold on Railroads, p. 69.
Tredgold - - -	27,500	8	
Regulators - - -	44,000	9	Dr. Gregory's Mathematics for Practical Men, p. 183.
Iditto - - -	27,500	Not stated	
Sassure - - -	34,070	8	
More, for Society of Arts	21,120	Not stated	
Smeaton - - -	22,000	Not stated	

These are much higher results than the average of his experiments, and would more nearly accord with the extremes obtained by him; but under such excessive fatigue, the horses were speedily exhausted, and died rapidly. Nearly one hundred horses were employed; they were of good quality; their average height was 15 hands ½ inch, and their weight about 10½ cwt., and they cost from 20*l.* to 40*l.* each. They had as much corn as they could eat, and were well attended to.

The total quantity of work done by the horses, and its cost, was as under:—

Required quantity of water drawn 16 feet, the average height, }	124,332
20,220,000 gallons - - - - -	4,360
Do. earth, 5,160 yds. 1 ton 6 cwt. per yard - - - - -	

Total weight drawn to the surface - - - 128,692

Total cost of horse labour, including a boy to drive each horse, 13s. 3d. 14s. 3d., or 2s. 6d. per ton the average height of 16 ft.

Mr. P. Rennie made some experiments on the amount of work performed by horses tracking down on roads. On the upper end of the crest of the foot a pulley was hung; over this the towing rope was passed, and the amount of resistance to be overcome by given weights, &c. as exactly as possible, the power exerted by the horse.

The results arrived at by these means were so various, that he could not draw any average conclusions, as the power exerted varied between 1 lb. and 1 ton, and the power diminished, as the speed was increased. He thought that 2½ miles per hour was an average estimate, and that it should not exceed 4 miles per hour, although in all estimates of horse power, the speed was considered to be at an average of 4½ miles per hour, and all experiments were reduced to that standard.

Mr. Rennie, some years ago, had made numerous inquiries respecting the work done by horses in drawing upon common tar-pike roads, and found that four good horses could draw an ordinary stage coach with its complement of passengers, at the rate of ten miles an hour; that if they ran at a 10 miles in the hour, the horses must rest one day in each week; that good horses, so worked, would last only five years, each horse drawing about half a ton. He had been informed by wagoners, that good horses would walk at the rate of 2½ miles per hour, for twelve hours out of twenty-four, making 30 miles a day; and that they would continue to do such work day by day, each horse drawing six tons, for many years, provided they had not been worked hard when young.

It is desirable to know the average speed at which the different rates of work had been performed; this was essential in order to find any value to be put upon the results given. Coach proprietors calculated that at a speed of 10 miles per hour, a horse was required for every mile going and returning, so that one horse was kept for every mile of road. Now supposing a four horse coach, with an average load, to weigh 2 tons, the load for each horse was 10 cwt.; whereas in the case of a horse drawing a cart, the gross load frequently amounted to 2 tons, but the speed was reduced to 2 miles per hour, at which pace he conceived that 16 miles per day might be considered a fair day's work; this therefore was double the distance with four times the load, or eight times the coach work, but with a heavier horse.

The law that the quantity of work done was as the square root of the velocity,—or as the cube root of the velocity, in equal times,—is confined to work upon canals, or bodies moving through the water.

Mr. Rennie had tried some experiments on the force of traction of the boats on the Grand Junction Canal. The towing rope is attached to a dynamometer, which had previously been attested by weights.

The horse, although urged at first starting, was afterwards allowed to fall into his natural speed, which was 2½ miles per hour on the average of 20 miles. The maximum speed was 4 miles, and the minimum 2 miles, per hour. The dynamometer indicated an average of 100 lbs., which was capable of overcoming the resistance of the loaded barge of 25 tons, being in the ratio of 1500. The weight of the horse was about 11 cwt.

He also tried many experiments upon a fast boat, lent to him in 1833 by the late Colonel Page. These experiments were principally made in order to ascertain the comparative resistance of vessels moving through water at different velocities, and the Grand Junction Canal afforded a convenient opportunity of undertaking them.

The boat was 70 feet in length, 4 feet in breadth, and drew 9 inches of water.

The traction indicated by the dynamometer the following resistance:—

Miles per hour.	Do.	Miles per hour.	Do.
At 2½ the resistance was 20		At 6 the resistance was 97 to 214	
3	27	7	250
3½	30	8	336
4	36	9	411
4½	60	10	575
5	70 to 75	11	642

One horse was employed in these experiments.

Average 336

Two horses were employed in these experiments.

Stakes were fixed near the margin of the canal, so as to ascertain the rise and fall of the wave caused by the boat in passing; and it was observed that when a boat passed with a velocity of from 4 to 6 miles per hour, the rise of the wave was 3 inches, and the fall 3 inches, making a wave of 10 inches in depth; and when the velocity was $11\frac{1}{2}$ miles, the rise was reduced to 2 inches, and the fall to 2 inches.

Great difference existed in the power of horses, their weights and structure; and the large dray horses used by Messrs. Hatchay, Perkins, and Co. did a full average day as assessed by Boulton and Watt; but considering the average power of strong and weak animals, he had adopted 22,000 lbs. raised 1 foot high as the standard; much, however, depended on the nature of the work performed.

Mr. Haslewood has given the following statement of the work performed by a London brewer's horse per day; the cost of feed and of wear and tear per horse per annum being derived from actual experience among a large number of horses at Messrs. Truman, Hanbury, and Co.'s brewery. The food, &c., is supposed to have cost the same per quarter per truss, &c., each year.

Years	Pounds Weight drawn 4½ Miles per Horse per Day.	Pounds Weight drawn 1½ Miles per Horse per Day.	Average Pounds Weight drawn 13 Miles per Horse per Day.	Cost of Food and Sticks per Horse per Annum.	Difference per Horse per Annum.

Mr. Hartmore mentions a case which occurred in a work near Plymouth, which he believed would give the fair value of the work actually performed daily by a horse for a considerable period.

A quarry-wagon, weighing 3½ tons, carrying an average load of stone of 5½ tons, was drawn by one horse along a railway 960 feet in length, 260 of it being level, and the remaining 700 feet having an inclination of 1 in 138. During 48 working days the number of trips was 1,382, or an average of 27½ trips each day; the time of performing each trip was 4 minutes, or at a speed of 2.72 miles per hour; and the total weight drawn, including that of the waggon, was 23,950,000 lbs.

Repeated experiments proved, that upon the incline of 1 in 138 the waggon in their ordinary working state would just remain stationary; the friction was therefore assumed to be 16.2 lbs. per ton; by calculation it was found that the horse raised 59,320 lbs. 1 foot high per minute during the 6 working hours each day, the useful effect, or net amount of stone carried, being 21,738 lbs. raised 1 foot high per minute. This difference between the work done and the useful effect arose from the necessary strength and weight of the waggon.

The animal employed was a common Devonshire cart-horse, 8 years old, 15 hands high, and weighed 10½ cwt.; he continued doing the same work throughout a whole summer, remaining in good condition; but a lighter horse was found unequal to it.

HORSESHOES. The ordinary method of making these is well known. There has however been lately introduced with much success a machine for making horseshoes. One of these machines has been erected at Chillington Ironworks, Widdershampton, by the inventor, Mr. Henry Burden, of Trury, New York. As early as 1835 he took out a patent for a machine for making horseshoes, which he improved upon in 1843, and this was turned to practical account by the production of a considerable number of horseshoes. The present machine, however, which was patented in 1857, is entirely different from the former ones, and is a very remarkable piece of mechanism. In the previous machines the piece of iron bar of which the shoe was to be made, was rolled into shape before being bent, and the pressure of the rollers being in the direction of its length, the bar, when it was pressed, was naturally rather extended in length than width, and the widening which is required at the crown of the shoe was not properly effected. By the present plan the bar, after being heated, enters the machine by a feeding apparatus, a piece of the required length is cut off, and, by a stroke from a piece of steel, shaped like the inside of a horseshoe, is bent, and falls upon a dolly or wheel beneath, corresponding to one on a cylinder above,

and that supplied by pressure, the desired shape, two hands are kept at the same moment holding the ends of the thread, or both of the string, and drawing them towards the required length. These operations have very considerable effect on the quality of the fabric, and by an immense apparatus, which is flattened by a curved beam, which the wheel gives it as it passes at the mouth of the machine. The thread thus made is put through the iron-rod in shape and in the position of the loop—a most important point with regard to the value of hosiery, and they can be put on, when the machine is in proper order, at the rate of 60 per minute, which means that we can now finish in a day, and the quantity is enormous, far beyond what is very ordinary. As the bar is bent before being put in the frame, the pressure at the crown is in the direction of the width, and hence the widening is really effected.

HOSIERY. (*Hosiérie*, Fr.; *Strumpfweber*, Germ.) The stocking frame, which is the great improvement of this business, though it is a part of the machine, is a complicated machine, which consists merely of a system of parts, and a very considerable degree of attention, provided an accurate knowledge of the nature of the fabric of the hosiery. This nature is totally different from the nature of the fabric which constitutes cloth, as the slightest inspection of a stocking will show, for the thread of having two distinct systems of thread, the warp and the weft, which are woven together by crossing each other at right angles, the warp is composed of a single thread united or looped together in a peculiar manner, which is called stocking-stitch, and sometimes chain-work.

This is best explained by the view in *fig. 963*. A single thread is formed into

a number of loops or waves, by arranging it over a number of parallel needles, as it were at *a*; these are retained or kept in the form of loops or waves, by being drawn or looped through a smaller loop or wave formed by the thread of the previous course of the work, at *b*. The fabric thus formed by the union of a number of loops is really unravelled, because the stability of the whole piece depends upon the ultimate fastening of the first end of the thread; and if this is undone, the loops formed by that end will open, and release the subsequent loops

one at a time, until the whole is unravelled, and drawn out into the single thread from which it was made. In the same manner, if a thread in a stocking piece falls, or breaks at any part, or drops a stitch, as it is called, it immediately produces a hole, and the extension of the rest can only be prevented by fastening the end. It should be observed that there are many different fabrics of stocking-stitch for various kinds of ornamental hosiery, and as each requires a different kind of frame or machine to produce it, we should greatly exceed our limits to enter into a detailed description of them all. That species which we have represented in *fig. 963* is the common stocking-stitch used for plain hosiery, and is formed by the machine called the common stocking frame, which is the groundwork of all the others. The operation, as we see, consists in drawing the loop of a thread successively through a series of other loops, so long as the work is continued, as is very plainly shown for one stitch in *fig. 964*.

There is a great variety of different frames in use for producing various ornamental kinds of hosiery. The first, which forms the foundation of the whole, is that for knitting plain hosiery, or the common stocking-frame.

Of this valuable machine, the invention of Mr. Lee of Cambridge, a side elevation is given in *fig. 963*, with the essential parts. The framing is supported by four upright posts, generally of oak, ash, or other hard wood. Two of these posts appear at *a* and *b*, and the connecting cross rails are at *c* and *d*. At *e* is a small additional piece of framing, which supports the hosiery's seat. The iron-work of the machine is bolted or screwed to the upper rails of the framework, and consists of two parts. The first rests upon a sole of polished iron, which appears at *n*, and to which a great part of the machinery is attached. The upper part, which is generally called the carriage, runs upon the iron sole at *n*, and is supported by four small wheels or trucks, as they are called by the workmen. At the upper part of the back standard of iron are joints, one of which appears at *q*, and to these is fitted a frame, one side of which is seen extending to *n*. By means of these joints the end at *r* may be depressed by the hosiery's hand, and it returns, when relieved, by the operation of a strong spring of tempered steel, acting between a cross bar in the frame, and another below. The action of this spring is very apparent in *fig. 966*. In the front of the frame, immediately opposite to where the hosiery sits, are placed the needles which form the loops. These needles, or rather hooks, are more or less numerous, according to the coarseness or fineness of the stocking; and this, although unavoidable, proves a very considerable abatement of the value of a stocking-frame. In almost every other machine (for example, those em-

played in spinning or weaving), it is easy to adapt any one either to work coarser or finer work, as it may be wanted. But in the manufacture of hosiery, a frame once finished, is limited for ever in its operation to the same quality of work, with this exception, that by changing the stuff, the work may be made a little more dense or flimsy; but no alteration in the size or quantity of loops can take place. Hence where the manufacture is extensively prosecuted, many frames may be thrown idle by every vicissitude of demand; and where a poor mechanic does purchase his own frame, he is for ever limited to the same kind of work. The gauge, as it is called, of a stocking-frame is regulated by the number of loops contained in three inches of breadth, and varies very much; the coarsest frames in common use being about what are termed four-tones, and the finest employed in great extent about twelve. The needles are of iron wire, the manufacture of which is very simple; but long practice in the art is found necessary before a needle-maker acquires the dexterity which will enable him both to execute his work well, and in sufficient quantity to render his labour productive.

The process of making the needles is as follows:—Good sound iron wire, of a proper fineness, is to be selected; that which is liable to split or splinter, either in filing, jangling, or bending, being totally unfit for the purpose. The wire is first to be cut into proper lengths, according to the fineness of the frame for which the needles are designed, coarse needles being considerably longer than fine ones. When a sufficient number (generally some thousands) have been cut, the wire must be softened as much as possible. This is done by laying them in rows in a flat iron box, about an inch deep, with a close cover; the box being filled with charcoal between the strata of wires. This box, being placed upon a moderate fire, is gradually heated until both the wires and charcoal have received a moderate red heat, because, were the heat increased to what smiths term the white heat, the wire would be rendered totally unfit for the subsequent processes which it has to undergo, both in finishing and working. When the box has been sufficiently heated, it may be taken from the fire, and placed among hot ashes until both ashes and box have gradually cooled; for the slower the wires cool, the softer and easier wrought they will be. When perfectly cool, the next process is to punch a longitudinal groove in the stem of every needle, which receives the point or barb, when depressed. This is done by means of a small engine worked by the power of a screw and lever. The construction of these engines is various; but a profile elevation of one of the most simple and commonly used will be found in fig. 966. It consists of two very strong pieces of malleable iron, represented at A and C, and these two pieces are connected by a strong well-fitted joint at N. The lower piece, or sole of the engine at C, is screwed down by bolts to a strong board or table, and the upper piece A will then rise or sink at pleasure, upon the joint N. In order that A may be very steady in rising and sinking, which is indispensable to its correct operation, a strong bridle of iron, which is shown in section at R, is added to C, and direct its motion. In the upper part of this bridle is a female screw, through which the forcing screw passes, which is turned by the handle or lever H. To the sole of the engine C is fixed a bolster of tempered steel, with a small groove to receive the wire which is to be punched; and in the upper or moving part A, is a sharp chisel, which descends exactly into the groove, when A is depressed by the screw. These are represented at V, and above M. At U is a strong spring, which forces up the chisel when the pressure of

the screw is removed. The appearance of the primer, when the finishing is finished, will be presented to view by turning fig. 970, p. 471. When the finishing is finished, the wire are to be brought to a smooth point by filing or honing, the point of which should be very smoothly done, as, besides pointing the wire, it is generally to remove the sharp and elasticity which has been formed by the previous operation of twisting. The wire is next to be bent, in order to form the hook or barb, and this is done with a small piece of iron plate or dolly, which curves the point of the wire, and by its length regulates the length of the barb. The curve of the needle is now finished with a small hammer, to prevent it from turning in the socket in which it is afterwards to be put; and the point of the barb being a little curved by a pair of small pliers, the needle is completed.

In order to fit the needles to the frame, they are now cast into the sockets of lead, as they are called by the workmen, and this is done by placing the needles in an iron mould, which opens and shuts by means of a joint, and turning in the whole in a cast of fusion. In some operations, two needles are cast into the same socket. The form of the needle, when complete and fitted to its place in the frame, will be seen in fig. 967, which is a profile view of the needle-bar passing through the needle.

967

of iron called a verge, to regulate the position of the needles. When placed over the bar resting against the verge, another plate of iron, generally lined with soft leather, is pressed down upon the sockets or leads, in order to keep them all fast. This plate and the screw appear at 1. When the primer at *r* is forced down upon the barb, this sinks into the groove of the stem, and the needle is shut; when the primer rises, the barb opens again by its own elasticity.

The needles or hooks being all properly fitted, the next part of the stocking-frame to which attention ought to be paid, is the machinery for forming the loops; and this consists of two parts. The first of these, which sinks between every second or alternate needle, is represented at *a*, fig. 965, and is one of the most important parts of the whole machine. It consists of two moving parts; the first being a succession of horizontal levers moving upon a common centre, and called jacks, a term applied to vibrating levers in various kinds of machinery as well as the stocking-frame. One only of these jacks can be represented in the profile fig. 965; but the whole are distinctly shown in a horizontal position in fig. 968; and a profile upon a very enlarged scale is given in fig. 969. The jack shown in fig. 968, extends horizontally from *o* to 1, and the centre of motion

968

969

970

is at *x*. On the front, or right hand of the Jack at *o*, is a joint suspending a very thin plate of polished iron, which is termed a sinker. One of these jacks and sinkers is allotted for every second or alternate needle. The form of the sinker will appear at *a*,

As the jacks are in order that all may be exactly uniform in shape, they are cast out and finished between two circular plates of iron, which serve as guides to correct the form of each. The lower end of the jack at *i*, is tapered to a point, and when the jacks are put in their several positions, they are secured by a small iron pin, each of which is represented at *t*, in fig. 96, each being having a small circular hole each to receive the point of the jack, against which it presses by its own elasticity. In fig. 95, the centre is at *a*, the pointed tail is marked for want of room, the joint is at *o*, and the throat of the sinker, which forms the loop, is at *e*. The standards at *a*, upon which the jacks move, are called combs, and consist of pieces of flat round brass, pointed at the equal distance from each other. The cross bar *n*, which contains the whole, is of iron, with a perpendicular rib or rib on each side, leaving a vacancy between them, or a space to receive the bottom part or ends of the combs. The combs are then placed in the bar, with a few pieces of brass called a room, between each, to ascertain and preserve their distances from each other. These combs are exactly of the same shape as the combs, but have no tails. When the jacks and the combs are placed in the bar, it is laid with clay or no to form a mould, into which is poured a sufficient quantity of melted tin. When the tin has had time to cool, the combs and the jacks are easily taken out, and the tin remains well fastened and secured by the tin, which has been fused entirely round them. Thus they form a complete set of standards for the jacks; and a hole being drilled through each jack and each comb, was put through wires as a common centre for the whole.

The jacks and the combs are used for every shroud or round needle, in order to complete the part of the operation, a second set of standards is employed. These are in form and shape every way the same as the jack sinkers, but they are jointed at the top into pieces of tin, all of which are secured to the cross bar, *n*, fig. 95, and thus a chain of each kind descends between the needles, and the reason of two sets different in operation being employed, will be assigned in describing the mode of working the frame. The presser of the operation, of which something has already been said, appears at *r*; and of the two arms which support and give motion to it, one appears very plainly at *x*, its centre of motion being at *c*. The circular bend given to these arms, besides having an ornamental effect, is very useful, in order to prevent any part from interfering with the other parts which are behind, by elevating them entirely above them. The extremities of these arms at the termination of the bends behind, are connected by a cross bar, which has also a circular bend in the middle projecting downwards for a room similar to that already assigned. This bend is concealed in fig. 96, but visible in the front elevation, fig. 71. From the middle of the bend, the presser is connected with the middle treadle by a depending wire appearing at *u*, fig. 96, and thus, by the pressure of that treadle, the presser is forced down to close the barbs of the needle. The resistance of the presser is sometimes effected by means of a counterpoising weight passing over a pulley behind; and sometimes by the reaction of a wooden spring, formed of a strong hoop like that represented at *a*. The latter of these is preferred, especially by the Nottingham hosiers, because, as they assert, it makes the presser spring up with greater rapidity, and consequently saves time in working. How far this may be practically the case, it would be superfluous here to investigate; but it is obvious that the wooden spring, if very stiff, must add much to the hosier's exertion of his foot, already exercised against the united spring of all his barbs; and this inconvenience is

much improved of by those who have been accustomed to work with the common

At A are two rollers or wheels, of different diameters, revolving in opposite directions by which the jacks are relieved from the back springs, and the work is drawn up to form the lower part of the machine. About the larger wheel is a band of unspun yarn, from which the extension of which are a number of small wheels, the ends of which draw the jacks from the back springs. The smaller rollers by which the band is drawn up, with the ribbed rollers, so that the threads of the yarn pass alternately, turn the jacks thus in an inverted order. The movement of the loops at a point completely in the front elevation, is shown by fig. 971. In the slur, a thread is taken up the frame, will also be made manifest by fig. 972. In the frame, each jack is represented by a series, the tail part of three of which 1, 2, 3, are then wound up by the slur to its greatest length left or right; the slur is in the act of taking and the resulting form 4, 5, 6, 7, and 8, are obtained. When the slur has been released them. As the slur sets in the frame of the second set, a. a, fig. 973, the centre of the jacks, it is hardly necessary to remark, that the following set of loops must of course depress the jacks by which the work is done are now pulled, the jacks sinkers falling successively from the loops in every subsequent

minor of following them, and suspending them from the bar as they appear in the diagram, the position of the bar being represented by the line a, n. But when these are pulled down to the level of the former by the operator's hands, the whole frame will be completed, and the thread c, n, which is at 1 slack, will be brought to its full and proper degree of tension, which is regulated by stop screws, so as to be the proper amount at all times. The sinking of this second

set, in the way represented at fig. 973, where both kinds of sinkers appear in series, the first part expressing what is done at the point at which the thread of the other operator runs the thread, and the dark part what is done. The second set, or as they are called, the lead sinkers, from the slur, in the way represented at fig. 974, where both kinds of sinkers appear in series, the first part expressing what is done at the point at which the thread of the other operator runs the thread, and the dark part what is done. The second set, or as they are called, the lead sinkers, from the

a, will be brought nearer to its lower extreme point v, which is fixed. Again, when the force which has depressed a is removed, the spring c will revert to its former state, and the sinkers will rise. The raising of the jack sinkers and jacks takes place at the same time, by the hooper raising his hands; and for the cause of this we must revert to fig. 975. The lead sinkers in raising lay hold of notches, which raise the extreme parts of the set of jacks x, z, which are called half-jacks. Between the extremities of these at x, z, is a cross bar, which, in descending, presses at the intermediate jacks behind the common centre, and restores them to their original posture where they are secured by the back springs, until they are again relieved by the operation of the slur recrossing at the next course.

Working of the frame.—In order to work a frame, the whole apparatus being previously put into complete order, the hooper places himself on the seat a, in front, and provides himself with a bobbin of yarn or mull. This bobbin he places loosely on a vertical pin of wire, driven into one side of the frame contiguous to the needles, so that it may turn freely as the stuff is unwound from it. Taking the thread in his hand, he draws it loosely along the needles, behind the barbs, and under the throats of the sinkers. He then presses down one of the treadles to pass the slur along, and unlock the jacks from the back springs, that they may fall in a common. When this is done, the number of loops thus formed is doubled by bringing down the lead sinkers, and the new formed loops are lodged under the barbs of the needles by bringing forward the sinkers. The preceding course, and former fabric, being then again pushed back, the barbs are shut by depressing the middle treadle, and forcing down the presser upon the needles. The former work is now easily brought over the slat needles, after which, by raising the hands, both sets of sinkers are raised; the jacks are locked by the back springs, and the hooper goes on to another course.

From this it will be apparent, that the work made in the outset is well founded, for there are in reality no equal or distant movements in the working-frame. Although the wheels are nearly the same, they revolve upon their respective axes, excepting that of the carriage which gives the horizontal motion to the stockers, and that to merely an alternate motion to foot wheel. Yet the frame is a machine which requires considerable experience and care, both to work it to advantage, and also to keep it in good order. The consequences arise greatly from the small principle in which a number of moving parts must be included. Owing to this, the needles, which constantly and delicately handle the threads, are easily bent or injured. The same circumstances apply to with equal or greater force to the stockers, which must be so very thin as to be easily injured. But as these must work freely, both in a perpendicular and horizontal direction, however the motion, in a very confined and limited space, the slightest variation in either, from being truly and equally placed, may daily injure the others. When a hosieler, either ignorant of the mechanical laws of their relation to each other, or not disposed to wait for the assistance of another, attempts to rectify a fault, he in most cases increases them tenfold, and renders the machine incapable of working at all, until repaired by some more experienced person. The consequence has given rise to a set of men employed in this trade, and designated by the name of upstitchers, and these people, besides setting new frames to work, have frequently more employment in repairing old ones injured by want of care or skill, than many country spinners, who live in unhealthy partiality, find in tampering with the disorders of their kind.

It is now necessary to go further into detail respecting a machine so well known, and which requires practical attention even more than most others. It may, therefore, be sufficient to describe shortly some of its varieties, the most useful, and common of which is the rib-stick frame.

Rib-stick frame.—This frame, which, next to the common frame, is most extensively in use, is employed for working those striped or ribbed stockings, which are very common in all the different materials of which hosiery is formed. In principle it does not differ from the common frame, and not greatly in construction. The preceding general description will nearly apply to this machine with equal propriety as to the former; that part, however, by which the ribs or stripes are formed, is entirely an addition, and to the application of this additional machinery it may be proper to pay the chief attention, referring chiefly to *fig. 971*, which is a front elevation. This figure has been already referred to for the illustration of those parts of the machinery which are common to both, and those parts therefore require no recapitulation. The principle of weaving ribbed hosiery has considerable affinity to that of weaving that kind of cloth which is distinguished by the name of twilling, for the formation of stripes, with some variation, arising merely from the different nature of the fabric. In cloth weaving, two different kinds of yarn intersect each other at right angles, are employed; in hosiery only one is used. In the weaving of cloth, striped as diversity, in the cotton hosiery trade and in the woollen manufacture, the stripes are produced by reversing the yarns. In hosiery, where only one kind of yarn is used, a similar effect is produced by reversing the loops. To effect this reversing of the loops, a second set of needles is placed upon a vertical frame, so that the heads of the hooks may be nearly under those of the common needles. These needles are cast into an iron plate, pretty similar to the former, but more oblique or bevelled towards the point, so as to prevent obstructions in working them. They are also screwed in a bar of iron, generally lighter than the other, and secured by means of plates; this bar is not fixed, but has a pivot in each end, by means of which the bar may have a kind of oscillatory motion on these pivots. Two frames of iron support this bar; that in which it oscillates being nearly vertical, but inclined a little towards the other needles. *Fig. 975*, which is a profile elevation, will serve to illustrate the relative position of each bar to the other. The lower or horizontal frame, the ends only of which can be seen in *fig. 971*, under *o n*, appears in profile in *fig. 975*, where it is distinguished by *d*. The vertical frame at *w* is attached to this by two eccentric screws, which serve as joints for it to move in. On the top of this frame is the rib-needle bar at *f*, in *figs. 965* and *975*, and one needle is represented in *fig. 973* at *f*. At *g* is a small presser, to shut the barbs of the rib-needle, in the same manner as the large one does those of the frame. At *h* is one of the frame needles, to show the relative position of the one set to the other. The whole of the rib-bar is not fitted with needles like the other; for here needles are only placed where ribs or stripes are to be formed, the intervals being filled up with blank leads, that is to say, with sockets of the same shape as the others, but

without further, being merely designed to fill the bar and preserve the interval. The raised flange depends from the middle bar, by which the necessary distance upon the upper surface is given. The rising and sinking motion is communicated to this flange by a chain which is at right to the other bars, and which are wrought by the hander's heel when necessary. The pressure takes place partly by the action of the screw pressure, and partly by the motion of the needles in descending. A small iron roller is placed behind the rib-frames, which raise as they descend, and serve to form the large part of the rib-frames.

In the working of raised hosiery, the plain and ribbed courses are wrought alternately. When the plain are finished, the rib-frames are raised between the others, but an additional shaft is supplied. The rib-frames intersecting the plain ones, namely lay half of the last thread, and by doing so, being it through that which was in the rib-frames before, give it an additional supply, which reverses the line of shading, and raises the rib above the plain intervals, which have only received a simple knitting.

HOT-FLUE is the name given in England to an apartment heated by means of steam pipes, in which padded and printed calicoes are dried hard. Fig 978 represents

sents the simplest form of such a flue, heated by the vertical round iron stove A, from whose top a wide square pipe proceeds upwards in a slightly inclined direction, which receives the current of air heated by the body and capital of the stove. In this wide

channel there are pulleys, with cords or bands which suspend by hooks and connect the web of cotton from the mangle at *a*, where the operative sits, to near the point *A*, and back again. The strand may be repeated once or several times the pulleys are gradually drawn. At *b* is the driving power connected with the main shaft *u* shown. Near the feet of the operative is the mangle or reel upon which the woven goods are wound in an endless web, and their removal in the hot-air channel can be continued without interruption, as long as may be necessary.

Fig. 977 is a cross-section of the apparatus of the regular hot-flue, as it is mounted in the most valuable shape of England, that of James Thompson, Esq., of Preston, near Chorley, Lancashire. It consists of an arched apartment, nearly 30 yards long, by 18 feet high, and 10 feet wide. Thompson about one-half of this gallery divides in a horizontal floor supported on arches, above which is the draught space, through which the goods are finally passed before they escape from the flue. After they have been previously exposed to the hot air, and what is left of the lower apartment. A large square flue covered with cast-iron plates runs along the whole bottom of the gallery. It is composed of two long parallel tubes, whose sections are seen at *u, v, &c.* 977, covered with the cast-iron plates *r, r*, grooved at their ends into one another. The thickness of these plates is increased progressively as they come nearer to the draught or furnace. There are dampers which regulate the draught, and of course the heat of the stove. *A, A* are the air-passages or vent holes, left in the side walls, and which by means of a long iron rod, mounted with iron plates, may be opened or closed to suit the draught. *A, A* are the cast-iron supports of the tinned brass rollers which guide the goods along, and which are fixed to the cross pieces represented by *r, r*, fig. 977. *H, H* are iron bars for supporting the ventilators or fans (see FURNACE and VENTILATION). These fans are here enclosed within a wire grating. They make about 3000 turns per minute, and expel the moist air with perfect effect. *s* indicates the position of the windows, which extend throughout the length of the building. *t* is a gas light jet, placed at the side of each window to supply illumination for night work. The pipe is stretched along the whole extent of the gallery, and runs through it in the space of one minute and a half, being expanded during its passage to the heat of 215° Fahr.

In fig. 978, *A* is the iron door of entrance to the hot-flue gallery; at *b* is the padding machine, where the goods are padded with the steam mangle. The speed of this machine may be varied by means of the two conical drums *c, c*, which drive it; since, when the band *c, c* is brought by its forks, and adjusting screws, nearer to the narrow end of the lower drum, the cylinder upon the same shaft with the latter is driven quicker; and *rev. rev.* Over *b* is the cords are shown for drawing the drum mechanism into gear with the main shaft band, *r, r*, *r*; or for throwing it out of gear. The pulleys *r, r* carry the bands which transmit the motion to the padding machine. A cylindrical drum exterior to the hot-flue, covered with flannel, serves to receive the end of the series of pieces, and to draw them through the apartment. This mode of drying the padded cotton requires for each piece of 26 yards three pounds of coals for the furnace when a fan is employed, and four pounds without it. See CALICO PRINTING.

HUNGARY WATER. Supposed to be found only in a part of Hungary, where it is a common water prepared by heating mercury. See FALLEN CUBBER.

HYACINTH. The small water plant, which is cultivated for the transparent, beautiful coloured varieties of a flower. It is a small stem, from purple roots, in culture, which is orange red, passing into purple, red. Though not found wild at the present time it is a valuable gem, and was a very popular treasure when of a bright blue and fine from Italy. The larger forms are sometimes made wild. *Hyacinthus* is the wild and native species of certain rivers in Egypt, and in the name of *hyacinth*, mixed with various water sediments, in the bed of a stream at Ispahan (Hama Lora) in Persia, as well as in some of the same place. It is also found in abundance in Antwerp, in Germany, Saxony, the Tyrol, Transylvania, &c. In the same stream of Flanders, near in Norway, and in the bottom of Armand's lake at Munk in the Urals, Volga, at Lake Rook in New Guinea, at Hany in Persia, Scotland, Egypt, the East Indies and elsewhere. The hyacinth red varieties of some are sold by the inhabitants of Cayenne as inferior rubies. H. W. R.

HYDRATES are compounds of the water, H_2O , with water in solution or equivalent proportions. Thus, a saturated solution of calcium chloride in water, a solution of water, O , of which the part H_2O is the hydrate water. "The very different results performed by water in the various modes of combination, it is necessary to adopt a definite principle of nomenclature in this respect. . . . I shall apply the word *hydrate* only where the water is combined with a base, thus as a metallic oxide, thus, hydrate of lime, hydrate of potash, hydrated oxide of lead." — K.

HYDRAULIC CEMENTS. See MORTAR.

HYDRAULIC CRANES. The application of water-pressure to cranes is due to Sir Wm. Armstrong. These are now so generally applied, that although the subject belongs properly to engineering, it is thought advisable to include some notice of these valuable and interesting machines in this work. A statement made, by the request of the British Association in 1844, by the inventor himself, so completely explains all the peculiarities of these cranes, that the paper is reproduced from the proceedings of the Association.

"The employment of water-pressure as a mechanical agent having recently undergone a great and rapid development, I may be permitted to make a few observations on the extensive works by which its present importance has been attained. In so doing I shall commence with the year 1846, in which, after many preliminary experiments, I succeeded in establishing, upon the public quay at Newcastle-upon-Tyne, the hydraulic crane which has formed the basis of what has since been effected.

"This crane both lifted the weight and swung round in either direction by the pressure of water, and was characterised, like all other hydraulic cranes since made, by remarkable precision and softness of movement, combined with great rapidity of action.

"The experiment thus made at Newcastle having proved satisfactory, I soon afterwards obtained authority, through the intervention of Mr. Hartley, the Dock Surveyor of Liverpool, to construct several cranes and hoists upon the same principle at the Albert Dock in that town, where they were accordingly erected, and have ever since continued in operation.

"The next place at which these cranes were adopted was Grimsby New Dock, where an important step in the advancement of this kind of machinery was made by the suggestion of Mr. Rendel, who pointed out its applicability to the opening and closing of dock gates and sluices, and instructed me to extend its application to those objects. An extensive system of water-pressure machinery was accordingly carried out at that dock, and the result afforded the first practical demonstration that the pressure of a column of water could be advantageously applied as a substitute for manual labour, not merely for the cranes of goods, but also to give safe and rapid motion to those mechanical operations which are necessary for passing ships through the entrances of docks.

"In all these instances the moving column of water was about 200 feet in elevation. At Newcastle and Liverpool the supply was derived from the pipes communicating with the town reservoirs, but at Grimsby a tower was built for supporting a tank into which water was pumped by a steam-engine. In the former case, the fluctuation of pressure, consequent upon the variable draught from the pipes for the ordinary purposes of navigation, proved a serious disadvantage; but this objection had no existence at Grimsby, where the tank upon the tower furnished a separate source of power, undisturbed by any interfering conditions. Nothing could be more efficient for its purpose than this tower; but, in the natural course of improvement, I was subsequently led to the adoption of another form of artificial head, which possessed the advantage of being applicable, at a comparatively small cost, in all situations, and

lessening the size of the pipes and hydraulic machinery, by affording a pressure of greatly increased intensity.

The apparatus thus constructed for a water tower I named "the Accumulator," from the circumstance of its accumulating the power carried by the engine in charging it. The accumulator is, in fact, a reservoir giving pressure by load instead of by elevation, and it is so constructed that of every portion of this load, is to equalize the strain upon the engine in cases where the quantity of power to be supplied is subject to great and sudden fluctuations.

The construction of the accumulator is exhibited in fig. 979, and needs but

little explanation. A, cylinder, B, plunger; C, D, loaded weight case; E, F, guides for descent; G, pipe from forcing engine; H, pipe to hydraulic machine. It consists of a large cast-iron cylinder, fitted with a plunger, from which a loaded weight case is suspended, to give pressure to the water required by the engine. The load upon the plunger is so adjusted each way to produce a pressure in the cylinder equal to a constant pressure in elevation, and the apparatus is thus constantly charged by forcing the largest quantity of water which can be drawn from it at once by the machine in action, so that all the hydraulic machines with which it is connected. Whenever the engine pumps more water into the accumulator than passes direct to the hydraulic machine, the loaded plunger rises and makes room in the cylinder for the surplus, but when, on the other hand, the supply from the engine is less, for the moment, than the quantity required, the plunger, with its load descends and makes up the deficiency out of store.

The accumulator also serves as a regulator to the engine; for when the loaded plunger rises to a certain height, it begins to close a throttle valve in the supply pipe, so as gradually to reduce the speed of the engine until the descent of the plunger begins calls for an increased production of power.

The introduction of the accumulator, which took place in the year 1851, gave a great impulse to the extension of water-pressure machinery, which is now either already applied, or in course of being applied, to the purpose of cransage throughout all the great dock establishments in London, as also to a considerable extent in Liverpool and other places. I have also applied it extensively to railway purposes, chiefly under the direction of Mr. Brunel, who has found a multitude of cases, involving lifting or tractive power, in which it may be made available. Most of these applications are well exemplified at the new station of the Great Western Railway Company in London, where the loading and unloading of trucks, the hoisting into warehouses, the lifting of loaded trucks from one level to another, the moving of turn-tables, and the hauling of trucks and traversing machines are all performed, or about to be so, by means of hydraulic pressure supplied by one central steam-engine with connected accumulators. Mr. Rendel also, after having successfully adopted the low-pressure system to the working of the gates and shuttles at Grimsby, has since applied the high-pressure, or accumulator system, to the same purposes at other new docks, and a similar adaptation is being made by other eminent engineers at most of the new docks now in course of construction.

I have also adapted hydraulic machinery to the opening and closing of swing-bridges and draw-bridges of large dimensions, and, in fact, there is scarcely any mechanical operation to which human labour has been hitherto applied as a mere

raising power, which may not be efficiently performed by means of water-pressure containing great incompressibility and accumulation. Even if least injury be treated as the basis of the power, the transmission of an accumulation will be many times both expensive and dangerous. For example, a pair of heavy lock-pumps requires the motion of a revolution in raising of water, whose delivery is only half that which would be obtained, viz. when the pumps are being opened or closed. Now, if an accumulator, charged by lock-pumps, were used, the latter cylinders would be constantly closed if required, and the power retained in the accumulation by the continuous pressure of pumping would be given out in a continuous form, and thus the ultimate crane would be efficient with fewer shocks and greater regularity than where constant motion is thereby required.

The form of pump-motives which I generally use for charging the accumulator is represented in the sketch. It consists of a horizontal steam-cylinder, with two

force pumps connected directly with the piston. These force pumps are supplied with water from a cistern over the engine room, into which the water discharged by the cranes is generally brought back by a return-pipe, so that the water is not wasted, but remains continuously in use.

With a pressure representing a column of 1500 feet, the loss of head by friction in the pipes forms so small a deduction from the entire column as to be a matter of no consideration, and consequently the distance at which the engine may be situated from the points where the hydraulic machine may be placed is of little importance, except as regards the cost of the pipe. It is advisable, however, if the pipe be very long, to apply an accumulator at each extremity, so as to charge the pipe from both ends.

With regard to the mechanism of hydraulic cranes, the arrangement which I first adopted, and have ever since adhered to, consists of one or more hydraulic presses with a set of cylinders, used in the inverse order of lock and piston, for the purpose of obtaining an extended motion in the chain from a comparatively short stroke of the piston. This construction, which characterizes nearly all the varieties of the hoisting and hauling machines to which I have applied hydraulic pressure is exhibited in fig. 281, which represents one of these presses with cylinders attached, to multiply the motion tenfold. In cases where the resistance to be overcome is very considerably, I generally employ two such cylinders, with rams or pistons acting either separately or conjointly upon the same set of multiplying sheaves, according to the amount of power required.

In hydraulic cranes the power is applied, not only for lifting the load, but also for swinging the job, which latter object is effected by means of a rack or chain operating on the base of the movable part of the crane, and connected either with a cylinder and piston having a ternate motion, like that of a steam-engine, or with two presses applied to produce the same effect by alternate action.

The absence of any sensible elasticity in water renders the motions resulting from its pressure capable of the most perfect control, by means of the valve which regulates the inlet and outlet passages of the machines; but this very property, which gives so much certainty of action, tends to cause shocks and strains to the machinery, by resisting the momentum acquired by the moving parts. Take, for example, the case

of an hydraulic crane, weighing several tons, is suspended on the job, the machine being produced by the water working on one side of a piston and escaping from the

351

other. Under such circumstances, if the water-pump be suddenly stopped by the revolving valve, the piston and the pump, impelled forward by the momentum of the loaded job, the rest by an unyielding body of water deprived of outlet, would be brought to rest abruptly, as to cause, in all probability, the breakage of the machine. So also, in lowering a heavy weight with considerable velocity, if the escape-pipe be too suddenly closed, a similar risk of injury would arise from the abrupt stoppage of the weight, if a remedy were not provided; but these liabilities are effectually removed by applying, in connection with the water-passage to the cylinder, a small check-valve, opening upwards against the pressure into the supply-pipe, so as to prevent the put-up water in the cylinder to be pressed back into the pipe whenever it becomes exposed to a compressive force exceeding the pressure on the accumulator. By this means all jerks and concussion are avoided, and a perfect control over the movement of the machine is combined with great uniformity of action.

With regard to the kind of valves used for water-pressure machinery, I find that either lift-valves or slide-valves may be effectually applied, and kept tight under heavy pressures, provided that they be excluded from the water, and the valves be made of proper material.

In cases where a more perfect seal is required, or required that multiplying sheaves will be frequently added, I employ another method of various constructions. For heavy pressures, such as an accumulator affords, an arrangement consisting of three plungers, connected with a triple check, and bearing a general resemblance to a three-throw plunger pump, is well adapted for the purpose. The admission and exhaust valves are acted upon by weights and levers, and fitted in proper rotation by pins fixed for that purpose upon a separate shaft, and these valves are associated with relief-checks, to obviate the concussion which would otherwise be liable to take place at the turn of each stroke.

The liability of water-pressure machinery to be deranged by frost has often been adduced as an objection to its use; and upon this point I may observe — first, that I have never experienced any interference from this cause when the machines were placed, as they generally are, beneath the surface of the ground, or within a building; and secondly, that when they are unavoidably exposed, all risk may be prevented by letting out the water in frosty weather whenever the machines cease working.

When the working power consists of a natural column of water, the pressure rarely exceeds 250 grs per foot, and in such cases I have employed the rotative action of a pair of cylinders and plungers, with slide-valves, resembling in some degree those of a high-pressure engine, but having relief-valves, to prevent check at the turn of the stroke. *Fig. 98* shows a slide-valve adapted for the turning apparatus of a crane, but the relief-checks of which are equally applicable to a water-pressure engine of the construction in question. Two of these checks open against the pressure in the supply-pipe, so as to afford an escape for the water, which would otherwise be shut up in the cylinder when the exhaust port closes, and the other two communicate with the discharge-pipe, so as to draw in a portion of water to fill up the small vacancy which would otherwise be left in the cylinder on the closing of the admission port, a, supply pipe; b, exhaust pipe; c, c, pipes to cylinder; d, d, checks opening against

power, &c., which spring from exhaust. About four years ago I recommended the application of this principle to Mr. Harrison's last patent in Northampton, at the request of Mr. Sayer. Mr. Harrison's well-known patent, and two more, have recently been added at the same place. They are used for creating vapour, for heating materials from the bottom, for pumping water, and for driving a steam saw and other machinery. The Water-rate can be increased, as follows.

"If in progress of time railways should be generally extended into mountainous districts, as is to be done from Newcastle for manufacturing purposes, the rapid stream which should be such, to supply the power, and a water-lift may then be adopted for the purpose of water-pressure engines, in mountainous districts."

"The object, however, which I have chiefly had in view, is to first give an idea of the subject, and then to provide, in substance, of several instances, a method of working a machinery of this kind, a term not in the art, and extending over a large area, by means of transmission of power produced by a steam-engine and accumulated at a central point. The reason made of steam-

raising power by shafting could only be applied in cases where the machines were enclosed within a small compass, and where the accumulation of power necessary to meet varying requirements did not extend to such a distance. A direct wheel would affect compressed or exhausted air was almost equally inapplicable to the purpose I contemplated, in consequence of the many objections which are thereby involved, as well as the liability to leakage, which, in an extended system of pipes and machinery, requiring a multitude of joints, valves, and fittings, surfaces, would form an insurmountable difficulty. But the use of water as a medium of transmission is free from all these objections, and its fitness for the purpose intended is now thoroughly established by the results which have been obtained."

HYDRAULIC MACHINERY for MINES. See WATER AND WATER PRESSURE FOR MINES, TERMINES.

HYDRAULIC PRESS. See WATER PRESSURE MACHINERY.

HYDRIODIC ACID (*Acide Hydrique*, Fr.; *Hydrojodine*, Germ.) is an acid formed by the combination of 127 parts of iodine with 1 part of hydrogen by weight, and by measure equal volumes of iodine vapour and hydrogen combined without condensation. It is obtained pure and in the gaseous state by introducing into a glass tube, closed at one end, a little iodine, then a small quantity of roughly-powdered glass moistened with water, upon this a few small fragments of phosphorus, and lastly more glass; this order, iodine, glass, phosphorus, glass, is repeated until the tube is two-thirds filled. A cork and narrow bent tube are then fitted and gentle heat applied, when the hydriodic acid is liberated, and may be collected in dry bottles by the displacement of air. Another process is to place in a small retort 10 parts of iodide of potassium with 5 of water, add 20 parts of iodine, then drop in gradually 1 part of phosphorus and into small pieces, and apply a gentle heat; hydriodic acid will be formed abundantly, and may be collected as before stated. The following equation expresses the reaction—

Hydriodic acid greatly resembles hydrochloric acid; it is colourless, and highly acrid, it fumes in the air, and is very soluble in water. Its density is 4.4, and under strong pressure condenses to a yellowish liquid, which solidifies at 100° Fahr.

Hydriodic acid in solution is much more easily prepared, by suspending iodine in water, and passing a stream of washed hydropneumatic acid through it until the colour disappears; it is then heated to expel the hydropneumatic acid, then allowed to rest, when it may be decanted from the precipitate of sulphur. The reaction consists simply in the displacement of the sulphur by the iodine, $HS + I = HI + S$.

This liquid may be evaporated until it acquires a density of 1.7, when it consists of $HI + 111H_2O$. It then distils at 247° Fahr. without decomposition. The solution cannot be long kept, it being decomposed by the oxygen of the air with the liberation of iodine, which imparts a dark colour to it. Chlorine decomposes it instantly, with liberation of the iodine.

The solution of hydriodic acid and of the iodides possess the power of dissolving a considerable quantity of iodine, forming a dark solution. — H. K. H.

HYDROBROMIC ACID. *HBr*. See BROMINE.

HYDRO-CARBON. See CARBURETTED HYDROGEN.

HYDROCHLORIC ACID. (*Chlorhydrique*, Fr.; *Salzsäure*, Germ.) A compound of chlorine and hydrogen which is a colourless gas of a peculiar suffocating, pungent odour; it reddens vegetable blues, but possesses no bleaching property. The solution of hydrochloric acid in water is the MURIATIC ACID and SPIRIT OF SALT of commerce; absently *Muriatic Acid*. 2 volumes of chlorine and 2 volumes of hydrogen combine to form 4 volumes of this acid. HCl ; eq. 36.5. It is best prepared by heating a mixture of 6 parts of chloride of sodium (*common salt*) and 10 parts of concentrated sulphuric acid previously diluted with 4 parts of water, in a capacious glass retort, connected with a set of Woulfe's bottles. This acid is extracted on a large scale from sea-salt, by the action of sulphuric acid and a moderate heat; but it was originally obtained from the salt by exposing a mixture of it and of common clay to ignition in an earthen retort. The acid gas which exhales is rapidly condensed by water. 100 cubic inches of water are capable of absorbing no less than 48,000 cubic inches of the acid gas, whereby the liquid acquires a specific gravity of 1.2105 and a volume of 143 cubic inches. This vast condensation is accompanied with a great production of heat; whence it becomes necessary to apply artificial refrigeration, especially if a strong *acid* as the above is to be prepared. In general, the muriatic acid of commerce has a specific gravity varying from 1.15 to 1.20, and contains, for the most part, considerably less than 40 parts by weight of acid gas in the hundred. The above stronger acid contains 42.66 per cent. by weight; for when a cubic inch of water, which weighs 252.5 grains, has absorbed 4.0 cubic inches—160 grains of gas; and $332.5 + 160 = 492.5$; then $440.5 : 160 :: 100 : 42.66$. In general a very good approximation may be found to the percentage of real muriatic acid, in any liquid sample, by multiplying the decimal figures of the specific gravity by 200. Thus, for example, at 1.160 we shall have by this rule $0.162 \times 200 = 32.4$, for the quantity of gas in 100 parts of the liquid. Muriatic acid gas consists of chlorine and hydrogen combined, without condensation, in equal volumes. Its specific gravity is 1.247, air = 1.000.

By sealing up muriate of ammonia and sulphuric acid, apart, in a strong glass tube re-curved, and then causing them to act on each other, Sir H. Davy procured liquid muriatic acid. He justly observes, that the generation of elastic substances in close vessels, either with or without heat, offers much more powerful means of approximating their molecules than those dependent on the application of cold, whether natural or artificial; for as gases diminished only $\frac{1}{10}$ in volume for every degree of Fahrenheit's scale, beginning at ordinary temperatures, a very slight condensation only can be produced by the most powerful freezing mixtures, not half so much as would result from the application of a strong flame to one part of a glass tube, the other part being of ordinary temperature; and when attempts are made to condense gases into liquids by sudden mechanical compression, the heat instantly generated presents a formidable obstacle to the success of the experiment; whereas, in the compression resulting from their slow generation in close vessels, if the process be conducted with common precautions, there is no source of difficulty or danger; and it may be easily assisted by artificial cold, in cases where gases approach near to that point of compression and temperature at which they become vapours.—*Phil. Trans.* 1483.

The muriatic acid of commerce has usually a yellowish tinge, but when chemically pure it is colourless. It fumes strongly in the air, emitting a corrosive vapour of a peculiar smell. The characteristic test of muriatic acid in the most dilute state, is nitrate of silver, which causes a curdy precipitate of chloride of silver.

The preparation of this acid upon the great scale is frequently effected in this country by acting upon sea-salt in hemispherical iron pots, or in cast-iron cylinders, with concentrated sulphuric acid; taking 6 parts of the salt to 5 of the acid. The mouth of the pot may be covered with a slab of siliceous freestone, perforated with two holes of about two inches in diameter each, into the one of which the acid is poured by a funnel in successive portions, and into the other, a bent glass, or stone-ware tube, is fixed, for conducting the disengaged muriatic gas into a series of large globes of bottle glass, one-third filled with water, and laid on a sloping sand-bed. A week is commonly employed for working off each pot; no heat being applied to it till the second day.

The decomposition of sea-salt by sulphuric acid was at one time carried on by some French manufacturers in large leaden pans, 10 feet long, 5 feet broad, and a foot deep, covered with sheets of lead, and luted. The disengaged acid gas was made to circulate in a conduit of glazed bricks, nearly 650 yards long, where it was condensed by a sheet of water exceedingly thin, which flowed slowly in the opposite direction of the gas down a slope of 1 in 200. At the end of this canal nearest the apparatus, the muriatic acid was as strong as possible, and pretty pure; but towards the other end, the water was hardly acidulous. The condensing part of this apparatus was therefore

tolerable quantity, but as the decomposition of the salt could not be confined to the lower part, the acid mixture had to be drawn out of flame, in order to be completely decomposed in a reverberatory furnace; in this way nearly 50 per cent. of the muriatic acid was lost. And besides, the great quantity of gas given off during the emptying of the lead chambers was apt to suffocate the workmen, or seriously injure their lungs, causing severe bronchitis. The ready exit of muriatic acid is so considerable, and the loss of it incurred in the preceding process is of a considerable amount, that consequently, both in France and in England, exclusive of soda, for the soda manufacture, has been procured with the decomposition of the muriatic acid in the air. In the method now lately resorted to, the gaseous products are exhausted from extensive vats, where currents of water come from them and carry them off into the river. The surrounding vegetation is thereby saved in some measure from being burned up, an accident which was previously liable to happen when first produced the floating gases upon the ground. At Newcastle, Liverpool, and Manchester, where the consumption of muriatic acid brass is compared to the manufacture of soda, this process is now practised upon a vast scale.

The apparatus for condensing muriatic acid gas has been modified and changed, of late years, in many different ways.

The Hastringes apparatus. At the end of a reverberatory furnace, opening into a lead trough or pan, about 1 foot deep, of a width equal to that of the interior of the furnace, that is, about 5 feet wide, and 6½ feet long, is enclosed in masonry, having its upper edges covered with cast-iron plates or fire tiles, and placed upon a level with the passage of the smoke as it escapes from the reverberatory. The arch which covers that pan forms a continuation of the roof of the reverberatory, and is of the same height. The flame which proceeds from the furnace contains the murex of salt and sulphuric acid is made to escape between the vault and the surface of the iron plates or fire tiles, through a passage only 4 inches in height. When the heated air and vapours reach the extremity of the pan, they are reflected downwards, and made to return beneath the bottom of the pan, in a row, which is afterwards directed so as to lead the smoke into two lateral flues, which terminate in the chimney. The pan is thus surrounded as it were with the heat and flame discharged from the reverberatory furnace. A door is opened near the end of the pan, for introducing the charges of sea-salt, amounting to 12 bags of 2 cwt. each, or 24 cwt. This door is then luted on as tightly as possible, and for every 100 parts of salt, 110 of sulphuric acid are poured in, of specific gravity 1.391, containing 57 per cent. of dry acid. This acid is introduced through a funnel inserted in the roof of the furnace. Decomposition ensues, muriatic acid gas mingled with steam is disengaged, and is conducted through 4 stone-ware tubes into the refrigerator, where it is finally condensed. These refrigerators consist of large stone-ware carboys, called *dame-jars* in France, to the number of 7 or 8 for each jupe, and arranged so that the neck of the one communicates with the body of the other; thus the gas must traverse the whole series, and gets in a good measure condensed by the water in them, before reaching the last.

When the operation is finished, the door opposite the pan is opened, and the residuum in it is discharged, in the form of a fluid magma, upon a square bed of bricks, exterior to the furnace. This paste speedily concretes on cooling, and is then broken into fragments and carried to the soda manufactory. The immense quantity of gas exhaled in discharging the pan, renders this part of the operation very painful

283

to the workmen, and wasteful in reference to the production of muriatic acid. The difficulty of luting securely the cast-iron plates or fire tiles which cover the pan, the

impossibility of completing the decomposition of the salt, since the residuum must be run off in a liquid state, finally, the damage sustained by the melting and corrosion of the lead, &c., are among the causes why no more than 80 or 90 parts of muriatic acid at 1.179 are collected, equivalent to 25 per cent. of real acid for every 100 of salt employed, instead of much more than double that quantity, which it may be made to yield by a well conducted chemical process.

The cylinder apparatus is now much esteemed by many manufacturers. *Fig. 883* represents, in transverse section, a bench of iron cylinder retorts, as built up in a proper

furnace for producing muriatic acid; and *fig. 884* a longitudinal section of one retort with one of its carboys of condensation. *a* is the grate; *b*, a fireplace, in which two iron cylinders *c c*, are set alongside of each other. They are $5\frac{1}{2}$ feet long, 20 inches in diameter, about $\frac{1}{4}$ of an inch thick, and take 16 cwt. of salt for a charge; *d* is the ash-pit; *e e* are cast-iron lids for closing both ends of the cylinders; *f* is a tube in the posterior lid, for pouring in the sulphuric acid; *g* is another tube, in the anterior lid, for the insertion of the bent pipe of hard glazed stoneware *h*;

i is a three-necked stoneware carboy; *k* is a tube of safety; *l*, a tube of communication with the second carboy; *m m m* are the flues leading to the chimney *n*.

After the salt has been introduced, and the fire kindled, 82½ per cent. of its weight of sulphuric acid, of sp. gr. 1.80, should be slowly poured into the cylinder through a lead funnel, with a siphon-formed pipe. The three-necked carboys may be either placed in a series for each retort, like a range of Woulfe's bottles, or all the carboys of the front range may be placed in communication with one another, while the last carboy at one end is joined to the first of the second range; and thus in succession. They must be half filled with cold water; and when convenient, those of the front row at least, should be plunged in an oblong trough of running water. The acid which condenses in the carboys of that row is apt to be somewhat contaminated with sulphuric acid, muriate of iron, or even sulphate of soda; but that in the second and third will be found to be pure. In this way 100 parts of sea-salt will yield 180 parts of muriatic acid, of sp. gr. 1.19; while the sulphate of soda in the retort will afford from 208 to 210 of that salt in crystals.

It is proper to heat all the parts of the cylinders equally, to insure the simultaneous decomposition of the salt, and to protect it from the acid; for the hotter the iron, and the stronger the acid, the less erosion ensues.

Some manufacturers, with the view of saving fuel by the construction of their furnaces, oppose to the flame as many obstacles as they can, and make it perform numerous circulations round the cylinders; but this system is bad, and does not even effect the desired economy, because the passages, being narrow, impair the draft, and become speedily choked up with the soot, which would be burned profitably in a freer space; the decomposition also, being unequally performed, is less perfect, and the cylinders are more injured. It is better to make the flame envelope at once the body of the cylinder; after which it may circulate beneath the vault, in order to give out a portion of its caloric before it escapes at the chimney.

The fire should be briskly kindled, but lowered as soon as the distillation commences; and then continued moderate till the evolution of gas diminishes, when it must be heated somewhat strongly to finish the decomposition. The iron door is now removed, to extract the sulphate of soda, and to recommence another operation. This sulphate ought to be white and uniform, exhibiting in its fracture no undecomposed sea-salt.

Liquid muriatic acid has a very sour corrosive taste, a pungent suffocating smell, and acts very powerfully upon a vast number of mineral, vegetable, and animal substances. It is much employed for making many metallic solutions; and in combination with nitric acid, it forms the aqua regia of the alchemists, so called from its property of dissolving gold. See SODA MANUFACTURE.

Table of Hydrocyanic Acid by Dr. Ure

Atm. Pressure	Specific Gravity	Chemical Name	Weight	Atm. Pressure	Specific Gravity	Chemical Name	Weight

HYDROCYANIC ACID. *Syn. Cyanhydric acid, Prussic acid, CNH.* This highly important acid is regarded by all chemists as being formed on the exact type of the ordinary inorganic hydracids, such as the hydrochloric or hydriodic. The compound radical analogous to chlorine, which is contained in it, has received the name of cyanogen, and possesses the formula CN. That this body is precisely analogous in its relations to the simple salt radicals is rendered certain by numerous facts. It combines directly with metals to form compounds: it possesses the same vapour volume, and unites with hydrogen to form a hydracid, which in its turn decomposes the metallic oxides with formation of water. Thus we have, with metallic oxides and hydrochloric acid (M standing for a metal), $MO + HCl = MCl + HO$, and with hydrocyanic and metallic oxides (Cy standing for cyanogen), $MO + HCy = M(Cy) + HO$. Two volumes of chlorine and two of hydrogen yield four volumes of hydrochloric acid gas, and two volumes of cyanogen with two of hydrogen yield four volumes of hydrocyanic acid. The density of the vapour of hydrocyanic acid is consequently 0.9476. The theoretical number being 0.9343. Its density in the fluid state is 0.6967 at a temperature of 64°. It boils at 84° F. at ordinary pressures.

Hydrocyanic acid is never prepared in the anhydrous state except as a curiosity or for the purpose of scientific investigation. In fact it cannot be long preserved of great strength; a somewhat complex decomposition invariably taking place in it, with production of brown adhesive matters containing cyanide of ammonia, and also a substance by some considered to be an acid, and known as the *arsenicum*. Paracyanogen is probably formed at the same time. The constitution of arsenic acid is by no means well known, and even its very existence, as a definite chemical substance, is doubtful. It is singular that the presence of a mineral acid greatly retards the decomposition of prussic acid, especially if it be dilute: the pharmacopœian acid consequently may be preserved of uniform strength, in well filled and closely stoppered

bottles, for almost any length of time. The deadly nature of prussic acid unfortunately causes it to be only too frequently resorted to by the despairing or the murderer. Fortunately, however, in spite of its toxicity, the chemist possesses excellent means for its detection.

Preparation.—1. *Hydrated acid.* As prussic acid is largely employed in medicine, but in a very dilute form, it is usual to prepare it and dilute until of the proper degree of strength. The following process for preparing it will be found to give a satisfactory result, and, moreover, it may be performed on any quantity of materials. The apparatus for the purpose will vary with the scale to which the experiment is to be made. If on a few ounces, glass retorts and flasks answer well, if good condensation is ensured, by means of a Liebig's condenser well supplied with very cold water. If a large quantity of prussic acid is to be made, such as several gallons, the apparatus should consist of a retort or still with broad jacket by gridding. The head should be capable of adjustment with a steam-water adapter to a worm of the usual material enclosed in a tub of water. The joints are to be luted with a mixture of one handful of almond meal and five handfuls of linseed meal, worked with water to the consistency of putty. A solution of rough chloride of calcium in water is to be made and placed in a large iron pan, with a cover so contrived as to permit the still to drop in up to the flange. 14 parts of yellow prussiate of potash are then to be bruised in a mortar and mixed with dilute sulphuric acid prepared by adding 6 parts of sulphuric acid (density 1.850) to 43 of water. The head being luted on, a fire is to be kindled in the furnace under the iron pan, and the chloride of calcium bath is to be kept boiling constantly until 6 parts of acid have distilled over. The neck of the still should be placed in the funnel which conducts the acid to the Winchester quart bottles which are to contain the product, and a piece of wet bladder is to be stretched over the funnel to prevent evaporation of the acid into the laboratory. The worm used for the purpose must be ascertained to be perfectly clean, and, if prussic acid is to be frequently made, should be kept specially for that operation. To each Winchester quart of the acid distilling over, one drop of sulphuric acid may be added to insure its keeping. But the acid thus prepared generally keeps for a long time even without this precaution, owing probably to small traces of the sulphuric acid being carried over during the distillation.

It is quite impossible to conduct the operation so as to yield a product of uniform strength; it is absolutely necessary, therefore, to determine the percentage of real hydrocyanic acid, and dilute it to the required degree. It fortunately happens that 1 grain of hydrocyanic acid yields almost exactly 5 grains of cyanide of silver; for one equivalent of acid = 27 produces 1 equivalent of cyanide of silver = 134, so that $27 : 134 :: 1 : 4.96$. The acid produced will have, probably, to be reduced to one of two standards; namely, the so-called Scherck's strength, containing 3 per cent. of acid, or the P.L., containing 2 per cent.; 100 grains of the former should, consequently, yield 23 grains, and 100 of the P.L. 10 grains of cyanide of silver. In either case the calculation becomes obvious.

2. *The anhydrous acid.* Several processes for conducting this dangerous operation are known; the following is, perhaps, the most generally convenient. A large glass retort is so arranged that its neck is directed upwards at an angle of about 45° ; a cork fitted to the aperture in the neck connects a glass tube with a bottle containing a little chloride of calcium. From the latter vessel another tube proceeds to a U tube containing fragments of chloride of calcium, and from the latter a third, conducting the dehydrated vapour of prussic acid to an upright glass tube contained in a mixture of potash, 7 of oil of vitriol, and 14 of water. The retort is to be heated with a charcoal fire, and the temperature of the bottle and U tube, containing the chloride of calcium, is not to be allowed to fall below 90° , in order to prevent condensation of the anhydrous prussic acid taking place anywhere except in the tube contained in the freezing mixture. The vapour of anhydrous prussic acid is so dangerous that the greatest precaution must be taken to prevent inhaling the smallest portion.

Detection of prussic acid.—When prussic acid exists in moderate quantity in a solution it may be detected by first adding a few drops of potash, then a mixture of protosulphate and persulphate of iron, and finally a little hydrochloric acid; a bright blue precipitate indicates the presence of the acid. A much more delicate test, and one that is applicable when, from the dilution of the solution, the salts of iron are no longer capable of acting, is by the conversion of the prussic acid into sulphocyanide of ammonium. For this purpose the prussic acid is to be warmed on a watch glass with a drop of sulphide of ammonium, until the solution has become colourless. The addition of a trace of a solution of a persalt of iron will show, by the formation of a blood red colour, the presence of the acid sought. A very neat mode of applying this test is to place one drop of sulphide of ammonium on a watch glass inverted over

another containing the expanded fluid. On leaving the apparatus in a warm place, arranged in this manner, for a short time, the water vapor will be found to remain solid, by means of condensation, which, after drying, will be in a state well adapted for showing the reaction with a peroxide of iron—*C. G. W.*

HYDRODYNAMICS. The terminal part of a science which treats of the motion of fluids. This science has, of course, most important bearings on the propulsion of steam, water-wheels, &c., employed to facilitate the operation of the mine. It is not, however, possible to embrace this, which belongs to mechanical engineering, in this work.

HYDRO-EXTRACTOR. A name sometimes given to the machine employed for expelling the water from waxes, gums, &c. See *DISPERATOR*.

HYDROFLUORIC ACID. It was discovered by J. W. Klaproth, in 1780, that fluor spar and oil of vitriol would not run glass. Schlegel, in 1771, discovered that this peculiar property was due to the liberation of an acid from the fluor spar.

Hydrofluoric acid is thus obtained by placing finely powdered fluor spar in a leaden retort, and twice its weight of highly concentrated oil of vitriol. By a gentle heat the gas is distilled over, which must be collected in a receiver, in which, by means of a freezing mixture, it may be condensed into a liquid. If a solution of this acid is water is required, the extremity of the tube from the retort is carried into a vessel of water.

Hydrofluoric acid attacks glass with great readiness, by acting on its silica.

Glass upon which any design is to be etched, is covered with an coating wax, and the design made in the usual manner; this is placed over a leaden vessel, in which is a mixture of fluor spar and oil of vitriol; a gentle heat being applied, hydrofluoric acid escapes, and immediately attacks the glass. See *ETCHING*.

HYDROGEN. (Eng. and Fr. *Wasserstoff*, Germ.) A permanently gaseous, elementary body, the lightest of all known substances, its specific gravity being 0.0695; 100 cubic inches weighing, under ordinary pressure and temperature, only 2.14 grains. It is therefore nearly 14.5 times lighter than atmospheric air.

From its extreme lightness it was formerly used for filling balloons, but has been superseded for that purpose by ordinary coal gas, which can be produced at a much cheaper rate; the difference of buoyant power being compensated by increasing considerably the size of the balloon. It is itself inflammable, but not a supporter of combustion, its combination with oxygen forming water, which contains $\frac{1}{8}$ th of its weight of hydrogen.

It is generally prepared by the action of dilute sulphuric acid on zinc, although there are many other processes which furnish it; as the decomposition of steam by iron filings with the aid of heat, &c.

In the act of combining with oxygen, as when burnt in the oxyhydrogen blow-pipe, the greatest possible heat is obtained; a piece of stout platinum wire being fused when placed in the flame, which cannot be effected by the greatest heat obtained in our furnaces.

Hydrogen is sometimes used for soldering metals; in which process it is requisite to bring the two surfaces of the metal together in a perfectly metallic state at a high temperature. Hydrogen effects this completely; by its combustion it supplies the heat, and by entering into combination with the oxygen of the air, prevents the formation of oxides, which are so easily formed at the temperature required for the melting of the metals, and which, when present, prevent the union of the surfaces. See *ACTOGENON'S SOLDERING*.

Hydrogen is often used also for the reduction of metals from their different combinations; the reduction is effected by passing a current of hydrogen over the compounds heated to redness.

Its use in reducing ores on the large scale has been proposed, but as yet not found practicable.—*H. K. B.*

HYDROMETER. An instrument for ascertaining the specific gravities of liquids. Baume's hydrometer, which is much used in France, and other countries of the continent of Europe, when plunged in pure water, at the temperature of 55° Fahr., marks 0 upon its scale; in a solution containing 15 per cent. of common salt (the scale of soda), and 85 of water by weight, it marks 150; so that each degree is meant to indicate a density corresponding to one per cent. of that salt. See *ALCOHOLMETER* and *ASTROMETER*.

HYDROPHANE. A variety of opal which readily imbibes water, and when immersed it becomes transparent, though opaque when dry. It is found in Hungary, and in Ireland, near the Giant's Causeway, and at Croaghragh, Ballywaden.

HYDROSTATICS. The science which treats of the equilibrium of fluids, and of the pressure exerted by them.

In the engineering arrangements by which water is supplied to towns, hydrostatics becomes of the utmost importance. The highest possible level is obtained for the

reservoir, and from this a series of pipes is arranged through all the streets and houses. The bottom of the water is to 10 to 15 feet below the level, and hence all the pipes are filled with water, and in all such as are below the level of the water in the reservoir a pressure upward is exerted equal to the height of the reservoir above that point; and if a hole is put in the pipe, the water jets out with a force equal to this pressure. In the highest houses, the water perhaps only finds its level, and flows out without pressure quickly. See WATKIN PRINCIPLES OF HYDRAULIC ENGINEERING.

HYDROSULPHURETS. Chemical compounds of bases with sulphuretted hydrogen, or hydrosulphuric acid.

HYDROCOEBA COURBAIL. A tree growing in South America, from which the resin is obtained.

HYPEROXYMURIATES. The old and incorrect name of CHLORATES.

HYPOCHLORIC ACID. HOCl , Eq. 67.5. When finely powdered chloride of potash is gradually mixed in a paste with strong sulphuric acid, and heated in a bath of alcohol and water, a yellow gas is discharged which is this hypochloric acid, or the peroxide of chlorine. Although of much interest as a chemical compound, it has no use in the arts. See *Ure's Chemical Dictionary*.

HYPOCHLOROUS ACID. HOCl , Eq. 67.5. This acid is best obtained by dissolving red oxide of mercury finely divided through twelve times its weight of water, which is introduced into a bottle containing chlorine, and agitated until the gas is absorbed. An oxide of mercury is formed, which is removed by sublimation. The weak fluid obtained is put into a flask, and heated in a water bath, when the evolved gas is collected in a smaller portion of water, which becomes a pure solution of hypochlorous acid.

The salts are termed hypochlorites. See CHLORINE and BLEACHING.

HYPOSULPHATES. Saline compounds formed by the union of hyposulphuric acid with bases.

HYPOSULPHITES. Saline compounds formed by the union of hyposulphurous acid with bases.

Hyposulphate of Soda. The salts of the hyposulphuric acid are obtained from the hyposulphate of manganese, which is itself thus prepared: finely divided binoxide of manganese is collected in water, artificially cooled, and a stream of sulphurous acid passed through it. The binoxide gives up half its oxygen, becoming protoxide, which unites with the hyposulphuric acid which is formed, producing the soluble hyposulphate of manganese, which is separated from the excess of binoxide by filtration.

The following equation represents the reaction:—

If the temperature were allowed to rise, sulphuric acid would be formed, and not hyposulphuric:—

The hyposulphuric acid, unlike the hyposulphurous acid, may be obtained in the free state, and its solution permits even of being evaporated in *vacuo*, until it acquires the density of 1.347; but if carried further, it is decomposed into sulphuric and sulphurous acids.

The acid is obtained in the free state by adding baryta water to the hyposulphate of manganese: the soluble hyposulphate of baryta, filtered from the oxide of manganese, and precipitated exactly by the cautious addition of sulphuric acid, and filtered from the precipitate of sulphate of baryta, yields the pure solution of the acid, which may be evaporated in *vacuo*, as above stated.

It has no odour, but a very sour taste.

The hyposulphate of soda may be made directly from the manganese salt or from the free acid.

All the hyposulphates are soluble; they have not as yet met with any commercial application.

Hyposulphite of Soda. This salt, now so extensively used for photographic purposes, was first introduced by Sir J. Herschel. It may easily be prepared by the following process: viz. by transmitting through a solution of sulphide of sodium (prepared by fusing together in a covered crucible equal weights of carbonate of soda, and flowers of sulphur), a stream of sulphurous acid until it ceases to be absorbed; the liquid is then filtered and evaporated, when the hyposulphite of soda ($\text{NaO.SO}^2 + 5\text{H}_2\text{O}$) crystallizes out.

Another and perhaps better process consists in digesting a solution of sulphite of soda on flowers of sulphur. The sulphur gradually dissolves, forming a colourless

substance, which yields on evaporation crystals of hypophosphite of soda; the reaction being shown by the following equation:—

The baryta salt may be obtained in small brilliant crystals, by mixing an aqueous solution of chloride of barium and hypophosphite of soda.

The hypophosphorous acid is incapable of existing in the free state, for almost immediately on the addition of an acid to the solution of its salts, it is decomposed into sulphurous acid, with liberation of sulphur, ($\text{SO}^{\text{O}} = \text{SO}^{\text{O}} + \text{S}$).

The soluble hypophosphites have the power, in a marked degree, of dissolving certain salts of silver, as the chloride, iodide, &c., which are insoluble in water; forming with them soluble salts, whose solutions possess an intensely sweet taste, although the solutions of the hypophosphites alone possess a disagreeable bitter taste.

From the above reaction arises the principal value of the hypophosphite of soda, which is used by the photographer to dissolve off from the plate, after the action of the light on it, all the undecomposed silver salt, thus preventing the further action of the light on the picture.

A double hypophosphite of soda and gold is used for gilding the daguerreotype plate, and for colouring the positive proofs obtained in photographic printing. This double salt may be obtained in a state of purity, by mixing concentrated solutions of 1 part of chloride of gold, and 2 parts of hypophosphite of soda; by the addition of alcohol it is precipitated; the precipitate must be re-dissolved in a small quantity of water, and again precipitated by alcohol. Its formation is explained by the following equation:—

HYSON. A green tea. See TEA.

I.

IBEX. An animal of the goat kind, the hair of which is esteemed for some kinds of manufacture.

ICEHOUSE. (*Glacière*, Fr.; *Eishaus*, Germ.) Under the article FRIGIDITY, the different artificial methods of producing cold are enumerated. But for the uses of common life, in these climates, the most economical and convenient means of refrigeration in hot weather may be procured by laying up a store of ice in winter, in such circumstances as will preserve it solid during summer.

An icehouse should not be regarded as an object of mere luxury; in the southern countries of Europe it is considered among people in easy circumstances as an indispensable appendage to a country mansion. During the dog days, especially at those periods and in those districts where the sirocco blows, a lassitude and torpor of mind and body supervene, with indigestion or total loss of appetite, and sometimes dysenteries, which are obviously occasioned by the excess of heat, and are to be prevented or counteracted chiefly by the use of cold beverages. By giving tone to the stomach, iced drinks immediately restore the functions of the nervous and muscular systems when they are languid; while they enable persons in health to endure without much inconvenience an atmosphere so close and sultry as would be intolerable without this remedy. Icehouses, moreover, afford to country gentlemen a great advantage in enabling them to preserve their fish, butcher meat, dead poultry, and game, which would otherwise, in particular states of the weather, immediately spoil. Considering at how little expense and trouble an icehouse can be constructed, it is surprising that any respectable habitation in the country should not have one attached to it. The simplest and most scientific form is a double cone, that is, two cones joined base to base; the one being of stones or brick-work, sunk under ground, with its apex at the bottom, into which the ice is rammed; the other being a conical roof of carpentry covered with thatch, and pointed at top. The entrance should be placed always on the north side; it should consist of a corridor or porch with double doors, and be screened from the sunbeams by a small shrubbery. Such are the principles upon which an icehouse should be formed; but they will be better understood by the following explanation and figure.

A dry and sandy soil if possible should be selected; and here a cavity is to be dug about 16 feet in diameter, terminating below like the point of a sugar loaf. Its

ordinary depth for a family may be about 24 feet; but the larger the dimensions are, the longer will it preserve the ice, provided it be fixed. In digging, the workman should slope the ground progressively towards the axis of the cone, to prevent the earth falling in. This conical slope should be faced with brick or stone work about one foot thick, and jointed with lime mortar, so as to be air and water-tight. A well is to be excavated, at the bottom 3 feet wide and 4 deep, covered at top with an iron grating for supporting the ice, and letting the water drain away.

The upper cone may likewise be built of brick-work, and covered with thatch; such a roof would prove the most durable. This is the construction shown in fig. 244. Whatever kind of roof be preferred, there must be left in it an oblong passage into the interior. This porch should face the north, and be at least 4 feet long by 2½ feet wide; and properly closed by a well fitted door at each end. All round the bottom of this conical cover, a gutter should be placed to carry off the rain to a distance from the ice-house, and prevent the circumjacent ground from getting soaked with moisture.

Fig. 245 shows the section of a well-constructed ice-house. Under the ice chamber A the ice is rammed but the space B C is the grate of the drain-pipe. The portion D E is built in brick or stone; the base of the ice chamber slopes inward towards the centre at C. The upper part of the brick-work A B is a little way below the level of the ground. The wooden framework F G H I forms the roof, and is covered with thick thatch. J K is the wooden work of the door. At L the back is seen for lifting up a charge of ice, by means of the cord M passing over the pulley N, which enables the servant to raise it easily.

The ice-house should have no window to admit light; but be, so to speak, hermetically sealed in every joint, except at its escapement, which may terminate in a water trap to prevent circulation of air.

A clear day should be selected for charging the ice-house; but before beginning to fill, a quantity of long dry straw should be laid on the bottom crosswise; and as the ice is progressively introduced, straw is to be spread against the conical sides, to prevent the ice from coming into contact with the brick or stone work. The more firmly compacted the ice is, the better does it keep; with which view it should be broken into pieces with mallets before being thrown in. No layers of straw should be stratified among the ice, for they would make its body porous. Some persons recommend to pour in a little water with the successive layers of ice, in order to fill up its small crevices, and convert the whole into one mass.

Over the top layer a thick bed of straw should be spread, which is to be covered with boards surmounted with heavy stones, to close up the interstices in the straw. The inner and outer door should never be opened at once; but the one should always be shut before the other is opened.

Dry snow will rammed keeps equally well with hard ice, if care be taken to leave no cavities in the mass, and to secure its compactness by sprinkling a little water upon the successive charges.

To facilitate the extraction of the ice, a ladder is set up against its sloping wall at one side of the door, and left there during the season.

ICE BY THE RED-HOT PROCESS. See SENEZIOIAL STATE.

ICE-PRODUCING MACHINE. See FREEZING.

ICELAND MOSS (*Lichen d'Islande*, Fr.; *Flechtel Isl.*, Germ.) is a lichen, the *Cetraria Islandica*, which contains a substance soluble in hot water, but forming a jelly when it cools, styled *lichenine* by M. Guerin. This moss is called in the Pharmacopœia *Lichen Islandicus*. It appears to have derived its name from the circumstance that the Icelanders first discovered its medicinal qualities. Lichenine is prepared by extracting first of all from the plant a bitter colouring matter, by digesting 1 pound of it in 16 pounds of cold water containing one ounce of pearl-ash; then draining the lichen, calcinating with cold water, and boiling it in 9 pounds of boiling water, till 3 pounds be evaporated. The jelly which forms, upon cooling the filtered solution, is dark coloured, but, being dried and redissolved in hot water, it becomes clear and colourless. Lichenine consists of 39.33 carbon, 7.24 hydrogen, and 53.43 oxygen. The mucilage of Iceland moss is preferred in Germany to common paste for dressing

the way of water in the lamp, because it remains dark, being in hydrostatic equilibrium. It is also covered with the glass for saving paper in the vat. The normal pressure is produced from the lamp's pressure in the oil.

HOLLAND SPAR. Crystalline substance of which the most beautiful specimens are brought from Holland. These are particularly for their double refraction, and brilliant crystals in numerous polished double refraction, *specimen*.

IDWALL-STOSE. A gem for which have been. It is obtained from the older stone of the Swedish district.

HUXANTHINE. A substance which might be employed for dyeing yellow derived from the leaves of the common holly.

ILLUMINATION. The science of determining the relative values of different sources of illuminating power.

It is one of the most important that we should be enabled with facility to determine the relative value of the light which we receive from various sources. The only way in which this can be effected, is by comparing with some standard source of light the illuminating power of a candle. Dr. Fire, who was an original occasion to direct his attention to the subject of illumination, proposed many very important and exact experiments to some of which it appears important that we should direct particular attention. All the original papers in the case of illumination many parts are now obsolete, but as much of it is still of considerable practical value, the following selection have been made, all such being distinguished by Dr. Fire's name. After many experiments to determine a standard, Dr. Fire says:—

"After comparing lights of many kinds, I find every source to conclude that a large wax candle of three to the pound, either long or short, that is, either 12 or 15 inches in length, as manufactured by one of the great wax-candle makers, and furnished with a wick containing 27 or 28 threads of the best Turkey cotton, is capable of furnishing a most uniform, or nearly invariable standard of illumination. It affords one-tenth of the light emitted by one of the Argand lamps of the Tertiary class, and one-eleventh of the light of my mechanical lamp, when such lamp is made to burn with its maximum flame, short of smoking."

Dr. Fire, however, for many of his determinations employed the French mechanical lamp, known as Carcel's lamp; and in connexion with this the following remarks occur:—

"Mr. Samuel Parker, long advantageously known to the public for his admirable and portable lamp, as well as other inventions subservient to domestic comfort, having obtained a patent for a new lamp, in which the oil is heated by a very simple contrivance, in the center, to any desired degree, before arriving at the wick, I instituted an extensive series of experiments to determine its value in the production of light, and consumption of oil, compared to the value of other lamps, as well as candles, in these respects."

In 1855 A, A, B, B, is a section of the cylinder which constitutes the burner; the oil being contained between the inner and outer cylinders, and receiving heat from the flame of the lamp which passes up through the inner cylinder, and is reverberated more or less against its sides by the top of the metal chimney being notched and bent back. It is a slide-valve which is opened to allow the oil to descend to the wick, and is shut when the burner is to be separated from the pipe of supply, at A, for the purpose of recharging it with oil. The flame is not fed, not by raising or lowering the wick, as in common lamps, but by raising or lowering the bell-mouthed glass chimney which rises at its bottom on three points, and is moved by means of the rack-work mechanism. The chimney cylinder is of the size of a pint imperial, and should be made entirely full before lighting the lamp, so as to leave no air in the cylinder, which, by its expansion with the heat, would otherwise cause an overflow of the oil.

The following arrangement was adopted in these experiments for determining the relative illumination of the different lights. Having trimmed, with every precaution, my French mechanical lamp, and charged it with sperm oil, I placed it upon an oblong table, at a distance of 10 feet from a wall, on which a white sheet of paper was stuck. One of Mr. Parker's hot-oil lamps, charged with a quantity of the same oil, was placed upon the same table; and each being made to burn with its maximum brilliancy, short of smoking, the relative illumination of the two lamps was determined by the well-known method of the comparison of shadows; a wire a few inches long, and of the thickness of a crow-quill, being found suitable for enabling the eye to estimate very nicely the shade of the intercepted light. It was observed in numerous trials, both by my own eyes and those of others, that when one of the lamps was shifted half an inch nearer to or further from the paper screen, it caused a perceptible difference in the tint of the shadow. Professor Wheatstone kindly enabled me to verify the precision of the above method of shadows, by employing in some of the experi-

ments, a photometer of his own invention, in which the relative brightness of the two lights was determined by the relative brightness of the opposite sides of a revolving colored ball, illuminated by them.

1. The mechanical lamp was furnished with a glass chimney 1·3 inch in diameter at the base, and 1·2 at the top; the whole bottom part was 1·8 inch long, and the narrow upper part 6 in. high. When placed at a distance of 10 feet from the wall its light there may be estimated as the square of the number, or 100. In the first series of experiments, when burning with its maximum flame, with occasional flickerings of smoke, it emitted a light equal to that of 11 wax candles, and consumed 912 grains of oil per hour. The specific gravity was quite pure, having a specific gravity of 0·87 compared to water at 100°. In a subsequent series of experiments, when its light was less flickering, and equal only to that of 10 wax candles, it consumed only 815 grains, or 0·1164 of a lb. per hour. If we multiply this number into the price of the oil (8s. per gallon) per lb. 11d., the product 1·2854d. will represent the relative cost of this illumination, estimated at 100.

2 The best oil lamp burns with a much steadier flame than the mechanical, which must be ascribed in no small degree to the rounded shape of the bell-mouthed glass chimney, whereby the air is brought progressively closer and closer into contact with the outer surface of the flame, without being furiously dashed against it, as it is by the rectangular shoulder of the common contracted chimney. When charged with sperm oil, and made to burn with a maximum flame, this lamp required to be placed one foot further from the screen than the mechanical lamp, in order that its shade should have the same depth of tint. Hence, its relative illumination was, in that case, as the square of 11 to the square of 1, or as 121 to 100. Yet its consumption of oil was only 696 grains, or somewhat less than 0.1 of a lb. per hour. Had its light been reduced to 100, it would have consumed only 576 grains per hour, or .082 of a lb. If we multiply this number by 114, the product 65664 will represent the relative cost of 100 of this illumination.

3. The hot-oil lamp being charged with the southern whale oil, of specific gravity 0.936, at 2s. 6d. per gallon, or 3d. per lb., when burning with its maximum flame, required to be placed 9 feet and 1 inch from the screen to drop the same tint of shade upon it as the flames of the other two lamps did at 10 and 11 feet with the sperm oil. The square of 9 feet and 1 inch = 82 is the relative illumination of the hot-oil lamp

with the southern wax, 22. It consumed 700 grs. a. or 0.111 of a pound per hour, but had it given 100 of light it would have consumed 911 grs., or 0.14 of a pound, which number being multiplied by its price 3d., the product 423.3d. will represent the relative cost of 100 of this light.

4. A hot-oil lamp charged with sperm oil of sp. gr. = 0.914, at 2s. 6d. per gallon, or 74d. per lb., when burning with an average flame extended to be placed at 9 feet 6 inches, to obtain the standard test of flame upon the screen. It consumed 700 grains per hour. The square of $9\frac{1}{2}$ feet is 90.25, which is the relative intensity of the light of this lamp. Had it consumed a light = 100, it would have consumed 911 grs., or 0.12 of a pound per hour—this number multiplied by the price per pound, gives the product 0.12d. as the relative cost of 100 of this light.

5. A hot-oil lamp charged with 17° and 60° (sperm and oil) (sp. gr. of sperm gravity 0.923), at 4s. 6d. per gallon, or 74d. per lb., had it to be placed 9 feet from the screen, it consumed 1003 grains per hour. Had its light been 100 of 0.12, the illumination would have been 1207 grains, or 0.143 of a pound per hour; which number multiplied by its price per pound, the product 1.43d. will represent the cost of 100 of this illumination.

6. In comparing the consumption of French angular lamp in general use with the mechanical lamp, it was found to give about one-half the light, and to consume two thirds of the oil of the mechanical lamp.

7. Wax candles from some of the most eminent wax-chandlers of the metropolis were next subjected to experiment; and it is very remarkable that, whether they were three, four, or six in the pound, each afforded very nearly the same quantity of light, for each required to be placed at a distance of 3 feet from the screen to afford a shadow of the same tint as that dropped from the mechanical lamp, estimated at 100. The consumption of a genuine wax candle, in still air, is, upon an average of many experiments, 123 grains per hour, but as it affords only $\frac{1}{11}$ of the light of the mechanical lamp, 11 times 123 = 1353 grains, or 0.1064 of a pound is the quantity that would need to be consumed to produce a light equal to that of the said lamp. If we multiply that number by the price of the candles per lb. = 30d., the product = 3063d., is the cost of 100 of illumination by wax. A wax candle, three in the pound (short), is one inch in diameter, 13 inches in length, and contains 27 or 28 threads, each about $\frac{1}{16}$ of an inch in diameter. But the quality of the wick depends upon the capillarity of the cotton fibrils, which is said to be greatest in the Turkey cotton, and hence the wicks for the best wax candles are always made with cotton yarn imported from the Levant. A wax candle, three in the pound (long), is $\frac{1}{2}$ of an inch in diameter, 15 inches long, and has 26 threads in its wick. A wax candle, six in the pound, is 2 inches long, $\frac{1}{2}$ of an inch in diameter, and has 22 threads in its wick. The light of this candle may be reckoned to be, at most, about $\frac{1}{11}$ less than that of the three in the pound. A well-made short three burns with surprising regularity in still air, being at the rate of an inch in an hour and a half, so that the whole candle will last 15 hours. A long three will last as long, and a six about 9 $\frac{1}{2}$ hours. Sp. gr. of wax = 0.960.

8. A spermaceti candle, three in the pound, is $\frac{1}{2}$ of an inch in diameter, 15 inches long, and has a plaited wick, instead of the parallel threads of a wax candle. The same candles four in the pound, are $\frac{1}{2}$ of an inch in diameter, and 15 $\frac{1}{2}$ inches long. Each gives very nearly the same quantity of light as the corresponding wax candles; viz. $\frac{1}{11}$ of the light of the above mechanical lamp, and consumes 142 grains per hour. Multiplying the last number by 11, the product, 1562 grains = 0.223 of a pound, would be the consumption of spermaceti requisite to give 100 of illumination. Multiplying the last number by 24d., the price of the candles per pound, the product, 5.352d. is the relative cost of 100 of this illumination.

9. Stearic acid candles, commonly called German wax, consume 164.5 grains, or 0.024 of a pound per hour, when emitting the same light as the standard wax candle. Multiplying the latter number by 11, and by 16d. (the price of the candles per lb.), the product 4.224d. will represent the relative cost of 100 of this illumination.

10. Tallow candles: moulds, short three, 1 inch in diameter, and 13 $\frac{1}{2}$ in length; ditto long three, $\frac{1}{2}$ of an inch in diameter, and 15 in length; ditto long four, $\frac{1}{2}$ of an inch in diameter, and 15 $\frac{1}{2}$ in length. Each of these candles burns with a most uncertain light, which varies from $\frac{1}{12}$ to $\frac{1}{16}$ of the light of the mechanical lamp—the average may be taken at $\frac{1}{11}$. The three consumes each 144 grains, or 0.2 of a pound, per hour; which number, multiplied by 14, and by 7d. (the price per pound), gives the product 2.52d. for the relative cost of 100 of this illumination.

11. Palmer's spreading wick candles. Distance from the screen 3 feet 4 inches, with a shadow equal to the standard. Consumption of tallow per hour 232.5 grains, or 0.0332 of a pound. The square of 3 feet 4 inches = 119 is the relative illumination of this candle = 119 : 0.0332 :: 100 : 0.29 = 10d. = 11.9 is the relative cost of this illumination.

12. Cocoa-nut stearine candles consumed each 168 grains per hour, and emitted a light equal to $\frac{1}{10}$ of the standard flame. Multiplying 168 by 16, the product 2,688 grains, or 0.441 of a lb., is the quantity which would be consumed per hour to afford a light equal to 100. And 0.441 multiplied by 10d., the price per lb., gives the product 4.41d. as the cost of 100 of this illumination per hour.

10. A gas Argand London lamp, of 15 lbs., a circle of $\frac{7}{8}$ of an inch in diam. & r. with a flame 3 inches long, afforded a light 78% compared to the mechanical lamp. Assuming the light of the mechanical lamp as before at 100, that of the best lamp is 121, and that of the above gas flame 78.7, or in round numbers 80, and the common New-A lamp in general was 50.

Collecting the preceding results, we shall have the following tabular view of the cost per hour of an illumination equal to that of the mechanical lamp, reckoned 100, or that of a tallow wax candle, three to the pound.

TABLE of COST per HOUR of ONE HUNDRED of ILLUMINATION.

	Price	Price
1. Parker's hot-oil lamp, with southern whale oil	- 0 18 75 or about	1 1/2
2. Mather's lamp or Carcel lamp, with sperm oil	- 1 3 00	1 1/2
3. Parker's hot-oil lamp, with sperm oil	- 0 90	1
4. Ditto ditto common oil or oil	- 0 70	1
5. Ditto ditto common oil or oil	- 1 00	1
6. French lamp in general use, with sperm oil	- 1 75	1 1/2
7. Wax candles	- 3 00	6
8. Sperm candles	- 5 00	5
9. German wax (Stearic acid) ditto	- 4 25	4
10. Palmer's spreading wick candles	- 2 00	2
11. Tallow (mould) candles	- 2 20	2
12. Common tallow candles	- 4 00	4

The following table contains, according to Peclot, the illuminating powers of different candles, and their consumption of material in an hour: the light emitted by a French Argand lamp, consuming 42 grammes (= 42 · 15 grains) in an hour, being called unity.

	Intensity of l. ghd.	Consumpt — per Hour.
Tallow candles 6 in lb	10'66	8'31
Stearine, or pressed tallow, 8 in lb. . . .	8'74	7'11
, 5 in lb. . . .	7'50	7'42
Wax candles, 5 in lb.	13'61	8'71
Spermaceti, 5 in lb.	14'40	8'92
Stearic acid, commonly called stearine, 5 in lb.	14'40	9'33

The following table shows the economical ratios of the candles, where the second column gives the quantity of material in grammes which is requisite to produce as much light as the Carcel lamp.—

	Quantity of Material.	Pipes per Kilogramme.	Cost of 1 foot per lineal
Tallow candle, 5 per lb. . .	7035	1 f. 40 c.	98 c.
, 8 per lb. . .	85-92	1 f. 40 c.	120 c.
Pressed tallow, 5 per lb. . .	94-99	2 f. 40 c.	277 c.
Wax candle, 5 per lb. . .	64 04	2 f. 40 c.	48 6 c.
Spermaceti ditto, 5 per lb. .	61-91	2 f. 00 c.	47-8 c.
Stearine, 5 per lb. . .	65-24	6 f.	57-1 c.

These results may be compared with mine given above. A kilogramme, or 1000 grammes = 15,440 grains = 2 1/2 lb. avoirdupois. — *Urr.*

The rule observed in the determination of these questions of illuminating power, is, according to the laws of optics, that the sum of the luminous rays from any source is inversely as the square of the distance from their source.

"The numerical estimation of the degrees of intensity of light constitutes that branch of optics which is termed PHOTOMETRY.

"If light be a material medium, a thing covered in minute points in all directions, it is plain that the same quantity which is diffused over the surface of a sphere concentric with the luminous points, if it reach its centre, will uniformly be diffused over larger and larger concentric spherical surfaces; and then its intensity, or the number of rays which fall on a given space, in each will be inversely as the whole surfaces over which it is diffused; that is, inversely as the square of their radii, or of their distances from the source of light. . . . Let a screen be placed behind an opaque screen, full of small equal and similar holes: the light will come through them, and be concentrated in all other parts, forming a parabolical bundle of rays, having the ends in the common vertex. If a sheet of white paper be placed behind this, it will be spotted over with small luminous specks, disposed exactly as the holes in the screen. Suppose the holes so small, their number so great, and the eye so distant from the paper, that it cannot distinguish the individual specks, it will still receive a general impression of brightness; the paper will appear illuminated, and present a mottled appearance, which, however, will grow more uniform as the holes are smaller and closer, and the eye more distant, and if extremely so, the paper will appear uniformly bright. Now if every alternate hole in the screen be covered, the paper will immediately receive only half the light, and will therefore be only half as bright as before, and *inter se* pass so the degree of illumination is proportional to the number of holes in the screen, or to the number of equally illuminated specks on the surface; i. e. if the speck be itself divided in size, and infinitely increased in number to number to the number of rays which fall on it from the original source of light." (*Herschel*.)

Repeating this Sir John Herschel proceeds and establishes the following definitions—
The real intrinsic brightness of a luminous object is the intensity of the light of each physical point in its surface.

The apparent intrinsic brightness of any object or luminary is the degree of illumination of its image or picture at the bottom of the eye.

The absolute light of a luminary is the sum of the areas of its elementary portions, each multiplied by its own intrinsic brightness.

The apparent light of an object is the total quantity of light which enters our eyes from it, however distributed on the retina.

Various instruments, called *photometers*, have been devised to measure the illuminating power of any body; these are, all of them, more or less defective, and the results which we obtain with the best of them are merely comparative with each other.

Bouguer's photometer consisted of two surfaces of white paper, of exactly equal size and reflective power, cut from the same piece in contact; these are illuminated, the one by the light whose illuminating power is to be measured; and the other by a light whose intensity can be varied at pleasure by an increase of distance, and can therefore be exactly estimated. The variable light is to be removed or approached, till the two surfaces are judged to be equally bright, when the distances of the luminaries being measured, or otherwise allowed for, the measure required is ascertained.

Newford's photometer. Before a screen of white paper, in a darkened room, is placed a blackened cylindrical stick, and the two lights to be compared are so placed that two shadows are thrown upon the screen side by side, with an interval between them about equal in breadth to either shadow. The brighter flame must then be removed, or the feather brought nearer to the screen, till the two shadows appear of equal intensity, when their distances from the lights must be measured, and their total illuminating powers will be in the direct ratio of the squares of the distances.

Ritchie's photometer consists of a rectangular box, about an inch and a half or two inches square, open at two ends. It is blackened within to absorb the extraneous light. Within, inclined at angles of 45° to its axis, are placed two rectangular pieces of plain looking-glass, cut from one and the same rectangular strip; these are fastened so as to meet in the middle of a narrow slit, about an inch long, and an eighth of an inch broad, which is covered with a slip of fine tissue or oiled paper, and a blackened card prevents the reflected images from mingling. If we would compare two lights, they must be placed at such a distance from each other, and from the instrument between them, that the light from every part of each shall fall on the reflector next it, and be reflected to the corresponding portion of the paper. The instrument is then to be moved nearer to the one or the other, till the paper on either side of the division appears equally illuminated. When the lights are thus exactly equalised, it is clear that the total illuminating powers of the luminaries are directly as the squares of their distances from the middle of the instrument.

Wheatstone's photometer is a small sphere with a reflecting surface, which being placed between the two lights, each light is seen on it by the spectator, the two being reflected from different points of the sphere's surface. By an ingenious but simple

mechanical contrivance, a rapid motion is communicated to the ball, and by the principle of the persistence of impressions, the spectator immediately sees two curved curves of different brightness. The lighter spot is removed until these curves seem of the same brightness, and the intensities of the luminous points are then as the squares of the distances.

Hansen's photometer consists of a sheet of cream-colored letter paper, rendered transparent over a portion of the surface by a mixture of spermaceti and refined naphtha, which is solid at room temperatures, but becomes liquid on the application of a very gentle heat. The mixture is liquefied and painted over the paper with a brush, leaving a round spot of the size of half a crown in the centre uncovered. When a light is placed on one side of the paper a dark spot is observed on the uncovered portion. When another light is placed on the other side of the paper, the spot is still distinctly visible, if the distance of the light is such that the reflected portion from the paper be either of greater or of less intensity than that transmitted. When the paper is so situated between the two flames that the transmitted and reflected light are of the same intensity, the uncovered spot is no longer visible.

It will be evident from these descriptions that it is possible only, by any of these contrivances, to compare one light with another; there is not any arrangement by which we are enabled to express absolutely the illuminating power. Upon the principle of comparison, and comparatively, the following tables have been constructed by the relative experimental results. The observations of Pictet have been already given. The following comparative view of wax and stearine candles manufactured in Berlin, which have been deduced from the observations of Scherlath, is of much value.

Kind of candle, and whence obtained.	Height of flame to centre of light	Consumption in one hour, in grammes	Illuminating power
Common wax candles, of Taubhanser - - -	4's	103.5	83.20
	6's	91.0	83.20
	8's	100.0	100.00
Wax candles, of Walker - -	4's	133.7	92.66
	6's	140.3	97.69
	8's	113.1	104.1
Stearine candles, of Motard -	4's	117.4	81.74
	6's	111.8	76.23
	8's	121.0	100.7
Stearine candles, of Magniet and Oelmichen - -	4's	120.5	86.11
	6's	122.7	92.66
	8's	123.0	96.54
Stearine candles from the same makers - - -	4's	118.1	85.86
	6's	145.0	100.0
	8's	124.5	92.67
Candles made from palm oil -	4's	115.3	82.56
	6's	115.3	82.56
	8's	167.3	113.70

These results show us that the mean illuminating power of wax and stearine candles is nearly the same.

The illuminating power of gases and of gas burners will be found in the article COAL GAS.

IMPERMEABLE, is the epithet given to any kind of textile fabric, rendered water-proof by one or other of the following substances;—

1. Linseed oil to which a drying quality has been communicated by boiling with litharge or sugar of lead, &c.

2. The same oil holding in solution a little caoutchouc.

3. A varnish made by dissolving caoutchouc in rectified petroleum or naphtha, applied between two surfaces of cloth, as described under Macintosh's patent. See CAOUTCHOUC.

4. Vegetable or mineral pitch, applied hot with a brush, as in making tarpauling for covering goods in ships.

5. A solution of soap worked into cloth, and decomposed in it by the action of a solution of alum; whence results a mixture of acid, fats, and alumina, which imbricate itself among all the woolly filaments, fills their interstices, and prevents the passage of water.

6. A solution of glue or isinglass, introduced into a stuff, and then acted upon by a clear infusion of galls, whereby the fibres get impregnated with an insoluble, impermeable, pulverulent leather.

7. Plaster work of plaster of Paris, made by mixing artificial or natural asphaltum with it.

INCUBATION, ARTIFICIAL. The Egyptians have from time immemorial been accustomed to hatch eggs by artificial warmth, which the art of heat is peculiarly adapted to. M. de Réaumur published in France, about a century and a half ago, an observation upon this subject, but M. Bonnemais was the first person who studied with determination all the circumstances of artificial incubation, and illustrated the process completely upon the large ostrich eggs. In the year 1777 he communicated to the Academy of Sciences an interesting treatise, which he had noticed, and the method employed by birds to keep their eggs warm, and he immediately prior to the French revolution he furnished the Parisian market with excellent poultry at a period of the year when the farmers had ceased to supply it. His establishment was ruined at that disastrous era, and to which has ever since been consigned or consigned with similar care. His apparatus for warming eggs is based upon the fact that it was founded upon the principle of the circulation of hot water, by the constant motions of its particles, in a returning series of convoluted pipes, a subject afterwards illustrated in the experimental researches of Count Rumford. It has of late years been introduced as a novelty into this country, and applied to warm the apartments of many public and private buildings. The following details will prove that the theory and practice of hot water circulation were as perfectly understood by M. Bonnemais a fifty years ago, as they are at the present day. They were then publicly exhibited at his residence in Paris, and were afterwards communicated to the world at large in the interesting article of the *Encyclopédie Technologique*, intitled *Incubation artificielle*, under the head of *Régulateur de Température*.

The apparatus of M. Bonnemais consisted 1. of a boiler and pipes for the circulation of water; 2. of a regulator calculated to maintain an equal temperature; 3. of a stove-apartment, heated constantly to the degree best fitted for incubation, which he called the *hatching pit*. He attached to one side a passage for or chick-room, for exchanging the chickens during a few days after hatching.

The boiler is represented in vertical section and ground plan, in figs. 987 and 988. It is composed of a double cylinder of copper or cast iron, *b*, having a grate *b* (see plan), an ascent at *d* (see plan). The water occupies the shaded space *c, c, h, g, g, e, e*, are five vertical flues for conducting the burnt air and smoke, which first rise in the two exterior flues *e, e*, then descend in the two interior flues *g, g*, and finally re-mount through the pipes *e, e*, in the central flue *h*. During this upwards and downwards circulation, as shown by the arrows in the section, the products of combustion are made to impart nearly the whole of their heat to the water by which they are surrounded. At the commencement, some burning paper or wood shavings are inserted at the orifice *m*, to establish a draught in this circulation chimney. The air is admitted into the ashpit at the side, in regulated quantities, through a small square door, movable round a rod which runs horizontally along its middle line. This swing valve is acted upon by an expanding bar (see **HEAT REGULATOR**), which opens it more or less, according to the temperature of the stove apartment in which the eggs are placed.

u is the upper orifice of the boiler, by which the hotter and consequently lighter particles of the water continually ascend, and are replaced by the cooled particles, which enter the boiler near its base, as shown in fig. 989 at *a*. If to farther details relative to the boiler it is needless to enter; for though its form, as designed by M. Bonnemais, is excellent and most economical of heat for a charcoal fire, it would not suit now of petroleum, on account of the obstruction to the pipes which would soon be caused by its soot.

In fig. 989 the boiler is shown at *a*, with the *r* which regulates the air dose of the ashpit. *n* is a stopcock for modifying the opening by which the hotter particles of water ascend; *o* is the water pipe of communication, having the heating pipe of distribution attached between *e, e*, which thence passes backwards and forwards with a very slight slope from the horizontal direction, till it reaches the passage *q, q, r, q*. It traverses this apartment, and returns by *a, a* to the orifice of the boiler *u*, where it turns vertically downwards, and descends to nearly the bottom of the boiler, discharging at that point the cooled and therefore denser particles of water to replace those which continually issue upwards at *u*. *z, z* is a tube surmounted with a funnel for keeping the range of pipes always full of water; and *x* is a siphon orifice for permitting the escape of the disengaged air, which would otherwise be apt to occupy partially the pipes and obstruct the aqueous circulation.

The faster the water gets mixed in the serpent's tube, the better the circulation will be, because it diffuses the heat between the water at the top and bottom of

the water, which also prevents its motion, will be greater. *W* represents a small reservoir of water, to supply the required moisture to the heated air, and *T* is the tube arranged along the trays *M N*, in an atmosphere analogous to that under the body of the hen.

When we wish to hatch eggs with this apparatus, the fire is to be kept up in the boiler, and as soon as the temperature has risen to about 100° F., the eggs are introduced, but only one-twentieth of the whole number intended, upon the first day; next day a like number is laid upon the trays, and thus in succession for twenty days, so that upon the twenty-first day the eggs first placed may be hatched for the most part, and we may obtain daily afterwards an equal number of chicks. In this way regularity of care is established in the rearing of them.

During the first days of incubation, natural as well as artificial, a small portion of the water contained in the egg evaporates by the heat, through the shell, and is replaced by a like quantity of air, which is afterwards useful for the respiration of the animal. If the warm atmosphere surrounding the eggs were very dry, such a portion of the aqueous part of the eggs would evaporate through the pores of the shells as would endanger the future life of the chick in *ovo*. The transpiration from the body of the hen, as she sits upon her eggs, counters to this destination in general; yet in very dry weather many hatching eggs fail from that cause, unless they be placed in moist downy posing straw. The water sources *M N* are therefore essential to success in artificial incubation.

After the chicks are hatched they are transferred into the nursery, *O Q*, on the front of which there is a small grated trough filled with millet seed. Small divisions are made between the levels of successive days, to enable the superintendent to vary their feeding to their age.

In order to supply an establishment of the common kind, where 100 eggs are to be hatched daily, a dozen of hens would be needed, and 150 eggs must be placed under them, as only two-thirds in general succeed. At this rate, 4500 mothers would be required to sit. Now supposing we should collect ten times as many hens, or 45,000, we should not be able to command the above number of chickens, as there is seldom a tenth part of hens in a breeding state. Besides, there would be in this case no fewer than 750 hens every day coming out with a fresh brood of chickens, which would require a regiment of superintendents.

Artificial Incubation by means of Hot Mineral Waters. — This curious process is described very briefly in a letter by M. D'Arceet. The following are extracts from his letter: —

"In June, 1823, I obtained chickens and pigeons at Vichy, by artificial incubation, effected through the means of the thermal waters of that place. In 1827 I went to the baths of Chaudes-Aigues, principally for the purpose of doing the same thing there. Finding the proprietor a sensible man, I succeeded in making a useful application of this source of heat to the production of poultry.

"The advantage of this process may be comprehended, when it is known that the invalids who arrive at Vichy, for instance in the month of May, find chickens only the size of quails; whereas, by this means, they may be readily supplied six months old.

"The good which may be done by establishing artificial incubation in places where hot springs exist, is considerable; it may be introduced into these establishments without at all interfering with the medical treatment of patients, since the hatching would go on in winter, at a time when the baths for other purposes are out of use.

[illegible]

The article known as "The Middle Ages must have been very dark to the eyes of the present day," by the Abbé Marco Polo had described the substance as "a white substance which I found in the place, it was for a long time regarded as a mineral, and was first obtained in 1753 by the process of igniting the pyrites of Hainault." It was classed among minerals, a class of which we were not at all acquainted.

[illegible]

annually to take root, and to supply indigo, and this was continued down to a very recent period, though it was well known that it was not indigenous to the East. In France, the use of indigo was forbidden in 1792, by consequence of an express representation from the states of the province of Languedoc, and this prohibition was afterwards removed several times. But in the well known edict of 1790, in which Custom was separated from the common laws, it was stated that indigo could be used without limit, and in 1797, doors were left at liberty to use indigo alone or to combine it with a mixture of indigo and wool. In England the use of foreign wool is forbidden, and by an act passed by the House of Commons, our doors were not allowed to burn with a single thread of indigo in every dyehouse where they could be found. This act remained in force for nearly a century.

It has been doubted whether the plant which is employed in America for the manufacture of indigo is a native of that country, or whether it was introduced by the Spaniards. It was remarked by the first voyagers on the new continent that the natives coloured their bodies and dyed their stuffs by means of indigenous plants which resembled the indigo plant of Asia. Francisco Fernandez, in the life of the father, says, that this plant grew in a wild state in the West India islands, and that it was cultivated for the purpose of supplying them with a blue pigment. He mentions that it was the same species of Mexico, and says, that the Americans were busy drying their hair black. He also, that they made from it a pigment, which they mixed with water and sugar, the same as the red colour of the Indians, and he describes also the method of preparing it. Nevertheless it appears that the Indians of Mexico and Andes really introduced indigo into America by the Spaniards, and were the plants employed by them for the manufacture of indigo in Mexico, Guatemala, and elsewhere, though some of the varieties produced by the influence of the climate and soil are very widely distinguished from the parent stock. The manufacture of indigo was at one time carried on extensively in Central America, and the West India Islands, and these countries formerly supplied the chief portion of the article consumed in Europe. The lodges of Guatemala at the same time exported all others a quarter. It consequently is, however, of the political distribution in America and the great inconveniences which have been effected in the manufacture of indigo by the sale and preservation of the countrymen in the East, its production in America has diminished very much, and at the present day, the indigo consumed in Europe is derived chiefly from India, and more especially from Bengal, Oude, and Madras. The remainder is imported from Java, Malacca, the Mauritius, and Senegal in the eastern hemisphere, and from Caraccas, Brazil, and Guatemala in the western. The East India and Brazilian indigo comes packed in chests, the Guatemala in ox hides, called *semas*. Its quality depends upon the species of the plant, its ripeness, the soil and climate of its growth, and the mode of manufacture.

The plants which are cultivated in the East India, are the *Indigofera tinctoria*, *And. disperma* and *pseudo-tinctoria*. The districts of Kishenagar, Jessore, and Murrabadabad, in Bengal, ranging from 85° to 90° east lat. and 22½ to 24° north long., produce the finest indigo. That from the districts about Hardwan and Roosree is of a coarser or harsher grain. Tyroet, in lat. 26°, yields a tolerably good article. The portion of Bengal most propitious to the cultivation of indigo, lies between the river Hooghly and the main stream of the Ganges. The ground having been ploughed in October, November, or beginning of December, the seed of the indigo plant is sown in the last half of March or beginning of April, while the soil being neither too hot nor too dry, is most propitious to its germination. A light unclouded sky, and a sunshine, with occasional light showers, are most favourable to its growth. From twenty-four to thirty pounds of seeds are required for sowing an acre of land. The plants grow rapidly, and will bear to be cut for the first time at the beginning of July, nay, in some districts, so early as the middle of June. The indications of maturity are the bursting forth of the flower buds, and the expansion of the blossoms, at which period the plant contains most colouring matter. Another indication is taken from the leaves; which, if they break across, when pressed flat, denote a state of maturity. But this character is somewhat fallacious, and depends upon the fertility or richness of the soil. When much rain falls, the plants grow too rapidly, and do not sufficiently elaborate the blue pigment. Bright sunshine is not advantageous to its production. The first cropping of the plants is best; after two months a second is made, but at the present day, planters never undertake a third or fourth.

Two methods are pursued to extract the indigo from the plant; the first effected by fermentation of the fresh leaves and stems; the second, by maceration of the dried leaves.

1. *From the recent leaves.*—In the indigo factories of Bengal, there are two large stone-built cisterns, the bottom of the first being nearly upon a level with the top of the second, in order to allow the liquid contents to be run out of the one into the other.

The upper vat is called the fermenting vat, or the steeping vat; its area is 20 feet square, and its depth 3 feet; the lower vat, called the beating vat, is as broad as the upper, but one third longer. The corners of the floor, as they come from the field, are stratified in the steeping vat, and are tied to within 3 or 4 inches from the beam. In order that the plants, during the fermentation, may not swell and rise out of the vat, beams of wood and two sets of iron hoops are laid closely over the surface of the plants, after which water is pumped upon them until it stands about 3 or 4 inches from the edge of the vessel. An active fermentation speedily commences, which is, compared with in 14 or 15 hours, a very long or shorter, according to the temperature of the air, the prevailing winds, the quality of the water, and the ripeness of the plants. Nine or ten days after the immersion of the plants, the condition of the vat must be examined; frothy bubbles are then seen rising like little pyramids, at first of a white colour, but becoming every day shablier, and then deep purplish-red. The fermentation is at this time violent, the fluid being in constant commotion, and apparently boiling; innumerable bubbles mount to the surface, and a dense copper-coloured crust covers the whole. As long as the liquor is agitated, the fermentation must not be disturbed; but when it becomes more tranquil, the liquor is to be drawn off into the lower vat. If it of the nature of the liquor is not to push the fermentation farther, because the quality of the whole indigo is thereby deteriorated; but rather to cut it short, in which case there is, indeed, a loss of weight, but the article is better. The liquor presents now a greenish yellow colour, which, when the indigo precipitates changes to green. The average temperature of the liquor is commonly 65° Fahr.; its specific gravity at the surface is 1.015; and at the bottom 1.022.

As soon as the liquor has been run into the lower vat, ten men are set to work to beat it with bars or shovels 4 feet long, called *beata*. Paddles which have also been employed for the same purpose. Meanwhile two other labourers clear away the compressed leaves and husks from the surface of the upper vat, remove the exhausted plant, set it to dry for fuel, clean out the vessel, and stratify fresh plants in it. The fermented plant appears still green, but it has lost three fourths of its bulk in the process, or from 12 to 14 per cent. of its weight, chiefly water and extractive matter.

The liquor in the lower vat must be strongly beaten for an hour and a half, when the indigo begins to agglomerate in flocks, and to precipitate. This is the moment for stopping; whether any error has been committed in the fermentation; which must be corrected by the operation of beating. If the fermentation has been arrested too soon, much froth rises in the beating, which must be allayed with a little oil, and then a rich foam appears. If large round granulations are formed, the beating is continued, in order to break if they will grow smaller. If they become as small as fine sand, and if the water clears up, the beating is allowed quietly to subside. Should the vat have been over fermented, a thick fat looking crust covers the liquor, which does not disappear by the introduction of a flask of oil. In such a case the beating must be repeated, and when the granulations become round, and begin to subside, and the liquor clears up, the beating must be discontinued. When the fermentation has been excessive, the froth or crust dissolves itself spontaneously into separate minute particles, that move about the surface of the liquor. On the other hand, a rightly fermented vat is easy to work; the froth, though abundant, vanishing whenever the granulations make their appearance. The colour of the liquor, when drawn out of the steeping into the beating, is brassy green; but as soon as the agglomeration of the indigo commences, it assumes the colour of Madeira wine; and speedily afterwards, in the course of beating, a small round grain is formed, which falls down and leaves the water transparent, when all the turbidity and froth vanish.

The object of the beating is threefold; first, it tends to decompose a great quantity of carbonaceous matter in the fermented liquor; secondly, to give the newly developed indigo the requisite dose of oxygen by the most extensive exposure of its particles to the atmosphere; thirdly, to agglomerate the indigo in distinct flocks or granulations. In order to hasten the precipitation, lime water is occasionally added to the fermented liquor in the progress of beating; but those who manufacture the superior quality of indigo avoid the use of lime, as it has a tendency to make the indigo hard and red. In the end of the beating vessel a beam is fixed upright, in which three or more holes are perforated a few inches in diameter. These are closed with plugs during the beating, but two or three hours afterwards, as the indigo subsides, the upper plug is withdrawn to run off the supernatant liquor, and then the lower plugs in succession.

The state of this liquor affords, on being examined, an indication of the success of both the processes. When the whole liquor has run off, a labourer enters the vat, sweeps all the precipitate into one corner, and empties the thinner part into a spout which leads into a cistern, 20 feet long, 3 feet wide and 3 feet deep. When all this liquor is once collected, it is pumped through a bag

manufactured indigo from the *Veronica tectoria* or *Veronica*. (Vide Transactions of the Society of Arts, vol. xxviii.) This plant, which grows the size of a small tree, is found in the lower regions of the mountainous tract of Rajahmundry, and also on hills in the neighbourhood of Madras and Pondicherry, and grows in a sterile as well as rich soil. The leaves begin to appear in March and April, and at the end of April have attained their full size, when they are ready for gathering. At the end of August they begin to become a yellow rusty colour and soon fall off. The leaves yield no colour, and the plant is several years old, but the best leaves for making indigo are those of the first year's plants. They improve when kept for a day or two, and when they begin to wither, they yield but a small portion of very bad colour, and when quite dry only a dirty brown foam. In this they differ from the leaves of the common Indigo plant, which may be dried before extraction without loss of colour. They also differ from the latter in not yielding their colour in cold water. With cold water only a hard, black, stony substance is obtained, not blue indigo. It is therefore necessary to employ hot water, which extracts the colour very readily. The leaves having been collected, are on the following day thrown into copper scalding vessels, which are then filled with cold water to within 2 or 3 inches of the top. Hard water is only a large quantity of carbonate of lime is better adapted for the purpose than rain water. The fire is then lighted and maintained rather briskly until the liquor acquires a deep brown colour. The leaves then begin to assume a yellowish colour, the heat of the liquor being about 150 to 160° Fahr. The fire is then removed and the liquor run off into the boiling vat. Here it is agitated from 1 to 30 minutes. It is then mixed with about 1/4 to 1/2 part of lime water, which produces a sandy granulation. After the sand has settled the supernatant liquor is of a clear Madeira wine colour. The quantity of colour obtained, amounts to 1 lb. from 250 lbs. of green leaves; but it varies according to the season and the state of the weather. In August and September, the produce is only one half or two-thirds of what it is in May and June, and even that is diminished if the weather is wet, or the leaves are treated immediately after being gathered. The scalding requires about three hours, and the agitation and precipitation the same time. The indigo is improved by treating it with a little sulphuric acid. The only fault it has is, that it breaks into small pieces, unless it has been dried slowly in the shade produced from the sun.

In the southern provinces of China a species of *Indigofera* is extensively cultivated for the sake of the dye which it affords. In the northern provinces two other plants are employed by the inhabitants for the same purpose. Mr. Forster, the well-known Chinese traveler, to whom we owe the description of these plants and of the process of manufacturing indigo from them, states that one of them is grown in the neighbourhood of Shu-chiao, and he has given it the name of *Indigo sinensis*. The other, which is a species of *Jussiaea*, is largely cultivated in the hilly country near Ningpo, or rather in the valleys among the hills. It seems to be easily cultivated; it grows most luxuriantly, and is no doubt very productive. Having evidently been introduced from a more southern latitude, it is not hardy in the province of Chekiang any more than cotton is about Shu-chiao; but nevertheless it succeeds admirably as a summer crop. It is planted at the end of April or beginning of May, after the spring frosts are over, and it is cleared from the ground in October. During the period it attains a height of a foot or a foot and a half, becomes very bushy, and is densely covered with large green leaves. It is cut before any flowers are formed. The plants are grown, not from seed but from cuttings. These cuttings consist simply of a portion of the stems of the previous year, which after being stripped of their leaves are tied into bundles, each containing upwards of 1000, and kept during the winter in a dry shed or outhouse, where after being firmly packed together they are banked round with dry loam, and covered with straw or litter to keep them from the frost. During the winter months the cuttings remain green and plump, and although no leaves are produced a few roots are generally found to be formed or in the act of forming when the winter has passed and the time for planting has become round. In this state they are taken to the fields and planted. The weather during the planting season is generally showery, as this happens about the change of the monsoon when the air is charged with moisture. A few days of this warm showery weather is sufficient to establish the new crop, which now goes on growing with luxuriance and requires little attention during the summer, indeed not except keeping the land free from weeds. In the country where this dye is manufactured there are numerous pits or tanks on the edges of the fields. They are usually circular in form and have a diameter of about 11 feet and a depth of 2 feet. About 400 pieces* of stems and leaves are thrown into a tank of this size, which is

* A Chinese catty is equal to 1 lb.

then cut to the stem with clear water. It has kept the plant in perfectly sound condition, and the water has become very turbid from the matter. At the present stage of the process the leaves are removed from the stalk with a small hand-made knife or scissor. When every portion has been removed, the water is employed to give the water a regular and rapid motion with the hands, the motion which is continued for some time. Then the part of the uppermost water is removed by hand to make a series of thin white water, which water has been taken out of the tank for the purpose. This is the white water, and the rest of the water is kept up for a few minutes longer. When the time of day has been reached in this way the water is allowed to come. Four or five more times the same process is repeated, leaving the water with hands, rather than for the purpose. The best of the water is a very strong yellow, while the rest is a pale yellow, coming from a greenish to a dirty yellow, while the first because of a small amount of the. During the process the head workman takes a portion of the liquid out of the tank and being a rapid with his hand. Later the operation is continued until it is done and its value is judged of by the hue it presents. The best of the water is kept for about half an hour. At the end of this time the whole of the surface of the liquid is covered with a thick coating of froth of the most brilliant yellow, in which the particles of indigo, especially near the surface. At this stage, it being desirable to separate the froth with the liquid below it, it is only necessary to throw a small quantity of cabbage or onion on the surface of the froth. The workman then stir and beat it gently with the flat brooms for a second or two, and the whole is nearly done. The liquid, which is now darker in colour, is allowed to remain for some hours, until the stirring matter has sunk to the lower stratum, when a second third of the liquid is drawn off and thrown away. The remaining third part is drawn into a small square tank on a lower level, which is covered over with straw, and here it remains for three or four days. By this time the remaining matter has separated. It is from the water, which is now nearly clear, and at the bottom of the tank or four in less of the bottom in the form of a thick paste, and of a beautiful blue colour. In this state it is packed in barrels and exported to the market for sale.

This part of China. Like the Shan-hai idon, made from *Indigo indigo*, it is called "T'ien ching" by the Chinese — *Geological and Agricultural Gazette*, April 18th, 1881.

The cultivation of indigo in Central America, has fallen off very much of late years. Nicaragua formerly exported annually about 200,000 lbs. of it in the bulk. At present the export probably does not exceed 100,000 or 200,000 bales. Under the government of Spain, the state of San Salvador produced from 1,000 to 10,000 bales annually. A piece of ground equal to two acres generally produces from 100 to 150 lbs. at a cost of not far from 30 to 40 dollars.

There is an indigenous biennial plant abounding in many parts of central America, which produces indigo of a very superior quality, but gives less than half the weight which is afforded by the cultivated species. The *Indigofera disperma* is the species employed in cultivation. It attains its highest perfection in the richest soils. It will grow, however, upon almost any soil, and is very little affected by drought or by superabundant rains. In planting it, the ground is perfectly cleared, usually burnt over, and divided with an implement resembling a hoe into little trenches, 2 or 3 inches in depth, and 10 or 14 apart, at the bottom of which the seeds are sown by hand, and lightly covered with earth. A bushel of seed answers for 4 or 5 acres of land. In Nicaragua it is usually planted towards the close of the dry season in April or May, and attains its perfection for the purpose of manufacture in from two and a half to three months. During this time it requires to be carefully weeded, to prevent any mixture of herbs, which would injure the quality of the indigo. When it becomes covered with a kind of greenish farina, it is in a fit state to be cut. This is done with knives at a little distance above the root, so as to leave some of the branches, called in the West Indies "ratons," for a second growth, which is also in readiness to be cut, in from six to eight weeks after. The crop of the first year is usually small, that of the second is esteemed the best, although that of the third is hardly inferior. It is said that some fields have been gathered for ten consecutive years without being re-sown, the fallen seed obviating the necessity of new plantings.

After the plant is cut, it is bound in little bundles, carried to the vat, and placed in layers in the upper or larger one called the *super* (*madura*). This vat holds from 1000 to 10,000 gallons, according to the requirements of the estate. Boards loaded with weights are then placed upon the plants, and enough water let on to cover the whole, which is now left to steep or ferment. The rapidity of this process depends much upon the state of the weather and the condition of the plant. Sometimes it is accomplished in 6 or 8 hours, but generally requires from 12 to 24. The proper length

of time is determined by the colour of the liquid water; but the great secret is to check the fermentation at the proper point, for upon this, in a great degree, depends the quality of the product. Without describing the plant, the water is now drawn off by evaporation in the lower vat or "water vat," where it is strongly and incessantly beaten in the smaller vats with paddles by hand, in the larger by wheels turned by horse or water power. This is continued until it changes from the green colour, which it at first displays, to a blue, and next the colouring matter, or "blue," shows a disposition to separate. This is sometimes hastened by the infusion of certain herbs. It is then allowed to settle, and the water is carefully drawn off. The pale granules, at which time it resembles a fine soft clay; after which it is put into small tubs, and then spread on cloths in the sun to dry. When properly dried, it is carefully sorted according to its quality, and packed in hide cases, 150 lbs. each, called *arrats*. The quality has not less than 9 gradations, the best being of the highest price. From 6 to 8 are called *flaves*, and are the best, from 3 to 6 from 1 to 3, the next, *brunes*. The two poorer qualities do not pay expenses. A measure of 100 yards square produces on an average about one ceroon at each cutting. After the plant has passed through the vat, it is required by law that it shall be dried and burnt, because in decomposition it generates by the million an annoying insect called the "indigo fly."

The following account of the manufacture of indigo on the Senegal is taken from Perottet's "Atte de l'Indigo."

The land destined to the cultivation of the plant ought to be perfectly level and free from undulations, so as to prevent the seed from being washed into the hollows or lower parts by the heavy rains so frequent in the tropics. Soils of a greyish colour abounding in clay are not adapted for the purpose, as they are too compact and cold. Sandy soil of a whitish colour must also be avoided. Light soils, abounding in humus or vegetable remains, and having a colour between grey and dark brown, are to be preferred to all others. The soil should at all events, not be one of retentive moisture. The quantity of indigo obtained from the same quantity of plant may vary, according to the soil, from 4 lbs. to 10 lbs. The soil which varies in a corresponding degree. The extent of ground which is required for the production of indigo in a large scale is great, as the refuse of the plant, after the extraction of the seed, is a manure which is found to be attended with very beneficial results. The ground, if new, must be turned up by means of a plough or hoe, to the depth of at least 10 or 12 inches, three times successively at intervals of 3 weeks before the sowing takes place. The sowing must only be undertaken in fine weather, never during heavy rain. The seed employed should be perfectly ripe, and of a year, not more than one year old. It is to be left in the seed-vats to which it is retained until the time when it is wanted. The latter are then put into a wooden mortar and reduced to fragments, and the seed is separated by winnowing from the dust, debris, &c. with which it is mixed. The sowing is to be effected broad cast and as evenly as possible. It should take place, if possible, just before the approach of rain, which the use of a harrow is not required, as the rain generally has the effect of completely leveling the ground and covering up the seed with soil. The *Indigofera tinctoria*, and its varieties *macrocarpa* and *emarginata*, being a plant with a much branched system, it is not necessary, in sowing it, to take more than from 6 to 7½ klogs of seed to 1 arpent of ground; but the *Indigofera arida*, being more sparingly branched, and therefore taking up less room, requires to be more thickly sown. At about ten or twelve days after sowing, when the young indigo has attained a height of about 81 to 100 million trees, the ground must be carefully weeded, and this operation must be repeated as soon as the weeds have again made their appearance and commenced to interfere with the growth of the crop. When the season is favourable three months are generally sufficient to enable the plants to attain the degree of development necessary for the production of indigo. At the period when inflorescence commences the plant is far richer in colouring matter than at any other. As soon, therefore, as there are any indications of flowering, and when the lower leaves, in the axils of which the flowers appear, begin to acquire a yellowish tint, and when pressed in the hand produce a slight crackling noise, no time must be lost in cutting down the plant. This is effected by means of good knives or sickles, and as near the ground as possible. The stems, after being cut, are tied together into bundles of leaves and carried to the manufactory. Since the colouring principle of the indigo is extremely susceptible of change by the action of destructive agencies, it is necessary to use the utmost dispatch in gathering the crop, and to have the manufactory of such a size in proportion to the plantation, that no time may be lost in working up the material as soon as gathered. The plants must on no account be cut when they are moistened either with rain or dew, because in this case they acquire a blackish

what remains in the liquor is a little of the indigo pressed into a drying press and mixed with an equal volume of clean water. If there is found found the fire inferior to the first, it is of a lower quality, and is not used for the same purpose, but if in the contrary the liquor appears of a brown colour, and if it is allowed to stand a few drops of clean water with the filter the liquor will be found to be in grains, the process must be arrested. The liquor must be kept from an hour and a half to two hours. The indigo must be well mixed with about 1/4th of its volume of clean water, and a small amount of the liquor has been settled. Its appearance is very the liquor which is placed at different depths in the case of the vessel, the clear liquor is then run off in separate portions and permitted to run away, where being taken into one of the vessels is allowed to be carried away with the water, by means of a running channel, but the bottom of the last vat the liquor must be well watered to the bottom, and being thrown in a canal is received in a small vessel or flask. The filter runs in a round or square covered vessel, the top of which is on a level with the surface of the ground, and which is placed in the open air. When the liquid has run through the filter, the liquor which remains behind in a state of pure is mixed up again with water, and the mixture is poured in a canal, and allowed to run in a moderate stream. The refuse matter, consisting of leaves of the plant, the roots, and the stems, while the liquor is being run through the filter, is thrown away, and is well watered to the bottom. Underneath the filter is a wooden lid, consisting of two pieces which are fastened together at the sides and meet in the middle. At the bottom of the filter, the mixture of water and liquor is introduced into the filter, the latter must always be kept full of hot water, the mixture being sufficient almost to fill it entirely. The liquor is now run gradually to the bottom point, and the process is continued for about two hours. In order to prevent the liquor from adhering to the bottom and sides of the boiler, the liquor must be kept constantly stirred with a wooden rake. The object of the boiling is to drive away all the carbonaceous matter which is still present in the liquor, to remove the soluble extraneous matters which would render the indigo dull and inferior, to prevent the fermentation or putrefaction of the indigo which would otherwise take place, and lastly, to facilitate the subsequent process of filtering and pressing. The fire having been removed, the liquor is allowed to stand for some time, and as soon as the indigo has settled, the liquor is run off by means of a tap fixed in one of the sides of the boiler. The fire at top is then opened, and the indigo is run off with the water and received in a filter, consisting of blue Guinea cloth stretched on a frame. The first portions of liquid which run through are usually coloured with indigo, and must therefore be caught in a separate vessel and poured on the filter again. As soon as the liquor has percolated through the indigo, which is now a compact paste, is removed from the filter by means of a wooden ladle and put into a press, which consists of a wooden box, the press is well watered. The press having been filled with cloth, the indigo is put in, the press is fastened round it as evenly as possible, a wooden lid is dropped on the cloth, and the press is mounted to pressure by means of a screw, and the liquor is run through at the bottom, which takes place as soon as the indigo has been reduced to about a third of its original volume. The press is then opened, the indigo is taken out of the cloth, laid on a table and divided by means of a knife into pieces of a cubical shape. These cubes are then taken to the drying shed, where they are placed on trellises covered with matting or very thin cloth, so as to admit of the free passage of air. Care must be taken not to dry them too rapidly, otherwise the cakes would crack and split into fragments, which are then of little commercial value, and it is therefore necessary to protect them from currents of dry air by covering them with canvas or Guinea cloth. During the drying process, which occupies from 8 to 10 days, the cakes should be turned several times. They are then evenly packed in boxes, each box holding about 25 kilogrammes. The boxes should be lined with paper.

It may be remarked, that when the indigo is of good quality, the volume of the paste diminishes very little when subjected to pressure. If the process of filtering takes up much time and the pressing is attended with difficulty, it may be asserted that the indigo will turn out of bad quality. This may proceed from the plant having been overgrown, or from the maceration or the boiling process having been continued too long, or from the employment of too large a quantity of hot water. The difficulty experienced in pressing the indigo paste, and which is often so great as to cause the cloth in which it is enveloped to break, is caused by the presence of a mucilaginous or viscid substance mixed with the indigo, which may be removed by treating the paste again with boiling water, and repeating the operations of filtering and pressing.

In regard to the state in which indigo exists in the plants from which it is derived, and the nature of the process by which it is obtained, various opinions have been

with the oxygen element by the vegetable system. If these plants contained red matter, the juice would, however, turn blue the moment it became exposed to the atmosphere, which is not always the case. The necessity for a long process of fermentation in order to obtain the coloring matter would then not be very apparent, for more than half of the coloring matter would be a product of all that was necessary for the process. The coloring matter, however, is destroyed if the process of fermentation is carried too far, as is the case with the supposition that it is a stable substance, and that it is a decomposed substance, since indigo-blue is a body not easily decomposed except by very powerful agents.

In order to throw some light on this subject, an investigation was undertaken by Schrank and the author, in which indigo-blue exists in the *Indigo tinctoria*, or common indigo plant, the only plant of this kind in Europe that yields any considerable quantity of the coloring matter. Schrank succeeded in obtaining from that plant a solution of very peculiar properties, to which he gave the name of *Indican*. This substance has the appearance of a yellow or light brown transparent syrup. It has a bitter taste. It is very easily soluble in water, alcohol, and ether; its solutions are yellow and have an acid reaction. Its compounds with bases are yellow. When its watery solution is mixed with a strong acid, such as a muriatic or sulphuric acid, no color takes place at first, but on leaving the solution to stand, or on heating it, it becomes blue and precipitates, then turns to a purple color, and at length deposits a quantity of purple indigo-blue, which is quite insoluble in water. These floccs remain for the most part of indigo-blue, but they contain also a red coloring matter and a small amount of a resinous substance. The supernatant liquid contains a peculiar kind of sugar, and on being distilled, yields carbonic, formic, and acetic acids. It thus appears that the plant does not contain indigo-blue ready formed either in the blue or colorless state, that the latter exists in the vegetable juice in a state of combination with sugar, forming a compound of that peculiar class known to chemists as *glycosides*. This compound is readily dissolved by water, and the indigo-blue may then be liberated and precipitated from the solution by means of acids, and probably a long series of agents, but the simultaneous action of oxygen is not necessary during the process of decomposition, which the compound undergoes in yielding indigo-blue. Now if, as is very probable, the various species of indigo plants contain indigo-blue in similar substances, the phenomena which take place during the process of manufacturing indigo may easily be explained. During the steeping process the indigo is dissolved, and in consequence of the fermentation which then takes place in the liquor it is decomposed into indigo-blue and sugar. The former would then be precipitated, but a new ammonia is, according to most authors, evolved at the same time; the indigo-blue is, by the simultaneous action of the alkali and the sugar, or other fermentative matter contained in the liquid, reduced and dissolved, forming a true indigo vat, from which the coloring matter is afterwards precipitated by the combined action of the atmospheric oxygen and the lime, during the heating process. According to Schrank, the distillation may be observed in the decomposition of indican during the first period, indigo-blue is the chief product of decomposition; during this period, the red and brown resinous matters make their appearance with very little indigo-blue. The formation of carbonic, acetic, and formic acids is, according to Schrank, dependent on that of the brown resinous matters. It would appear, therefore, that the copious discharge of carbonic acid, as well as the acid taste, attributed to acetic acid, sometimes observed during the manufacture of indigo, are phenomena which indicate the formation, not of indigo-blue, but of other substances, which may prove very injurious to the quality of the indigo. These substances being soluble in alkali, but insoluble in water, are precipitated, as soon as the liquid loses the alkaline reaction which it possesses at the commencement, and becomes acid. Though indigo-blue is a body of very stable character, not easily decomposed when once formed, except by potent agencies, and the assertion of Perrotet and others, that "nothing is more fugitive and more liable to be acted on by destructive agencies, than the coloring principle of the indigo-plant," will be easily understood when the following facts, mentioned by Schrank, are taken into consideration. If a watery solution of indican, the indigo-producing body, be boiled for some time, it then yields by decomposition, not a trace of indigo-blue, but only indigo red, and if it be boiled with the addition of alkalis, it then gives neither indigo-blue nor indigo-red, but only the brown resinous matters before mentioned. The mere action of alkalis is therefore sufficient to cause the molecules, which would otherwise have gone to form indigo-blue, to arrange themselves in a totally different manner and yield products which bear very little resemblance to it. It is evident, therefore, that one of the chief objects to be kept in view by the manufacturer of indigo, is the proper regulation of the process of fermentation, so as to prevent the formation of the other products, which take the place of indigo-blue, and are formed at its expense.

dried. The plants are either round, or fluted, and square, or of irregular shape. The quality is very unequal. Java produces the flatter, square, or less elongated masses, the quantity approaching that of Brazil. Both these kinds are consumed chiefly on the continent of Europe.

Guatemala indigo is exported from the country in skins or hide wrappers, each containing about 1 lb. of the root. It is said to be made irregular pieces, which are more or less brittle, compact, lighter than water, and of a bright blue colour with an occasional tinge of white. There are three kinds of the Guatemala indigo, viz. 1. *Barva*, which is the best, and superior in quality, that of the finer Brazilian indigoes; 2. *Atlixco*, and 3. *Copala*, which is the lowest in quality, being heavy, difficult to break, and of a dingy red colour. Of the first kind very little now reaches the market. The indigo of Caraca is, generally speaking, inferior to that of Guatemala.

The manufacture of indigo was formerly carried on in St. Domingo, but has for some time been entirely abandoned.

The indigo of commerce, even when not adulterated, is a mixture of different matters. When it is heated in a state of fine powder to 212° F. it loses from 5 to 10 per cent. in weight, the loss consisting of water. When the dry powder is heated in a crucible, a great part of it burns away, and there is left at last a greyish ash, consisting of the carbonates and phosphates of lime and magnesia, silicate of lime, alumina, oxide of iron, clay, and sand. These matters are partly derived from the plant, partly from the lime and the impurities of the water employed in the manufacture. The quantity of impurities retained in ordinary indigo varies very much. In the finer qualities it amounts on an average to about 10 per cent. of the weight, whilst in the inferior qualities, especially of Mexican indigo, it sometimes rises to between 30 and 40 per cent. The organic portion of the indigo, or that which is dissipated when indigo is heated, also consists of several different substances.

By treating indigo with various solvents, Berzelius obtained, besides indigo-blue, the true colouring matter of indigo, three other bodies, viz. *indigo-gluten*, *indigo-brown*, and *indigo-red*, which seem to be contained in various proportions in all kinds of indigo. Indigo-gluten is obtained by treating indigo with dilute sulphuric, muriatic, or acetic acid, and then with boiling water. It is left on evaporation of its solutions as a yellow transparent extract, which is soluble in spirits of wine, and easily soluble in water, more diffusible in cold liquids. Its taste is like that of extract of meat. It yields by dry distillation much ammonia and a fixed oil, and behaves in most respects like vegetable gluten. On treating the indigo, after being freed from the indigo-gluten, with hot strong caustic lye, the indigo-brown is either with a little indigo-blue dissolved, forming a dark brown, almost black solution, from which the indigo-brown after filtration from the portion insoluble in alkali is precipitated by means of acid. After being purified, indigo-brown has the appearance of a dark brown transparent resin, which is almost tasteless and quite neutral. By dry distillation it affords ammonia and capricumatic oil. It is decomposed by nitric acid and chlorine. It combines both with acids and bases. Its compounds with alkalis are dark brown, and easily soluble in water. The compound with baryta is not easily soluble in water, and that with lime is insoluble. By boiling the alkaline compounds with lime in excess the indigo-brown may be separated and rendered insoluble. The green substance obtained by Clavel from indigo seems to have been a compound of indigo-brown with ammonia containing a little indigo-blue, either in a state of combination or mechanically intermingled. Indigo-brown seems to bear a great resemblance in many of its properties to the brown resinous substances obtained by Schunck in the decomposition of indican with acids. From its constant occurrence in all kinds of indigo, it may be inferred that it is not a mere accidental impurity, but stands in some unknown relation to indigo-blue. As long, however, as its origin and composition are unknown, this must remain a mere supposition. After the removal of the indigo-gluten and indigo-brown, the indigo is exhausted with boiling alcohol of specific gravity 0.83. A dark red solution is obtained, which is filtered and distilled, when the indigo-red contained in it is deposited as a blackish brown powder, which is quite insoluble both in water and in alkaline liquids. Indigo-red, according to Berzelius, is amorphous, but by distillation in vacuo yields a white crystalline substance, as well as unchanged indigo-red. Concentrated sulphuric acid dissolves it, forming a dark yellow solution, which deposits nothing on being mixed with water; the diluted solution is rendered colourless by wool, which at the same time acquires a dirty yellowish-brown or red colour. The description given by Berzelius leaves it doubtful whether the indigo-red obtained by him from indigo was a pure unmixed substance. From the leaves of the indigofern, as well as from those of the *Jussiaea bartramia*, a substance may, according to Schunck, be extracted which has received from him the name of *indurbin*, but which seems to be merely indigo-red in a state of purity. This substance has, according to Schunck, the following properties: it crystallizes in small silky needles of a brownish-purple colour, which when rubbed

with a hard body show a bright coppery brown. When carefully heated it gives to strongly reddish, and on a very slow fire it gives a very pure red in the form of long plates, many of which having a slight metallic lustre. It dissolves in concentrated sulphuric acid, forming a solution of a beautiful purple colour, which when diluted with water yields a deep red and then parts a fine purple colour in cooling, brown and black. It is insoluble in water, but dissolves in boiling alcohol with a suspended purple colour. It is insoluble in a strong solution of water exposed to the gradual action of a sun and strong winds, just as the indigo does, forming a solution from which it is again precipitated on exposure to the rays of the atmosphere. This solution does not turn purple. In some of its properties this body bears a striking resemblance to indigo, and the comparison of the two is almost exact.

It has been doubted whether these various solutions or impurities with which indigo is associated produce any effect in the various processes to which it is submitted by Schwarzenberg, to which a prize was awarded by the French Institute in 1810. On the author arriving at this conclusion that neither indigo, nor any of its impurities, nor any of the various processes to which it is submitted, can be prepared with pure indigo blue. Nevertheless differences are observed in dealing with different kinds of indigo, which may be explained on the supposition that water, though being indigo-blue, takes part in the process. In the ordinary blue variety, made with sulphuric acid, any effect which might be produced by indigo, by the indigo-brown is destroyed by the loss of water with it, and the indigo is precipitated. Indigo, however, dissolves, as we would expect, in alcohol with a blue and red colour, and the alcohol imparts a purple colour to it. In the red variety indigo, the presence may be detected by precipitating a portion of the liquor, and treating the precipitate with boiling alcohol, which then usually assumes a red colour. It is possible, therefore, that a small part of the indigo produced is impregnated with indigo-brown, and is indigo-brown.

The portion of the liquor which remains after treatment with spirit alkali, and alcohol, contains essentially indigo-blue, the true coloring matter of indigo, which, however, with such earthy particles, and other impurities. In order to purify it, the residue, which still remains, is to be mixed with lime, the quantity of which must amount to twice the weight of the crude indigo, and which has been previously dried with water. The mixture is then put into a bottle capable of holding about 150 times its volume of water, and the bottle is filled up with boiling water and shaken. A quantity of finely powdered proto-phosphate of iron, amounting to 1/2 of the weight of the lime is then added, the bottle is closed with a stopper, well shaken, and left to stand for several hours in a warm place. The mass gradually becomes green, and the indigo-blue is then converted by the precipitated proto-phosphate into red indigo, which dissolves in the excess of lime, forming a deep yellow solution. This solution when clear is poured off from the deposit into a vessel containing a sufficient quantity of dilute nitric acid to supersaturate the whole of the lime. The red indigo which is precipitated in greyish-white flocks, is agitated with water until it has become blue, and the regenerated indigo-blue is collected on a filter and washed with water, in order to remove the chloride of calcium and excess of nitric acid. The following method of obtaining pure indigo-blue has been recommended by Priestley: 4 oz. of crude indigo and the same weight of grape sugar are put into a bottle capable of holding 12 lbs. of water; a solution of 6 oz. of concentrated caustic soda in 1 lb. of alcohol is then added, after which the bottle is filled with hot spirits of wine of 75 per cent, and the whole is fitted up for use. The liquor becomes at first white, and then yellow, and on being filtered and left exposed to the air, deposits the indigo-blue in small crystal or scales, which are to be filtered off and washed at first with alcohol, and then with water.

Pure indigo-blue has the following properties:—Its colour is dark blue inclining to purple. When rubbed with a hard body it assumes a bright coppery brown. It has neither taste nor smell, possesses neither acid nor basic properties, and belongs, as regards its chemical affinities, to the class of indifferent substances. Its specific gravity is 1.50. When heated in the open air it melts, boils, and burns with a smoky flame, leaving a carbonaceous residuum. But when it is heated in a vessel partially closed, or in vacuo, it begins to evolve at a temperature of about 550° F. a violet coloured vapor, which condenses on the colder parts of the apparatus in the form of long crystalline needles, which are blue by transmitted light, but exhibit by reflection light a beautiful coppery lustre. These needles are insoluble in alcohol. A great portion of the indigo-blue is however decomposed during the heating process. Indigo-blue is insoluble in water, alcohol, and dilute acids. Boiling alcohol and boiling oil of turpentine dissolve a minute quantity of it, and deposit it when on cooling. Fixed oils also dissolve a little of it at a heat exceeding that of boiling water, yielding blue solutions, the colour of which, when the heat is further increased, changes, becoming

to Mr. Cruik, first to crystallise and then to distil. By the action of dilute nitric acid on indigo, a blue crystalline acid is converted into isatin, a body soluble in water and crystallising to red needles. Colourless indigo-purpur, dissolving in water, a substance having properties very similar to those of isatin. Both isatin and colourless indigo-purpur, with different reagents a great number of products of decomposition, some of which have, however, as yet found any application in the arts. By the action of concentrated nitric acid indigo-blue is converted, first into indigo-crystal, a white crystalline acid, and then into nitro-indigo-crystal, which is yellow and crystalline. The latter is sometimes employed for imparting a yellow colour to silk and wool, but it is generally prepared from cheaper materials than indigo-blue. The action of concentrated sulphuric acid on indigo-blue is very remarkable. When the acid is poured on the pure substance and gently heated it becomes in the first instance a green colour, which changes after some time to blue. No gas of any kind is evolved. When however crude indigo is employed, there is a perceptible disengagement of sulphurous acid, resulting from the action of the sulphuric acid on the impurities of the indigo, such as the indigo-gluten, &c. (1) adding water, a solution of a beautiful deep blue colour is obtained. The filtered liquid contains a peculiar acid, to which the names of *indigo-sulphuric*, *sulphur-indigo*, *indigo-sulphuric acid*, or *carbazone-sulphuric acid* have been applied.

This acid is a so-called double acid. It contains indigo-blue and sulphuric acid, but in such a peculiar state of combination, that neither of the two constituents can be detached by ordinary reagents, nor again eliminated as such from the compound. It sometimes with heat, without either of the two constituents separating. The compounds are called *indigo-sulphates*, and are, like the acid, of a dark blue colour. When the solution of indigo-blue in concentrated sulphuric acid is diluted with water, there is usually formed a small quantity of a dark blue flocculent precipitate, which is the phenomenon of Mr. Cruik, or the *indigo-purple of Herapain*. It is a compound of indigo-blue with sulphuric acid, containing less of the latter than indigo-sulphuric acid. It is always formed when the quantity of sulphuric acid employed is not more than eight times that of the indigo-blue, or when the action of the acid on the latter has continued for only a short time. By heating it with an excess of acid it is changed into indigo-sulphuric acid. Though soluble in concentrated sulphuric acid, it is insoluble in the dilute acid, and hence is precipitated on the addition of water. On filtering and washing, however, it begins to dissolve, as soon as the free sulphuric acid has been removed, and may then be completely dissolved by pure water. The solution has a blue colour, just like that of indigo-sulphuric acid. Its compounds with bases have a blue colour with a purplish tinge. The blue acid liquid filtered from the indigo-purple on being supersaturated with carbonate of potash or soda, deposits a dark blue powder, which consists of the indigo-sulphate of potash or soda. These compounds are too little in water containing a large quantity of neutral salts, and are therefore precipitated when the excess of sulphuric acid is neutralised by carbonate of potash or soda. As soon, however, as the sulphate of potash or soda has been removed by washing, the indigo-sulphate may be dissolved in pure water, yielding a dark-blue solution. The indigo-sulphates of the alkalis may also be prepared by steeping wool, previously well cleaned, in the solution in sulphuric acid. The wool takes up the colour, becoming of a dark blue colour, and after having been well washed with water, in order to remove the excess of acid as well as the impurities which are always present in the solution when crude indigo has been employed, is treated with carbonate of potash, soda, or ammonia, which separate the acid from the wool, and produce blue solutions containing the salts of the respective bases. The indigo-sulphates of the earths and metallic oxides, which are mostly insoluble blue powders, may be obtained from the alkaline salts by double decomposition. By an excess of caustic alkali, indigo-sulphuric acid is immediately decomposed, giving a yellow solution, from which it is impossible to obtain the acid again. By means of reducing agents, such as sulphuretted hydrogen, nascent hydrogen, proto-salts of tin and iron, &c., indigo-sulphuric acid is decolorised, but the colour is restored by the oxygen of the atmosphere. Indigo-sulphuric acid, in a free state or in combination with alkalis, is employed in the arts for the purpose of imparting a blue colour to silk and wool. It has very little affinity for cotton fibre, but is nevertheless employed occasionally for bluing white cotton-yarn and other bleached goods.

By treatment with strong boiling caustic potash or soda lye, indigo-blue is gradually decomposed and converted into a colourless crystalline acid, *anthranic acid*. By weak solutions of caustic alkalis, it is not in the least affected. If, however, it be subjected to the combined action of an alkali or alkaline earth and some body having a strong affinity for oxygen, such as protoxide of iron or tin, sulphur, sulphurous or phosphorous acid, or organic matters, such as grape-sugar, &c., it disappears by degrees, yielding a yellow solution, containing in the place of indigo-

to a fine powder, as we laid off, and each of them is treated with about 12 times its weight of concentrated sulphuric acid in a flask or porcelain basin. After being heated at a temperature of 150° to 175° F. for about 4 hours, and occasionally well agitated, the two liquids are mixed with water, so that the volume of the two shall be exactly equal. Two equal measures of a weak solution of hypochlorite of lime are then taken, and to the first is added a quantity of the solution of pure indigo. The colour is developed by the excess of sulphuric acid in the solution destined to the blue colour of the concentrated acid. More of the solution must be added until the liquid becomes a greenish tinge, and the number of measures necessary for the purpose is noted. The same experiment is then made with the solution of crude indigo. The quantity of indigo-blue in the latter is of course in inverse ratio to the number of measures which are requisite in order to take up the weight of the solution which is indicated. If, for example, the same quantity of hypochlorite of lime dissolves 17 measures of the solution of pure indigo, and 24 measures of the solution of crude indigo, then the quantity of indigo-blue is $17 : 24 :: 100 : x$, and $x = 81.4$.

A number of samples of indigo may be tested in this manner at the same time. Care must be taken to prepare a fresh solution of hypochlorite for every series of trials, and this solution undergoes a constant standing, which is quite inappreciable as a standard of comparison. It is necessary also to pay great attention at the moment when the greenish colour indicating an excess of the solution of indigo begins to appear, for it will soon be found that this colour disappears after standing a few minutes, and a fresh quantity of the blue solution must then be added cautiously, until the greenish tinge becomes permanent, even after standing for some time. Modifications of this process have been introduced by various chemists by the use of permanganate of potash, chlorate of potash, or chromate of potash, in the place of hypochlorite of lime; but as the principle in which this process depends is in each case identical and the modulus operandi is almost the same, it will be unnecessary to enter into any minute description of these modifications. The whole method is, however, open to serious objections, and the results which it affords cannot at all be depended on. In the first place, it is difficult to institute a strict comparison between the different shades of colour resulting from the decomposition of the sulphate of indigo in different cases, since the purplish-green tinge observed when an excess of the pure sulphate has been added to the decomposing agent, gives place to a dirty olive or brownish-green, when a solution of crude indigo is employed, in consequence of the impurities contained in the latter. Secondly, it is almost impossible to avoid the formation of a certain quantity of sulphurous acid during the action of concentrated sulphuric acid on crude indigo. This sulphurous acid, during the following operation, becomes oxidized before the blue sulphate is destroyed, and hence the percentage of indigo-blue is apparently raised. In employing this method, it is common to find more than 80 per cent. of indigo-blue in a good sample of indigo, whereas the best qualities seldom contain above 60 per cent., and average qualities between 40 and 50 per cent. This method may show a percentage of 70 indigo-blue, when the method first described indicates between 30 and 60.

3. The third method of estimating the indigo-blue is performed in the following manner. Equal weights of the samples to be tested are treated with equal quantities of concentrated sulphuric acid in the manner above described, and the solutions are then diluted with water and introduced into graduated glass cylinders, water being added to each until they all exhibit exactly the same shade of colour. The richer the sample is in indigo-blue, the greater will be the quantity of water necessary for this purpose, the number of measures of water required in each case indicating the relative amount. The great objection to this method consists in the circumstance, that the different kinds of indigo do not give the same shade of blue when their solutions in sulphuric acid are diluted with water, some exhibiting a pure blue colour, others a blue with a greenish, or purplish tinge. It therefore becomes difficult to institute an exact comparison between them.

Preparation of indigo in dyeing.—As indigo-blue is insoluble in water, and as it can penetrate the fibres of wool, cotton, silk, and flax only when in a state of solution, the dyer must study to bring it into this condition in the most complete and economical manner. This is effected either by exposing it to the concurrent action of alkalis and of bodies which have an affinity for oxygen superior to its own, such as certain metals and metallic oxides, or by mixing it with fermenting matters, or finally, by dissolving it in a strong acid, such as the sulphuric. The first method is that which is employed in the

Copperas or common blue vat.—Before being used the indigo must be broken into small pieces, the size of nuts, moistened with hot water, and then left for a day; after

which it is reduced to a soft paste in a mill. The indigo mill is represented in the next, and next.

It is a four-sided stone wheel, $\frac{3}{4}$ of 11 in. in diameter, 18 inches broad, and 12 inches deep, cylindrical or rounded in the last part, and revolving upon gudgeons in a wooden frame. It has an iron bar *h*, consisting of two levers, between which the mill is set so as to revolve on a vibrator motion from the crank *e*. In the construction, a frame *c*, which is connected to the centre by two pieces *d*, is caused to revolve and

the part allowing movement to six iron rollers *f, f, f*, four inches in diameter, three being on each side of the frame, which triturate the indigo mixed with water into a fine paste. This mill is capable of grinding 1 cwt. of indigo at a time. Whenever the paste is uniformly ground, it is drawn off by the screw *g*, which had been previously fixed up by a screw plug, in order to prevent any of the indigo from lodging in the crevice of the crank, and thereby causing the action of the rollers.

Mills of other forms are also used commonly. One of these consists of a horizontal iron wheel, open at the top, in which a stone of corresponding shape is fixed, so as to leave a small space between it and the sides and bottom of the vessel, in which the indigo and water are necessary triturated with water, the motion being produced by means of a vertical shaft fixed to the centre of the stone.

The other ingredients necessary for setting the vat are sulphates or pyrites of iron, newly washed, quinine, and water. Various proportions of these ingredients are employed, as for instance, 1 part by weight of indigo (dry), 4 parts of copperas, and 1 of lime; or 1 of indigo, 2 of copperas, and 3 of lime; or 1 of indigo, 14 of copperas, and 20 of lime; or 1 of indigo, $\frac{1}{2}$ of copperas, and 1 of lime. The sulphate of iron should be as free as possible from the red oxide of iron, as well as from sulphate of copper, which would re-oxidise the reduced indigo-blue. The vat having been filled with water to near the top, the materials are introduced, and the whole after being well stirred several times is left to stand for about twelve hours. The chemical action which takes place is very simple. The protoxide of iron which is set at liberty by the lime reduces the indigo-blue, and the indigo-white is then dissolved by the excess of lime, forming a solution, which, on being examined in a glass, appears perfectly transparent and of a pure yellow colour, and becomes covered whenever it comes into contact with the air, with a copper-coloured pellicle of regenerated indigo-blue. The sediment at the bottom of the vat consists of sulphate of lime, peroxide of iron, and the insoluble impurities of the indigo, such as indigo-brown, iron, &c., with lime, as well as sand, clay, &c. If an excess of lime is present, a little reduced indigo-blue will also be found in the sediment in combination with lime.

The copperas vat is employed in dyeing cotton, linen, and silk. The cotton goods no other kind of vat is used at the present day. The dyeing process itself is very simple. The vat having been allowed to settle, the goods are plunged into the clear liquor, and after being gently moved about in it for some time are taken out, allowed to drain, and exposed to the action of the atmosphere. Whilst in the liquid the fabric attracts a portion of the reduced indigo-blue. On now removing it from the liquid it appears green, but soon becomes blue on exposure to the air in consequence of the oxidation of the reduced indigo-blue. On again plunging it into the vat, the de-oxidising action of the latter does not again remove the indigo-blue which has been deposited within and around the vegetable or animal fibre, but on the contrary, a fresh portion of reduced indigo-blue is attracted, which on removal from the liquid is again oxidised like the first, and the colour thus becomes a shade darker. By repeating this process several times, the required depth of colour is attained. This effect cannot in any case be produced by one immersion in the vat, however strong it may be. The beauty of the colour is increased by finally passing the goods through

ulated sulphuric or nitric acid, which removes the adhering lime and oxide of iron. After being used for some time the vat should be reconstituted or fed with more lime and lignum, upon which the colour must first be stirred up, and then allowed to settle again, so as to leave the liquor clear. The liquor, however, is in course of time gradually renewed, and by degrees the vat becomes capable of dyeing all shades of blue. When the colour produced by it is only very faint, it is no longer worth while using it, and the contents are then thrown away. In dyeing cotton with indigo, it seems to be essential that the red and yellow blue should be in combination with lime. If pounds of soda be used instead it is impossible to obtain dark shades of blue.

When cotton piece goods are to be dyed of a uniform blue, they are not submitted to any preparatory process of bleaching or washing. Indeed the size contained in native goods seems rather to facilitate than to impede the dyeing process. In dyeing these goods a peculiar roller apparatus is employed. When certain portions of the fabric are to retain their white colour a different plan is adopted. The pieces having been bleached, those portions which are to remain white are printed with an indigo resist. These resist marks consist generally of some salt of copper, mixed with an appropriate thickening material. The copper salt acts by entering the regular interstices at the surface, and thus rendering it insoluble before it can enter the interior of the vegetable fibre; it is only when deposited within the fibre itself that the colouring matter becomes finally fixed. The pieces are now stretched upon square drying frames, made of wood or of iron, furnished with sharp hooks or points of attachment. These frames are supported by cords over a pulley, and the pieces are immersed and lifted out alternately at proper intervals. In dyeing, a set of 10 vats is used, the first vat containing 1 or 2 lbs. of indigo, and the quantity increasing gradually up to 10 lbs. in the last vat. The pieces are dipped for 7½ minutes in the first vat, then taken out and exposed to the air for the same length of time, then dipped in the second vat, and so on to the last. After passing through the last vat, a small bit of the calico is dried, in order to see whether the colour is sufficiently dark. If it is not, the whole series must be dipped once more in the same vat in which the last dipping was performed. When the bottom of the vat is raked up, as to have more lime in suspension, the vat becomes what the dyer calls *hard*, that is to say, the oxide of copper of the resist is precipitated in a compact state, and consequently acts with more efficiency. But when the vat has been at rest for some time, and there is little lime in suspension, then it is called *soft*. When it is in this state, the oxide of copper is thrown down in a bulky form, and when the pieces are afterwards agitated in the liquor, in order to detach the scale of iron, which always floats about in the vat, and attaches itself to the fabric, and which if left adhering would cause light stains, technically called *grounding*; then the oxide of copper is also detached, and the indigo penetrates to those parts which are to remain white. When cotton yarn is dyed in the copperas vat, the latter is generally heated by means of steam pipes passing through the liquor, the colour being given to the colour the particular place or figure, which is required in this class of goods. No preparatory process is required, except simply stretching in hot water. In dyeing, wooden pins are put through the hanks, the ends being in supports passing over the top of the vat, and the yarn is then slowly turned over, one half being in the liquor, the other half over the pins. It is then taken out, wrung, exposed to the air, and again dipped, this operation being repeated until the requisite shade is obtained.

The methods employed for producing the colours called *China blue* and *pearl blue* on calico have been described under Calico Printing.

The *urine vat* is prepared by digestion of the ground indigo in warmed stable urine, which first decoctifies the indigo-blue, and then dissolves it by means of its ammonia. Madder and alum are likewise added, the latter being of use to moderate the fermentation. This vat was employed more commonly formerly than at present, for the purpose of dyeing woollen and linen goods.

Wood vat.—In former times, wood was the only material known to the dyers of Europe for producing the blue colour of indigo. For this purpose it was previously submitted to a peculiar process of fermentation, and the product was named *pastel* in France. For most purposes indigo has taken the place of wood in the dye-house, and for cotton goods it is now used alone. In the dyeing of woollen goods, however, the use of wood has been retained to the present day, for the purpose rather of exciting fermentation and thus reducing the indigo which is employed at the same time, than of imparting any colour to the material to be dyed. Indeed, the wood used by woollen dyers in this country contains no trace of colouring matter. Various substitutes, such as rhubarb leaves, turnip tops, wild, and other vegetable matters, have accordingly been tried, but without success, since the fermentation is more steadily maintained by means of wood than by any other material. *Pastel*, which

It may be said as compared many different ways; but it is essentially a

[illegible]

From the high price of turpentine in logwood, and even oak bark, and the difficulty of procuring it, to a considerable degree, in the manufacture of ink, has always injured it.

The ink made by this process is much more rich and powerful than any of the ink commonly sold. To bring it to the standard a half more water may safely be added, or even twenty gallons of the black ink may be made from that weight of materials, so I have ascertained.

Sun-ack and I would admit of only about one half of the copperas that galls will take to bring out the maximum amount of black dye.

Lewis, who made exact experiments on India, obtained the proportions of three parts of gum to one of sulphate of iron, which, with a strong glue, will answer very well; but good glue will admit of more iron oxide.

Red ink.—This ink may be made by adding for three or four days a weak vinegar, Brazil wood chipped into small pieces, the infusion may then be poured upon the wood for an hour, removed and the strong solution will give Arabic gum. A little alum improves the colour. A decoction of gamboge with a little water of ammonia, forms a more beautiful red ink, but it is fugitive. An extremely poisonous red ink of the same kind may be made by dissolving gamboge in weak water of ammonia, and adding a little camphor.

Blue ink.—Mr. Berthollet's patent blue ink is made by dissolving Prussian blue in a solution of gum arabic. The blue powder is washed in dilute nitric acid. M. Herberger has given the following as the best formula for blue ink:—

Mix 4 parts of gamboge with 10 parts of water, add 2 parts of water, then add 4 parts of cyanide of potassium dissolved in a little water, collect the precipitate formed, wash it with several additions of water, allow it to drain, and it will require about 200 parts; add to this one part of gum arabic, and 4 grains of carbonate of the cyanide by adding the latter to the water. The solution of gum arabic must be aqueous, and some appearance of green is produced at first on the surface of the ink. It may be kept without any addition for a long time.

Chinese Indelible Ink.—I have seen, that lamp black purified by potash lye, when mixed with a solution of glue and dried, formed an ink which was preferred by artists to that of China. M. Morveau, in his interesting treatise entitled *De la Peinture et l'Encre*, says, that the Chinese do not use glue in the fabrication of their ink, but that they add vegetable juices, which render it more brilliant and more indelible upon paper. When the best lamp black is levigated with the purest solution or solution of glue, it forms no doubt an ink of a good colour, but when the strong fracture, and is not so permanent on paper as good Chinese ink, and it is then as good as worthless into a tremendous jelly. One may be deprived of the essential property by leaving it for a long time, or subjecting it to a high heat in a paper vessel. But as ammonia is apt to be generated in this way, M. Morveau recommends a gum made by sulphuric acid to be used in preference to glue. He gives, however, the following directions for preparing this ink with glue. Into a solution of glue he pours a concentrated solution of gallic acid, which occasions an elastic mucous looking precipitate. He washes this matter with hot water, and dissolves it in a strong solution of clarified glue. He filters anew, and concentrates it to the proper degree for being incorporated with the purified lamp black. The strongest principle of vegetable does not precipitate gallic acid when its acid is liberated, as to this by mixing the nut-galls with lime-water or magnesia. The first mode of making the ink is to be preferred. The lamp black is said to be made in China, by collecting the soot of the oil of sesame. A little camphor (about two per cent.) has been introduced in the ink of China, and is supposed to improve it. Infusorial galls renders the ink permanent on paper.

Indelible ink.—A very good ink, capable of resisting sulphuric, nitric, and acetic solution with a hair pencil or quill, may be made by mixing some of the ink made by the process above with a solution of gum arabic. This is the Chinese ink. It writes well, but other than the Chinese ink, but they are all of a very temporary nature. The following is a recipe for a thickened ink, which may be used upon paper or cotton cloth, previously washed with a solution of soda, and dried. It is the ordinary permanent ink of the day. Before the cloths are washed the writing should be exposed to the sun, or to bright daylight, which blackens and fixes the oxide of silver. It is easily discoloured by chlorine and ammonia.

A good permanent ink may be made by mixing a strong solution of chloride of platinum, with a little potash, sugar, and gum to thicken it. The writing made therewith should be passed over with a hot smoothing iron to fix it.

Another indelible ink may be prepared by adding lamp black and lumps to a solution of the gluten of wheat in acetic acid. The ink is of a beautiful black colour, at the same time cheap, and cannot be removed by water, chlorine, or dilute acids. M. Herberger gives the following directions for its preparation. Wheat gluten is carefully freed from the starch, and then dissolved in a little weak acetic acid. The liquid is now mixed with so much rain water that the solution has about the strength of wine vinegar, that is, neutral. $\frac{1}{10}$ th of its weight of carbonate of soda, 10 grains of the best lamp black and 2 grains of iron are mixed with 4 ounces of the solution of gluten, and a little oil of olive added. This ink may be employed for writing linen, as it does not resist mechanical force.

Indelible ink of Dr. Traill is essentially the same as the above.

French indelible ink is made of iodine dissolved in rosin dissolved in oil for writing with quills, and through which is passed a wire pen.

Ind. Præparata.—This is essentially a combination of lamp black, — finely divided carbon, — with oil. Mr. L. Berthollet is a combination made by him in the factory of Arts, well adapted to the ordinary uses of a good ink.

1st. It must be made strong and easy, and work sharp and clean.

2nd. It must not have too much density for the type, but have a much greater affinity for the paper, and adhere to it freely upon it.

3rd. It must dry almost immediately on the paper, but not dry at all on the type or rollers; this is a great desideratum, especially for newspapers.

4th. It should be perfectly proof against the effects of time and chemical reagents, and never change colour.

5th. It must be paid to the quality of the inked oil employed, and even the character of and from which the oil is obtained should not be neglected.

The ink must be far from the fatty matters, and the pure oil is heated with great care at a carefully regulated temperature, and during the heating, the best yellow soap is added to give it consistency, and the required dryers are added as ordered with it. The best black is that obtained from the smoke of lighted, the combustion being carefully regulated. The black is ground up carefully with the drying oil, which has removed some what of the character of a varnish, and the ink is complete.

Gold and silver inks are prepared by grinding upon a porphyry a gold or silver leaf, with white honey, and these are reduced to the fluid consistent state of dividers. The honey is thoroughly washed from the leaf with spirits, and these are mixed up with good water.

INKING ROLLER. See PRINTING.

IODINE (*Iod.* *Iris*; *Iod.* *Grec.*) is one of the elementary substances; it was accidentally discovered in 1812 by M. Courtois, a manufacturer of saltpetre at Paris. He found, that in the manufacture of soda from the ashes of seaweeds, the residual vessels, in which the processes were conducted, became much corroded; and in searching for the cause of this corrosion, he discovered this now important substance. It was first described by Courtois in 1813, but was afterwards more fully investigated by Davy and Gay-Lussac.

Gay-Lussac and Courtois at first looked upon hydriodic acid as hydrochloric acid, until Sir H. Davy announced the idea of its being a new and peculiar acid, and being as a substance analogous to its chemical relations to chlorine.

It was named iodine from the Greek word *ἰώδης*, violet-coloured, in account of the colour of its vapour.

Iodine exists in many mineral waters in combination with potassium and sodium.

In the mineral kingdom, iodine has been found in one or two rare urals, so in a mineral brought from Mexico, in which it is said to be combined with silver, and also in one from Sicily in combination with zinc.

It exists also in very small quantities in sea water, from which it is extracted by many sea-weeds which have therefore a concentration of it; these sea-weeds when dried and burnt yield an ash containing a small help, from which all the soda of commerce was previously obtained, but the chief value of the ash now is in account of the iodine which it yields. The following is the process most generally adopted for the extraction of the iodine from the sea-weeds.

The sun-dried sea-weed is incinerated in a shallow excavation at a low temperature, for if the temperature was allowed to run too high a considerable quantity of iodide of sodium would be lost by volatilization. The half-burned ash or kelp which remains is broken into fragments, and treated with boiling water, which dissolves about one half of the ash.

The liquid thus obtained is evaporated, when on cooling the more crystallisable salts separate, viz. sulphate and carbonate of soda, with some chloride of potassium. The mother liquor at this point contains the iodide of sodium, sulphide of sodium, sulphide and some carbonate of soda. This liquor is then mixed with about one-eighth of its bulk of sulphuric acid, and allowed to stand for twenty-four hours; carbonic and sulphureous acid, and sulphuretted hydrogen gas escape, a fresh quantity of sulphate of soda crystallizes out, mixed with a precipitate of sulphur.

The supernatant and liquor is then transferred to a leaden still, to which is adapted a double tubulated leaden head luted on with pipe-clay; it is then heated to 140° F., when bi-iodide of manganese is added.

The temperature may be gently raised to 212° F., but not higher, as some chlorine would come over, and combine with some of the iodine, forming chloride of iodine.

The iodine is condensed in spherical glass condensers, each having two mouths

The above analyses are of—1. A mass of 1 lb. weight, which fell at Bobrova, in Bohemia, in 1740. 2. A mass weighing 1,000 lbs., found in 1740, near Krasnopol, on the Yagor. 3. The same, at Vukovar, Hungary, from Emperor Joseph, which weighed 100 lbs. 4. A mass of 71 lbs. weight, which fell at Hradec, near Agram, in Croatia, on 5th May, 1771. 5. A mass in the Hungarian Museum, found in 1775, in the plain between the Great Fekete-Ezer and Great Rye, in the Com. County, originally weighing 10 lbs. 6. Found at Lébény, in Hungary, and weighed in 1941 lb. 7. From Chertovitz, in Austria. 8. From Lébény. 9. Is a more recent analysis of the same. 10. From Lébény in North America. 11. From Bitburg, near Trier, which weighed about 400 lbs.

According to Shepard (*Journal of American Journal*), the fall of meteoric stones is confined principally to two tracts. The one belonging to America lies between 23 and 41° N. lat. and is about 18° in length. Its direction is from N. E. to S. W., following the general line of the Atlantic ocean. Of all the occurrences of this phenomenon since the last 200 years, 400 per cent. have taken place within these limits, and usually in the neighbourhood of the equator. The spots of the earth, however, with the exception that it extends to the westward of the equator, is bounded by the same degree of latitude, and follows a similar course, and sometimes it is that it has more than twice the width of the American tract. Of the numerous kinds of meteoric stones, which are found within this area, and were also considered to be that half of the same which extends along the Atlantic.

The most remarkable specimens of meteoric iron are, that found by Dr. Raimon de Cella, in Tucuman, in South America, in 1764, weighing 100 lbs.; that discovered in 1764 on the Ilha de Ilheus, in Brazil, estimated to contain 17 parts of Fe, and to weigh 17,000 lbs.; and that of the Ilha de Ilheus in Louisiana, weighing above 100 lbs., and presenting distinct octahedral crystals.

c. 1. *Native Steel-Iron*.—This substance has all the characters of cast steel; it occurs in a kind of small brittle nodules, with a finely crystalline, and a fracture usually fine grained. It is brittle when heated by the fire, and is easily fused in under the hammer. At Mittern, about 100 miles west of the village of Hradec, near Nory, department of the Allier, is a spot where there had been a mass of burning coal. A mass of 10 lbs. 6 oz. of native steel was discovered in that place, besides a great many small pieces.

2. *Mispickel, Dioprasite, Arsenical iron, Arsenisches*. This mineral is found massive, granular, or columnar, and disseminated. It is brittle, with an uneven fracture; colour, a very white, or almost steel grey, with a grey or very white streak; specific gravity 6–6.2. When heated in a closed tube it yields first a red, then a brown sublimation of sulphur, and arsenic, and then metallic arsenic. Some varieties contain silver or gold, in others part of the iron is replaced by cobalt. Viewed as a double sulphide and arsenide of iron, its formula would be $\text{FeS}_2 + \text{FeAs}$, which requires iron, 27.5; sulphur, 12.9; arsenic, 46.6. A specimen analysed by Plattner gave, iron, 34.46; sulphur, 20.7; arsenic, 45.46. Mispickel is common in the mines of Freiberg in Saxony, and in the tin mines of Hohenstein, Silesia, and in Cornwall. It is of no use as an ore of iron, but it is occasionally worked for the silver it contains, and as an ore of arsenic.

3. *Yellow sulphuret of iron; Prismatic iron pyrites, or Marcasite*.—The bronze or brass yellow colour enables us to recognize this mineral. At the blowpipe it gives off its sulphur, and is converted into a globule of malleable by the heat. It is brittle, with a conchoidal or uneven fracture. Sp. gr. 4.9–5.1. It is soluble in water, and with deposition of sulphur, but is scarcely affected by hydrochloric acid. It is a disulphide of iron (FeS_2), 46.7 iron, 23.3 sulphur. Plattner found 42.9 iron, 52.7 sulphur; and Herschel, 46.4 iron, and 53.6 sulphur. It is very liable to decomposition, being sometimes oxidized to sulphate of iron, and sometimes to hydrated peroxide, the sulphur becoming altogether eliminated. It is one of the most common minerals in rocks of all ages and climes; it occasionally contains both gold and silver. It is used for the manufacture of sulphur, sulphuric acid, and alum, but as an ore of iron it has no commercial value.

4. *Hexahedral iron pyrites, or pyrite*.—This mineral is distinguishable from the former only by its colour and form of crystallization, and was hence till lately confounded with it by mineralogists. Its surface is often radiated.

5. *Magnetic iron pyrites, pyrrhotine, the magnetite of the Germans*.—This mineral occurs chiefly in the igneous and crystalline, or other stratified rocks, in veins with various ores. Its colour is between bronze yellow and copper red, with a pinchbeck-brown tarnish, streak greyish-black, and more or less magnetic. When heated in an open tube it yields sulphurous fumes, but no sublimation, before the blowpipe on charcoal in the reducing flame it fuses to a black strongly magnetic globule; it is

in by sulphur, and evolving sulphur hydric acid, and depositing sulphur. A. G. H. has shown several ways in which a large quantity of sulphur may combine with the sulphur of FeS₂, and he adopts for it the formula FeS₂ + 4FeS, agreeing with the 44 iron and 40 sulphur, which agrees very closely with the analyses that have been made by S. G. J. R. H. Rose, and others.

6. *Iron black of iron*; *Magnetite*, or *crystalline iron ore*. — This very rich and valuable ore occurs regularly in igneous or metamorphic rocks, either in distinct crystals, or, as in many basalts, disseminated through the mass, when it frequently imparts magnetic properties to the rocks, especially to greenstone, serpentine, or basalt. It also forms veins in granite, in chlorite, mica, hornblende, and clay slate, or basalt. It also forms veins in granite, in chlorite, mica, hornblende, and clay slate, or basalt. The largest known masses occur in the northern parts of the globe, in Scandinavia, Lapland, Siberia, and North America. Less extensive masses occur in the Harz, in Saxony, Ilmenau, Styria, and in Southern Europe, in Elba and Spain. *Magnetite* is the most important ore of iron in Norway, Sweden, and Russia. The Hammeberg mine in Sweden, wrought in an open quarry 150 feet broad, and 200 feet deep, furnishes the Oeregrund iron, largely imported into England for the manufacture of steel. Some highly magnetic varieties, especially from Sweden and the Harz, form natural magnets, possessing great power. *Magnetite* iron ore fuses with extreme difficulty; it is not acted upon by nitric acid, but when powdered is soluble in hydrochloric; its specific gravity varies from 4.24 to 4.4. The chemical formula of pure magnetite is Fe₃O₄, containing 72.4 per cent. of iron, and 27.6 of peroxide of iron, or of 24.0 iron, and 27.6 oxygen, which agrees closely with the analyses of Berzelius, Koenig, and Karsten.

Two specimens of magnetic iron ore from Cornwall had the following compositions (Dr. Neill):

Water	2.50	5.20
Peroxide of iron	28.00	18.00
Peroxide of iron	41.40	60.50
Oxide of manganese	16	26
Alumina	3.20	3.60
Lime	0.60	0.56
Magnesia	1.00	1.53
Sulphur	0.04	0.04
Sulphuric acid	0.50	0.57
Insoluble residue	24.20	9.40

99.60 98.95

7. *Hematite*; *Spanish iron*; *Iron ore*; *Iron ore*. — This ore has a metallic lustre, and is black to steel grey, but often tarnished; the light transmitted through the thin edges of the crystals appears of a beautiful red colour. Its powder is always of a well marked brown red hue, passing into cherry red, which distinguishes it from the black and ore; its fracture is conchoidal or uneven; it is brittle, and its specific gravity is 5.2. Its chemical composition is Fe₂O₃, 70.03 iron, and 29.97 oxygen, but it sometimes contains oxide of titanium, or titanite acid, rhombic, or silica; in the red-tinged flame of the blowpipe, it becomes black and magnetic.

Hematite is one of the most abundant ores of iron. The specular variety occurs chiefly in the older crystalline rocks in large beds or veins. The mines of the island of Elba celebrated from antiquity, still furnish the finest crystals, which occur in streaks of the massive variety along with pyrites and quartz; fine crystals are likewise produced from St. Gothard, Framont, in the Vosges mountains, the Harz, Altenberg in Sweden, and from Katharinenburg in the Ural. Beautiful specimens of the massive variety occur at Zorge and other parts of the Harz, at Tiscroft in Cornwall, Tavistock in Devonshire, in Wales, Cumberland, and Perthshire. It also occurs in various rocks, as in Auvergne, on Vesuvius, Aina, and the Lipari Islands, especially Stromboli, where some fine crystals, three inches broad and four long, have been procured.

8. *Red hematite*. — These ores are found in the greatest abundance in the mountains or carboniferous limestone formations. The most abundant deposits in this country are those of Lancashire, Cumberland, and the Forest of Dean, where the ore exists in almost unlimited quantity. In the latter locality they were worked most extensively at a very early date, and though as a class they are not rich, yet from the great masses in which the ore is found, its cost of production is very low, about 2s. to 2s. per ton (*Blackwell*). The iron made from the Forest of Dean ore, is of

the quality which red-ore is generally substituted for the substitution of the place. This ore is raised extensively for shipment to the iron works of South Wales.

The varying quality of the Forest of Dean ore is shown by the following analysis (Dr. Nock):

	I.	II.	III.	IV.	V.
Water	7.15	2.60	2.60	2.11	2.70
Carbon	37.90	37.32	37.90	14.18	14.40

Insoluble residue	5.1	2.7	3.00	5.10	1.00
	100.00	100.00	100.00	100.00	100.00

The hematite of Whitehaven occurs in the carboniferous limestone near the outcrop or surface edge of the slaty rocks upon which that formation rests. The greater part of the excavations from which it is extracted are subterranean, and it is necessary to enter the mass of iron ore in which the workings are carried on, that it is difficult in such situations to obtain a clear idea of the nature of the important deposit. (Harrison *Geol.*, 67, 214) Some of the hematite of the Whitehaven district is exported on the spot, at the Chester Moor and Workington works, and 261,700 tons are sent into the iron-making districts. In the year 1852, 100,000 tons were sent away by road and railway from the Ulverston district, and no less than 600,000 tons of hematite were exported during 1855 (*Hunt*), for the supply of Staffordshire, South Wales, and other districts from these two localities. Considering its quality, it brings but a low price, viz. from 11s. 6d. to 12s. 6d. per ton.

The following analyses of some carefully selected samples of the hematite of the carboniferous limestone are by Messrs. Park and Spiller, *Memoria of the Geological Survey of Great Britain. The Iron Ores of Great Britain. Part I.*

	Central Mass.	Clons. Mass.	Ulverston.	Ulverston, Mass. and Ulverston.
Peroxide of iron	93.18	90.36	86.50	94.25
Peroxide of manganese	0.24	0.10	0.21	0.25
Alumina	-	0.37	-	0.51
Lime	0.07	0.71	2.77	0.05
Magnesia	-	0.06	1.45	trace

Sulphuric acid	trace	trace	0.11	0.00
Bisulphide of iron	trace	0.00	-	0.00
Water, hygroscopic	-	-	-	0.05
" combined	-	-	-	0.17
Insoluble residue	5.60	8.51	6.92	5.16
Carbonic acid	-	-	2.90	-
	101.15	100.20	100.00	100.00

The carboniferous limestones of Derbyshire and Somersetshire also contain spots and pockets of hematite, though of a quality not equal to those of Lancashire; the same ore is also met with in the Devonian series of Devon, West Somerset, and Cornwall.

9. *Brown Hematites; Brown oxide of iron; Hydrous oxide of iron.*—This species affords always a yellow powder, without any shade of red, which passes sometimes into the bistre brown, or velvet black. At the blowpipe it becomes brown, and very attractable by the magnet; but after calcination and cooling the ore yields a red

and Caradoc. In the *Erzkong*, near *Jagers* in *Saxia*, it occurs in grains, and is wrought into iron bars. The *Blackband* and *Black*, near *Salisbury*, in the county of *Wiltshire*, and *Widmore* in *Wiltshire*, are the largest and finest, while in *Arthall* and the *Harz* are found large veins in graywacke or Devonian limestone. Other very extensive deposits of this ore are found in the *Pyrænée*, and the *Haute* provinces of *Spain*, as near *Kilma*; and at *Pon* near *León* in *New Castile*. Most of these localities yield fine crystals, and these also occur in certain veins at *Journival* in *Belgium*, *Freiburg* in *Saxony*, *Kiautschou* in the *Harz*, *Isère* in the *Pyrenées*, *Almadén* in *Castile*, and in many of the mines of *Cornwall*, particularly the rare hexagonal prisms (*Nod.*). In England the crystalline carbonate of iron occurs in the Devonian of South Devonshire and North Devon, and in the earlier Silurian limestones of North Devon.

The specific gravity of sparry carbonate of iron varies from 3.65 to 3.67. Its positive form is like that of carbonate of lime, as shown elsewhere. Whilst changing this form, its crystals are composed of containing various quantities of carbonate of lime, till it passes wholly into a mineral. When heated before the blowpipe it turns brown without melting, and becomes attracted to the magnet after being slightly heated in the flame of a candle. Even by a direct exposure to the air after separation from the acid, it also becomes the same brown, but not without improving the magnetic quality; after long exposure to the air it becomes wholly converted into hydrated hematite.

The variations in composition of this important mineral are shown in the following analyses.

	Sparry Hematite	Pyritic Pyrites	Iron Limonite	Iron Siderite	Heavy Siderite	Nod. Siderite
Peroxide of iron	63.75	50.00	47.85	54.41	57.03	52.56
Benzoic acid of iron	-	-	-	-	5.15	-
Peroxide of manganese	0.75	0.50	1.77	25.41	12.00	4.00
Stagnation	0.25	0.70	0.00	-	4.52	2.41
Lime	traces	-	0.94	-	traces	1.20
Carbonic acid	34.00	38.20	35.22	25.75	25.80	36.68
	98.75	99.40	100.00	100.17	100.02	99.73

This ore, viewed as a metallurgical object, is one of the most interesting and valuable that is known; it affords *natural steel* with the greatest facility, and accommodates itself best to the Catalan smelting forge. It was owing in a great measure to the peculiar quality of the iron which it produces that the excellence long remarked in the cutlery of the Tyrol, Styria, and Carinthia was due. It was called by the older mineralogists, *steel ore*.

Coal measure iron stones.—The compact carbonates of iron has no relation externally with the sparry variety. It comprehends most of the clay ironstones, particularly those which occur in flattened spheroidal masses of various sizes among the coal measures. The colour of this ore is often a yellish brown, reddish grey, or a dirty brick red. Its fracture is close grained, it is easily scratched, and gives a yellowish brown or grey powder. It adheres to the tongue, has an odour slightly effluvescent when breathed upon; blackens at the blowpipe without melting, and becomes attracted by the magnet after calcination. The ironstones of the coal formation admit of a natural division into two great classes, viz. the *gray*, and the *blackband* or *carbunaceous*. The earthy or lithoid carbonates occur in some regions in the upper limestone shales, and they extend upwards through the coal measures proper towards their higher limits; they likewise occur in extensive beds in the Jurassic formation, particularly in North Yorkshire; near the upper limit of the lias, or base of the oolites proper; and again higher, as nodules and perhaps as beds, in the middle oolites, or Oxford clays. They are also found extensively as courses of nodules in the Wealden series, and as beds in the green sand. When these gray carbonates contain lime in abundance, and when clay is not largely present, they are sometimes changed by atmospheric influences into hydrated hematites; in Northamptonshire, for example, and widely in France. The only great coal fields in Great Britain in which these ores do not occur in sufficient abundance to form the basis of a large production of iron, are those of Northumberland and Durham, and of Lancashire. The great importance of the argillaceous and blackband ironstones of our coal-fields is clearly shown by the fact, that they supply at least *nine-tenths* of the entire iron produced

Remarks. They vary considerably in their percentage of iron, which is generally not more than 30 per cent., but occasionally ranges as high as 40 per cent. They are rarely used where they contain less than 20 per cent. The varying proportions of iron, silica, and alumina which they contain is shown in the following analysis of the ore from different localities.

The quality of the iron produced from the argillaceous ironstone is extremely good, provided the coals used for smelting are good. The ore is always used in a calcined state, by which it loses in weight about one-third or one-fourth, the loss consisting of carbonic acid and water. The production of iron in South Wales, North Staffordshire, Northumberland, and Durham, rests almost entirely on the great beds of this mineral. In Scotland the ore almost exclusively used is the *blackband* or *carbonaceous ironstone*, immense deposits of which occur likewise in the coalfield of North Staffordshire; this variety sometimes contains as much as 25 to 30 per cent. of carbonaceous matter, but is usually free from much earthy matter; it often contains phosphoric acid in quantity sufficient to communicate to the iron the quality of cold shortness. The discovery of this class of ironstone in Scotland by Mr. Musket in 1801, and the power of using it at once in the furnace by means of hot blast, constituted a new era in the manufacture of iron, and gave to Scotland, till then an iron making district of little importance, the pre-eminence over all others, for the production of soft fluid iron, best suited to ordinary foundry purposes.—*Blackwell*.

In France the clay carbonates of the coal measures are only found of sufficient value to work in three localities, — in the coalfields of the Gard, of the Aveyron, and of a very limited extent in the coalfield of the Loire, near St. Etienne.—*A. Dickson*.

In America it is largely distributed over Pennsylvania, Maryland, Virginia, Ohio, Illinois, North Carolina, and Kentucky; but from the difficulties of working it in the blast furnace, it is not in general use.

13. *Phosphate of iron; Blue iron; Vivianite*.—The colour of this mineral varies from indigo-blue to blackish green; the earthy variety is white in the beds, but changes blue on exposure to the air; heated in a closed tube it yields much water, attumescens, and becomes spotted with grey and red; before the blowpipe, if charred, it fuses to a grey, shining, metallic granule. Transparent indigo-coloured crystals of phosphate of iron, sometimes an inch in diameter and two inches long, occur with iron and copper pyrites in the tin and copper veins at St. Agnes in Cornwall. It was first found in the auriferous veins at Vorapatak in Liebenberg; the earthy varieties are very common in Cornwall, Styria, North America, Greenland, and New Zealand. A specimen from St. Agnes, Cornwall, gave Stromyer—phosphoric acid, 31.18; protoxide of iron, 41.27; water, 27.48; and another from New Jersey yielded to Rammeisberg—phosphoric acid, 30.40; protoxide of iron, 33.91; peroxide of iron, 12.69. It is sometimes used as a pigment, but is of no use as a smelting ore.

14. *Schönberg iron ore*, from the green schist of Schönberg, is formed by the oxidation of sulphide of iron, and is a blackish green mineral, of a fine crystalline texture.

15. *Chromite of iron*, (the black chromite of Chrome),—This mineral occurs in large crystals in the crystalline rocks. It was first discovered at Gams, in the Vorarlberg, in France, and is found in Saxony, Silesia, Bohemia, and Norway, also in Norway, and in large quantities in the Erzgebirge, near Katharinenberg. It has a blackish green color, in a brownish-black streak, yellowish to reddish brown. A specimen from Norway, analysed by Von Koenig, gave protoxide of iron, 24.6; peroxide of iron, 14.6; alumina, 9.02; magnesia, 2.18; and silica, 4.31; a specimen from Chester in Pennsylvania, yielded to Sjöberg protoxide of iron, 24.6; peroxide of iron, 39.1; alumina 13.6; and silica, 10.0. It is used in the preparation of various pigments. For the treatment and use of the ore, see Chromite.

16. *Malachite of iron*, (Malachite of iron), Wulfen.—This mineral, which is rather rare, occurs in great beauty associated with copper ore in Cornwall; it has an olive green color, and is rather brittle. Its composition, according to the analysis of Berzelius, is, silica, 1.04; peroxide of iron, 30.1; protoxide of iron, 12.6; water, 5.9.

17. *Malachite of iron*.

18. *Quartz of iron*, (Quartz of iron), Hübner.—This mineral, which occurs in the form of crystals, is found in the brown coal at Krumm, near Böhmen, in Bohemia, and at the same place in Hesse, Germany, according to the analysis of Hammerberg, of silica, 4.4; peroxide of iron, 11.13; and water, 1.47.

19. *Titanium of iron*, (Titanium of iron), Hübner.—This variety occurs in various forms, and is the most common of the iron ores, in the form of a blackish ore, at Gams in Salzburg, in the Erzgebirge at Krumm in Southern Norway; and in the form of a blackish ore, at Teufelsrand, and Kragers, near Arendal. It is extremely infusible, and is considered injurious when mixed with other ore. Its chemical composition, according to H. Rose and Scheerer, is a combination of peroxide of iron, and blue oxide of titanium, in various proportions, the specific gravity increasing with the amount of iron.

20. *Titanium of iron*, (Titanium of iron), Wulfen.—occurs with tin ore, forming fine crystals, at Auerberg in Saxony, at Schönbachwald in Bohemia; and in France, in quartz veins. In Cornwall, especially near Redruth, it is sometimes so abundant as to render the iron wholly valueless. An analysis of a specimen from Cumberland gave Berzelius tangent acid, 75.77; protoxide of iron, 15.32; protoxide of manganese, 6.72; and silica, 1.25.

There is abundance of evidence that iron was well known in the early ages, and was applied to various useful purposes. The earliest method of working the furnace when it was erected seems to have been by exposing them to the wind (the furnaces, performed with bellows, were built on ruins, and could only be worked when there was a strong breeze; the fire was regulated by opening and shutting the apertures. Mr. Park gives in his "Travels in Africa," the following interesting account of an iron-making operation in Katsina, at which he has witnessed "The iron men were working the furnace of a hen's egg; a bundle of dry wood was first put into the furnace, and covered with a considerable quantity of charcoal; over this was laid a stream of iron ore, and then a layer of charcoal, and so on until the furnace was quite full. The furnace was a circular tower of clay, about 10 feet in height and 7 in diameter, perforated in two places with withes, to prevent the clay from cracking and falling to pieces by the violence of the heat. Round the lower part, on a level with the ground, but not so low as the bottom of the furnace, which was somewhat conical, were made seven openings, into each of which were placed three tubes of clay, and the openings again plastered up in such a manner that no air could enter the furnace but through the tubes, by the opening and shutting of which the fire was regulated. The fire was applied through the top of the tubes, and blown for some time with bellows made of goat's skin. The operation went on very slowly at first, and it was some hours before the furnace appeared above the furnace; but after this it burst with great violence all the first day, and the people who attended put in at times more charcoal. On the day following the fire was not so fierce, and on the second night some of the tubes were withdrawn, and the air allowed to have free access to the furnace; but the heat was very great, and a bluish flame rose some feet above the top of the furnace. On the third day from the commencement of the operation all the tubes were taken out, the ends of many of them being vitrified with the heat, but the metal was not removed until some days afterwards, when the whole was partly cool; part of the furnace was then taken down, and the iron appeared in the form of a large irregular mass, with pieces of charcoal adhering to it. It was sonorous, and when any portion was broken off, the fracture exhibited a granulated appearance like broken steel."

That the iron-ores of Scotland and the Cornish mines were extensively worked by the Romans during the period of their power in Britain, appears from the numerous beds of iron-ore that have been discovered in the Forest of Dean; it is probable that that was the principal seat of their manufacture, as the iron-ore in that form of cast-iron, and even, have been known to be varied in Yorkshire and in other counties. During the reign of William the Conqueror, the iron-ore was the chief article the trade of England that was chiefly carried on, the Forest of Dean supplied the iron-ore.

It is remarkable, when the art of smelting was first discovered, that the first furnace to have been first used in England by Edward the Third, who made them in the invasion of Scotland in 1327, at Croy, and at the siege of Calais in 1346. These furnaces were not however cast, but were constructed in the same principle as the modern construct their furnaces; a number of iron bars fitting as close as possible to each other were arranged round a cylinder of wood, and were then joined together by driving in a long pole; the wood being driven out, there remained an iron pipe which formed the furnace. This mode was superseded by using the furnace of bricks.

During the 14th and 15th centuries, iron-ore was not only imported into this country from Germany, Poland, and other places, but also from Spain; but as several improvements in the manufacture had taken place in the latter of this period in Poland, it was much to be wished that the knowledge of the latter country, respecting the improvements in the manufacture of iron, should be introduced into this country. During the reign of Elizabeth, the consumption of iron in this country was so great that it was deemed necessary to enact laws to prohibit the export of iron-ore, and to prevent the selling of timber for fuel; persons concerned in the manufacture of iron were consequently compelled to turn their attention to the finding of some substitute for charcoal, and in the reigns of James the First and Charles the First many attempts were made to succeed in this point, but without success; the consumption was the entire and constant of iron making in many parts of the country, and a great decrease in the manufacture in others; so much so indeed was the failure of all the experiments made to substitute pit-coal for charcoal, that all attempts were abandoned till the early part of the next century, when pit-coal was first used in 1711 by Mr. Abraham Darby in his furnace at Coalbrook Dale; and in the 4th volume of the Philosophical Transactions, published in 1747, it is stated, that "Mr. Forth, from iron and coal, both got in the same Dale (Coalbrook), makes iron brittle or tough as he pleases, there being cannon thus cast so soft, as to bear turning like soft iron." Notwithstanding, however, the establishment of the fact that iron-ore could be smelted, and iron manufactured with pit-coal, and although great efforts were made, by increasing the column of blast, by the substitution of steam power for that of horses and human labour, there appears to have been a steady and progressive improvement in the quantity of iron produced in this country; and recourse was had to foreign markets, particularly to those of Sweden and Russia, for the necessary and increasing demand. Thus, the imports of iron between the years 1711 and 1776, were as follows:—

									Tons.
1711	to	1715	-	-	-	-	-	-	15,643
1729	"	1733	-	-	-	-	-	-	23,501
1750	"	1755	-	-	-	-	-	-	34,072
1761	"	1766	-	-	-	-	-	-	4,000

In 1740 there were only 59 blast-furnaces in work in England and Wales, the total make of which amounted to not more than 17,350 tons, being an average of 294 tons per annum for each furnace, a quantity very little exceeding that sometimes made in a single week in some of the furnaces in Wales at the present day.

The earliest contrivance for throwing a powerful and constant blast into the furnace was a forcing pump, worked by a water wheel or by a steam engine; and it appears that the first cylinders, at least of any magnitude, were erected at the celebrated Carron Iron Works in the year 1766 by Mr. John Smeaton. These cylinders were four feet six inches in diameter, exactly fitted with a piston, moved up and down by means of a water wheel; in the bottom of the cylinder was a large valve, like that of a bellows, which rose as the piston was lifted up, and thus admitted the air into the cavity of the cylinder below. Immediately above the bottom was a tube which went to the furnace, and as it proceeded from the cylinder, was furnished with a valve opening outwards. Thus when the piston was drawn up, the valve in the bottom rose and admitted the air that way into the cylinder, while the lateral valve shut, and prevented any air from getting into it through the pipe. When the piston was thrust down, the valve in the bottom closed, while the air, being compressed in the cavity of the cylinder, was violently forced out through the lateral tube into the

There were four of these large cylinders applied to blow the furnace, and it was contrived, that the strokes of the pistons became alternately, producing an almost non-stop blast of air, of triple or quadruple quantity, was thus obtained, and effects equivalent to those given by the previous method followed. The same furnace that formerly yielded one and twelve tons weekly now was able to produce forty tons in the same period, and in the average in one year 1,500 tons of metal (Switzerland); and such was the impetus given to the trade by this unexpected success of a powerful blast with pit-coal, that in 1780 the manufacture of pig iron in England, Wales, and Scotland amounted to 61,000 tons, being an increase of 30,750 tons on the quantity annually raised previous to the introduction of pit-coal.

A new era in the history of the iron manufacture may be considered to have been established in 1780, by the introduction of the double power engine of James Watt, the singular and increased effects of which powerful machine were soon felt in most of the iron districts: the proprietors of furnaces greatly increased their make, and fresh capital was embarked in the trade. In the short period of eight years, the manufacture of pig iron was nearly double, being in the year 1786, (according to the returns sent to the chairman of the committee of the House of Commons, on the subject of the coal trade, when Mr Pitt had it in contemplation to add to the revenue by a tax upon coal at the pit mouth,) 121,79 tons, from 121 furnaces—104 English and Welsh, and 17 Scotch; the English and Welsh furnaces producing an average of 1,018 tons each per annum, and the Scotch furnaces 946 tons. In 1804, the number of furnaces in Great Britain was 173, and the make 288,206 tons of pig iron. During an interval of ten years, of 1814-27 tons per annum, of these 173 were coke furnaces, the average produce of each of which had risen to 1,466 tons. In this year great exertions were made in the iron trade, in consequence of the proposal of Lord Henry Petty to levy, as a war tax, a duty of 4s. per ton on pig iron; but introduced a bill into the House of Commons having this object, and succeeded in carrying it, notwithstanding a powerful opposition, by a majority of ten members; the measure was however abandoned.

In France, in 1801, the quantity of cast iron produced amounted to 140,000 tons from 100 blast furnaces, of which only one (that of Creusot) was worked with coke. In 1804, a description of the English process of making iron was published by order of council, by M. de Bonnaud (an engineer of mines); another engineer of mines (M. de Gualbert), after having passed several months in England, established at St. Etienne the second blast furnace in France, wherein the minerals were treated in the same manner as the English, and in which coke was employed; but the difficulties he had to encounter proved a bar to his success, and he is said to have died prematurely from the grief and trouble which the enterprise occasioned him (See p. 107.) The employment of pit-coal in the manufacture of iron received a very slow development in France, for in 1818 the quantity of cast iron made with coke was very small, and no wrought iron was prepared with pit-coal; in 1824 not more than 3,000 tons of cast iron were made with coke, but in 1828 it had risen to 17,000 tons. Though this did not amount to a tenth of the whole produce, nevertheless the quantity of bars made with pit-coal amounted in this year to 49,000 tons, being nearly one-third of the total manufacture of wrought iron.

Cast iron, using that term in the sense in which it is now understood, must have been wholly unknown to the ancient metallurgists, for even in the smelting of their poorer ores, where they urged their ferrous with the greatest heat they could command, using probably lime as a flux, the red-hot metal was allowed to cool in the bed of the furnace, and was never run into pigs as in the modern practice; their best iron was produced in one operation and after cooling and separating the scoria, it was forged at once into tough hard bars under the tilt hammer. The time and fuel consumed in these ancient methods was enormous, and the iron that remained in the scoria, amounted to fully one half of the original metallic contents of the ore.

The modern process of iron smelting differs materially according as the fuel employed is charcoal or pit-coal. As an illustration of the method adopted when the former is used, the following details of the manufacture of the celebrated "Oregrund iron" may be taken, premising that the operations vary in a few particulars in other countries where different kinds of ore are dealt with. The Oregrund iron is made from the magnetic ironstone of Dannemora in Sweden. The ore, in moderately large pieces such as it comes from the mine, is first roasted. For this purpose an oblong coffin of masonry, 15 feet long, 15 feet wide, and about 6 feet in depth, open at top, and furnished with a door at one of its smaller extremities, is entirely filled with logs of wood over this the ore is piled to the height of from 5 to 7 feet, and is covered with a coating of small charcoal, almost a foot and a half in thickness. Fire is then communicated to the bottom of the pile, by means of the door just mentioned.

and in a short time the combustion spreads through the whole mass, the small quantities of pyrites that still remain in the ore, and by the combination of the sulphur, the necessary gas being driven off, and the ore, thus being very hard and dense, becomes nearly ready for use. In the course of twenty days from the beginning of combustion, and the ore being sufficiently used is transformed to a shaggy mass, where it is poured dry, and afterwards rolled through a mill with rollers, which will reduce it to any size, larger than a half-inch to 12 inches. It is then ready for use. The resulting slag is a strong, quadrangular piece of iron, the surface of which, though rough in form, is not very much disturbed. It may be sometimes in general, so regulated, that it is regular, though some pieces have a tendency of being the lower it is, and they are then considered of the upper, and is put off by 12 inches, through the upper end of which the blast of wind from the furnace machine is admitted into the furnace, and from the lower the melted matter, both scoria and metal, is discharged from time to time at the pleasure of the workmen.

The furnace is kept filled with charcoal, above, and well covered, after which other rate charges are added of ore, either native, or mixed with fragments of the quartz any flux) and charcoal, the blast is let up, and the process is then being to keep the charcoal in a good state, the upper part of the furnace, is usually heated as long as it arrives in the form of the blast, when it is made in a blast of iron, the bottom of the furnace is covered with a melted slag. Part of the slag that flows to the lower part of the furnace is usually removed, to allow the metal to flow out, and at the end of every such hour the iron is left in the furnace for a short time, when it forms from the top to the bottom. As soon as the iron has flowed out, the aperture is closed again, and then the furnace is kept in constant activity during the first six months of the year, the other six months are employed in repairing the furnace, making the metal, and reducing the regular process of work and iron. The next process for converting the pig iron into a bar iron, for the purpose of a furnace is made up of, consisting of a large hearth, with a sloping roof, and from one to twelve inches below the level of the hearth. This cavity is filled with charcoal and iron, and in the center of the hearth is a large iron rod, and the iron is well covered with charcoal. The blast is then let up, and the pig iron being placed in the very focus of the heat, soon begins to melt, and as it begins, runs down into the cavity below, where, being out of the direct influence of the blast, it becomes solid, and is then taken out, and reduced to a smaller portion. The cavity being then filled with charcoal, it is then fired a second time, and after that, a third time, the whole of these three processes being usually done in between three and four hours. As soon as the iron has become solid it is taken out, and very slightly hammered to free it from the adhering scoria; it is then returned to the furnace, and placed in a corner, out of the way of the blast, and well covered with charcoal, where it remains, till, by further gradual cooling, it becomes sufficiently compact to bear the tilt hammer. Here it is well beaten till the scoria are forced off, and it is then divided into several pieces, which, by a repetition of heating and hammering are drawn into bars, and in this state is ready for sale. The proportion of pig iron is obtained from a given quantity of ore is subject to considerable variation, from the difference in the metallic contents of different parcels of ore and other circumstances; but the amount of bar iron that a given weight of pig metal is expected to yield is regulated very strictly, the workmen being expected to furnish four parts of the former for five parts of the latter, so that the loss does not exceed 20 per cent.

In some parts of America, particularly in the states of Vermont and New Jersey, the Catalan forge is extensively employed for smelting the rich magnetic ores which

there abound. The form of this forge (which is nearly uniform every where), and the manipulation with it in America, is thus described by O'Brien. —The whole is a level hearth of some width, from 6 to 8 feet square, at the corner of which is the fire-place, from 24 to 30 inches square, and from 12 to 18, often 20, inches deep. Inside it is lined with cast iron plates, the bottom plate being from 2 to 3 inches thick. Figure 293 represents a cross section through the fire-place and reverberatory, commonly called the iron of rever-

presents the fire-place, which, as remarked above, is of various dimensions. The inner *b* is from 7 to 8 inches above the bottom, and more or less in width ac-

subject to the same instances. The blast is produced by wooden bellows of the common form, or more generally by square wooden cylinders, urged by water wheels. The ore is chiefly reduced in the crystalline magnesian. This ore very readily falls in a regular scale, and when roasted varies from the size of a pea to the finest grain. Sometimes the ore is employed without roasting. In the working of such ores much depends on the skill and experience of the workman. The result is subject to considerable variation, that is, whether economy of coal or that of ore is our object. Thus a modification is required in the construction either of the whole apparatus or its parts only. The temperature varies in many respects. One workman by looking by the eye into the furnace, observes some of the expense of obtaining a good yield. Another by carrying the iron more laboriously at the common furnace, obtains a larger amount of iron, though at the sacrifice of coal. Good workmen pay great attention to the tuyere, and alter its dip according to the state of the operation. The general arrangement is as follows:—The hearth is lined with a good coating of charcoal dust; and the fire plate, or the plate opposite the blast, is lined with coarse ore, inasmuch as is at our disposal. If no coarse ore is employed, the hearth is lined with coal, and the small ore piled against a disk of coal dust opposite the tuyere. The blast is at first urged gently, and directed upon the ore, while the coal at the tuyere is kept cool. Four hundred pounds of ore are the common charge, two-thirds of which are then smelted, and the remaining third, generally the finest ore, is held to reserve, to be thrown on the charcoal when the fire becomes too brisk. The charcoal is piled to the height of two, sometimes even three and four feet, according to the amount of ore to be smelted. When the blast has been applied for an hour and a half, or two hours more of the iron is melted, and forms a pasty mass at the bottom of the hearth. The blast tuyere may be urged more strongly, and if any pasty or spotty mass yet remains, it may be brought within the range of the blast and melted down. In a short time the iron is run out, and the scum is permitted to flow through the tapping hole, so that but a small quantity of scum remains at the bottom. By turning the iron bars, the lump of pig iron is brought before the tuyere. If the iron is too pasty to be lifted, the tuyere is made to dip into the hearth; in this way the iron is raised from the bottom, directly before, or to a point above the tuyere, until it is worked into a coherent ball, twelve or fifteen inches in diameter. This ball is brought to the hammer or squeezer, and shingled into a bloom, which is either cut in pieces to be stretched by a hammer, or sent to the rolling mill to be formed into malleable bar iron. A mixture of fibrous iron, cast iron, and steel, is the result of the above process; the quality of the iron depends entirely on the quality of the ore, for there are no opportunities for the exercise of any skill to create improvement in the process; poor ores cannot be smelted at all. In Vermont, where the rich magnetic ores are employed, a ton of bloom costs about 40 dollars; 4 tons of ore, and 300 bushels of charcoal are required to produce 1 ton of bloom. The *Furnace à la Française*, or *Stück-ofen* of the Germans, holds a place intermediate between the *Common hearth* and the high blast furnace now in general use. The iron produced in the kind of furnace is generally of a very superior kind, but it is very laborious at the present time, on account of the great expense of its manipulation. The *Stück-ofen*, or *Alexander furnace*, as it is sometimes called, is a small cupola, its interior having the form of a double crucible. It is usually from 10 to 16 feet high, and 24 inches wide at bottom and top, and measures at its widest part about 8 feet. There are generally two tuyeres, both on the same side; the breast is open, but during the smelting operation it is shut by bricks. The furnace is heated previous to closing in the breast; after which charcoal and ore are thrown in; the blast is then

back, the two side stones, are laid on a bed of fire-bricks. These stones must be at least 4 feet and a half long, reaching from the back to the front of the furnace. They

must be made sufficiently heavy to be a proof of their soundness; the transverse section of the grain must be in all cases parallel to the fire, the side stones are sometimes square, but always beveled according to the slope of the hearth. If the stones at the top are square and are heated, the latter will crack and break, and therefore the top of the hearth quality. They should be from 24 to 24 inches square, or even larger, but they have, at a kind of arch, are cut at least the stones are heated. These stones are not much further than the front of the furnace, and are therefore scarcely four feet high, the top stone, however, is generally sufficiently high to reach at once the crucible in its throat, the stones are placed on the back stone, and the back stone is put in the throat of the furnace, and the stones between the throat and the rough wall of the furnace are filled and walled up with common brick or stone.

In starting a charcoal furnace, it is first the only done by turning a fire for several weeks in the interior, which has a temporary roof of bricks. The lower part of the furnace or the hearth is then filled gradually with charcoal, and when the fuel is well settled, and the furnace half filled, ore may be charged in; it is common advice to increase the draught by forcing grates by laying across the top a strong iron bar, as high up as the dam-stone, by resting upon this bar a row of iron bars or risers, and by pushing their points against the back stone of the hearth. There is not much to be made during the first 24 hours; most of the ore is transferred to the blast, and the iron which comes down gets cold on the bottom stone, where it is retained, the blast should not be urged too fast at first, but increased gradually, in order to avoid the serious evil arising from a cold hearth; if all goes well the hearth will be free from cold iron or clinkers in a week, the yield of iron will increase, and the fusion may be increased likewise. The average charge of charcoal, which should be dry, coarse, and hard, is about 15 bushels. According to Overman's experience, the most favourable height for a charcoal furnace is 5 or 6 feet; if lower this standard they consume too much fuel, if above they are troublesome to work; if it be desired to enlarge the capacity of a furnace, he thinks it better to increase the diameter of the throat, or to curve the vertical section. There is much difference of opinion among the makers of furnaces in the subject of the proper size for the throat of the furnace, the tendency of narrow throats would seem to be to consume more coal than wide ones; but in Pennsylvania and throughout the whole west, where narrow ones are preferred, the consumption of charcoal per ton of iron is from 160 to 180 bushels, while in the state of New York, and further east, where the furnace throats are wider, the consumption is from 120 to 130 bushels. Another subject which demands the most careful attention is the regulation of the blast. A weak charcoal will not bear a much greater pressure than from half a pound to five-eighths of a pound to the square inch; strong coarse charcoal will bear from three quarters of a pound to a pound; and again, it may be laid down as a rule that the larger the throat in proportion to the blast, the stronger ought to be the blast, and that a narrow top and wide bottom, which they permit a weaker blast, involve the loss of much fuel. In every case a careful regulation of the ores at charcoal furnaces will prove advantageous; this is the most careful of saving coal and blast, and of avoiding many annoyances in the working of the furnace.

With regard to hot blast, as applied to charcoal furnaces, Overman remarks, that under some circumstances it might be advantageous, but in others it is decidedly injurious; that it is, at least, a questionable improvement, and it may be doubted whether the manufacture of bar iron has derived any benefit from it; quaker iron, it has not. Hot blast is quite a help to imperfect workmen: it melts refractory ores, and delivers good foundry metal with facility.

English process of iron making.—Mr. Hunt, in his very valuable "Mineral Statistics," gives us the total quantity of pig iron produced in Great Britain in the year 1855:—2,456,064 tons, as follows.—

	Tons.
Northumberland	4,32,39
Derbyshire	666,194
Yorkshire, North Riding	152,370
" West Riding	93,000
Leicestershire	136,217
Lincolnshire	8,701
Gloucestershire	10,204
North Staffordshire	143,816
South Staffordshire and Worcestershire	97,200
Guernsey	11,000
North Devonshire	8,790
Went and Brecknock	2,040
North Wales	78,136
South Wales	663,479
Scotland	182,200

3,478,000

The number of furnaces in blast to furnish this amount of work are, in England, 322, distributed over 134 iron works; in Wales, 153, distributed over 47 works; and in Scotland, 133, over 32. To supply these furnaces there were raised 4,34,000 tons of ore, the estimated value of which, at a mean of 11s. per ton, was £4,77,400; that of the pig iron, at a mean price value of 31s. a ton, being 14,024,000. Of the amount of iron, 1,000 tons were agricultural cast-iron from the coal measures of North Devonshire and Worcestershire; nearly 1,000,000 tons from the coal measures of North and South Wales; and 2,217,000 tons agricultural cast-iron from Scotland. The annual production of pig iron over the whole world was estimated by Mr. Mackay in December, 1853, as follows:—

	Tons.
Great Britain	3,000,000
France	700,000
United States, &c. &c.	700,000
Prussia	200,000
Austria	200,000
Belgium	200,000
Russia	100,000
Sweden	100,000
Various German States	100,000
Other countries	200,000

6,000,000

From which it appears that the quantity of iron made annually in this island alone, is nearly, if not quite, as large as the total quantities produced in all other countries. The nature of the ore which forms the staple supply of the English furnaces (argillaceous carbonate), and the universal adoption of coke and coal as fuel, have led by necessity to a method of manufacture of iron quite peculiar to this country, and wholly inapplicable to those external elements that are carried on by means of charcoal. We shall proceed to describe the various steps of this manufacture in detail:—and first,

Of the blast furnace.—The blast furnaces at present in use are of various sizes, being from 35 to 60 feet in height, and at the *hoops*, or widest part, from 12 to 17 feet. The internal form commonly adopted consists essentially of two frustums of cones meeting each other at their bases, at the point where the widest part or the top of the *hoops* is situated. From this point the furnaces gradually contract both upwards to its mouth, and downwards to the level of the tuyeres below. The hearth, properly speaking,

is that part of the furnace only which receives the flux of metal and cinder, as they fall below the level of the tuyeres. It forms a short prolongation from that point of the lower inverted cone. From the lower upward the width gradually decreases to the *top* or head, which varies from 7 to 9 feet in diameter, according to the size of the furnace. The hearth is generally a cone, from 2½ to 3 feet square. The air is introduced by one, two, or three small apertures, called *registers*.

When two tubes are used, the diameter of each blow pipe is about three inches in diameter, and the pressure of the blast is from 24 to 30 lbs. on the square inch. To prevent the tubes from being cooled by the intense heat to which they are ex-

posed, a stream of cold water is caused constantly to flow round their vessels by an arrangement which will be immediately understood by an inspection of fig. 987, which represents a section of a tuyere near the vent, showing the cold water entering the space by the tube *a*, and the hot water running off by the tube *b*. The upper part of the furnace above the boches is called the *throat* or *body*. It is formed by an interior lining of fire-bricks, about 14 inches in thickness, between which and the exterior masonry is a lining of less refractory and comparatively porous air bricks, to allow for the escape of aqueous vapour. In the base of the furnace four arches are left; the back and sides are called *taps*, a *house*, the front is called the *chimney* *fall*; the bottom of the furnace is formed either of large

blocks of coarse gravel or of large fire-bricks. The materials are charged into the furnace through the tassel head, which is provided with one or more apertures for the purpose. The general form of a blast furnace is shown in fig. 986, and the following measurements represent the interior structure of two that worked well. —

	No. 1.	No. 2.
Height from the hearth to the throat or mouth	45	69
Height of the crucible or hearth	8	6
" of the boches	30	12
" of the cone	8	12
" of the chimney or mouth	2	2
Width of the bottom of the hearth	3	2
" at its upper end	12	17
" of the boches†	12	11
" at one-third of the belly	8	9
" at two-thirds of ditto	4	5
" at mouth	5	5
Inclination of the boches‡		

Fig. 989 represents the hearth and boches in a vertical side section. *a* is the *tuyere* stone, and *b* the *tuyere* plate, for confining the liquid metal in the hearth. The latter is wedged firmly into the side walls of the hearth; *c* is the dam-stone, which occupies the whole breadth of the bottom of the hearth, excepting about six inches, which space, when the furnace is at work, is filled before every cast with a strong binding sand. This stone is fixed in place by a cast iron plate *d*, called the *dam plate*, of considerable thickness and proper shape. The top of the dam-stone, or rather the notch of the dam-plate, lies from 4 to 8 inches under the level of the tuyere hole. The space under the tuyere plate, for 5 or 6 inches down, is rammed full for every cast with a strong loamy earth or even fine clay, a process called *tuyere stopping*.

* The width of the hearth varies greatly in the furnaces in different localities. In Scotland it varies from 6 to 8 feet; in the Welsh furnaces from 8 to 10 feet. When coke is used as fuel Mr. Trueman thinks 6 feet a sufficient width for all purposes; but with coal, with inclined furnaces, 16 to 19 feet across the boches, he thinks a 7 feet hearth to be more advantageous.

† The diameter of the boches in some of the Welsh furnaces is as much as from 14 to 16 feet.

‡ The angle with which the boches rise in different furnaces varies from 80° to 90°. Mr. Trueman thinks that when the full smelting power of the furnace is desired, the angle should not be less than 70°, which is about that of the Dutch furnaces.

The blowing machine employed in Scotland is generally run over by steam, in which a screw is fixed at each end of the cylinder, and made to revolve in the same way. The valves are top and bottom of the blowing cylinders are half covered with valves, which open and close when the vacuum is made with the cylinder, and afterwards closed by their own weight. A cylinder mounted on the top of the blast is exposed to the pressure both in the interior and exterior, whence blowing machines are always double-acting.

959

The pressure of the air is made to vary through a very considerable range, according to the nature of the fuel, and the season of the year; for as to ensure the atmosphere is well saturated it must be heated with a compensating force. The heat is from 11 to 15 pounds on the cubic foot, the average in Scotland being 13 lbs. The pressure is best given through a valve, the air being also very with the nature of the fuel and the air.

In a large apparatus employed at the Cyfarthfa works, moved by a full horse steam power, the piston rod of the blowing cylinder is connected by a parallel motion mechanism with the opposite end of the working beam of the steam engine. The cylinder is 9 feet 4 inches diameter, and 11 feet 6 inches high. The piston has a stroke 8 feet long, and it rises 13 inches in the cylinder. By calculating the area of the space passed by the piston in a minute, and supposing that the volume of the air expanded is equal to only 40 per cent. of that space, we find that 14,500 cubic feet of air are expelled every minute. Hence a horse power applied to blowing machinery of this nature gives an average of 1.7 cubic feet of air per minute.

At the establishment of Cyfarthfa for blowing iron and making furnace and the other corresponding works, three steam engines are employed, one of 100 horse power, another of 80, and a third of 10, which constitute on the whole a force of 190 horses, or 24 horses and 1/4 per furnace, supplying the fires to consume one-fifth of the blast. In the whole of the works of Messrs. Crawshaw, the proprietors of Cyfarthfa, the power of about 140 horses is expended in blowing 12 cooling furnaces and their satellite fires, which give from 2 to 2 1/2 lbs. of air per cubic foot of air per minute for the finest. Each of the furnace measures about 3.507 cubic feet of air per minute.

The form of the blast furnace from the boilers to the throat is explained in fig. 959 as a truncated cone, and such was formerly in variably the construction; but years have however considerable variations have been introduced. In Scotland the body of the furnace frequently is carried up cylindrical, or nearly so, for a considerable height, terminating with the usual truncated cone to the mouth; in other places a curved line is substituted for a straight one. The form adopted in some furnaces recently erected at Fife and Blair is shown in fig. 1000.

The diameter of the throat or filling place is a subject of very great importance to the operation of the furnace. Mr. Ironmasters are, we believe, agreed as to the propriety of the narrow top formerly adopted; the waste of fuel in such furnaces, where the width of the throat scarcely exceeds one-fourth of the diameter of the furnace, was very great, the average yield of coal to the ton of crude iron exceeding 8 tons; by enlarging the throat to one-third, the consumption of coal was reduced to 4 tons, and by enlarging the throat to one-half it was reduced to 2 tons. Mr. Trautman states that on reducing the diameter of the throat of a furnace at Glasgow from 9 feet to 6, the make of pig iron weekly fell off from 97 tons, to an irregular make of from 50 to 70 tons; and that while with the 9 feet throat the consumption of coal was 45 cwts. to the ton of iron, it rose with the 6 feet throat to 75 and 90 cwts., the quality of the iron being exceedingly bad. On enlarging the throat to 9 feet, the make, for a period of 6 months, averaged over 100 tons, with a good yield of coal and other materials. Mr. Trautman appears to question the utility of reducing the diameter of the furnace at the top, which was only adopted in the first place from an erroneous impression that the furnace could be filled best through a contracted mouth; but it may be questioned whether this widening of the throat may not be carried too far, so as to disperse the heated gases too rapidly, and whether a diameter much greater than one-half of the largest diameters of the furnace above the boilers can with safety be adopted. On this subject Mr. Kenyon Blackwell says, "If that part of the blast

furnace communicating at the point where it attains its greatest width were continued of the same wide dimensions upwards to its mouth, two objectionable results would ensue:

first the upper part of the furnace would be cooled by the too rapid dispersion of the

ascending column of heated gases; and by the entire absence of the reverberating effect of the contracted mouth; and secondly, the materials could not be equally spread over the firing holes over so wide a surface. The diameter of the upper part furnace ought, therefore, to be such as will cause the materials thrown in at the firing holes to distribute themselves equally in their descent over every part of the internal area of the furnace, and will produce such a reverberation only of heat as shall be sufficient to expel the water and carbonic acid contained in the materials, without consuming any of the carbon of the fuel, which ought to remain intact until it reaches the lower regions of the furnace, where it is required as carbonic oxide, and produces the reactions on which the reduction of the ore depends."

Calcination of the ironstone.—

This is effected either in kilns, or in the open air; the object being to separate carbonic acid, water, sulphur, and other substances volatile, at a red heat. The operation is performed most effectually, and probably at the smallest cost, in kilns. The interior shape of the calcining kilns differs in different works, but they may all be reduced to that of the common lamp-kiln. A coal fire is first lighted at the bottom of the kiln, and the ironstone is placed over and around, until the floor is covered with red hot ore; a fresh layer of ironstone, with about 3 per cent. of coal, is then laid on, to the depth of 6 or 9 inches; and when this is red hot, a second layer is added, and so on gradually till the kiln is filled; by the time this is done, the lowermost layer is cold and fit to draw, so that the working of the kiln is a continuous operation. When the ore is calcined in the open air, a heap mingled with small coal (if necessary), is piled up over a stratum of larger pieces of coal, the heap being 3 or 6 feet high, by 15 or 20 broad. The fire is applied at the windward end, and after it has burnt a cer-

1001

there a third, and so on; but the pieces constantly diminish in size until the whole measures 6 feet in height. From the bottom of the heap is then made, without particular care to the arrangement, the largest piece below and the smallest above, until it has reached a height of about 3 feet. To increase the heat, sticks of charcoal are placed, of 2 feet from each side, projecting above throughout the whole length of the ridge, which, when subsequently removed, leave vacant spaces for the introduction of burning coal. The ridge, being thus filled at once from 100 feet to 200, extends to the north and south. As soon as the lower strata of the stack wastes and flows down at any one part, and a burning of soft coals has commenced, the ridge is frequently topped the progress of the fire by means of a small pointed coal door, regulating the operation until the whole ridge is consumed, when it is left two or three days to cool; the covering on the side exposed to the wind is removed to clear and covered in stormy weather. When the fire is nearly extinguished, which occurs in two or three days, the ridge is drawn. The ridge of stack is small, but not very economical. The fire proceeding from the upper part of the ridge in a downward direction, leaves the lower and inferior parts, sometimes the whole of the upper strata, to waste before that in the inferior has acquired the temperature necessary for charring, and is still in want of a supply of air, which cannot be furnished from within, and must not be excluded by a covering. During the time, therefore, that the lower part of the heap are being converted into coke, the upper part is being rapidly, though unavoidably, consumed. For further details respecting the ridge see the articles Coal and Coals.

"The *bellows*" is a cold blast furnace is an operation which requires much fuel and expense. A fire of wood is first lighted on the hearth, upon this is placed a quantity of coke, and when the whole is well kindled, the furnace is filled to the throat with regular charges of calcined ore, limestone, and coke, and the blast, which should at first be moderate, is turned on. At the works around Merthyr Tydfil, the first charges generally consist of 3 cwts. of calcined argillaceous ore, and 1½ cwt. limestone, to 4 cwts. of rich coke; this burden is kept on for about 10 days, it is then increased to 6 cwts. of calcined ore and 2½ cwt. of limestone (*Truran*). The cinders usually make their appearance in about 12 hours after the blowing, the metal flows in about 10 hours after, collecting in the hearth to the extent of four or five tons in 24 hours after blowing. If all goes on well about 22 tons of metal will be produced in the first week, 34 tons in the second, 55 in the third, and 70 tons in the fourth; after 10 or 12 weeks the produce will average 110 tons. If during the furnace in its infancy a much greater produce of iron may be obtained, than in the maturity of its subsequent working. Mr. *Truran* relates the following case in point. A furnace was blown in at the Abercromby works with such volumes of blast and rich burden of materials that a cast of 20 tons was obtained within 14 hours after applying blast. The first week's blowing produced 260 tons, at which rate it continued for two or three weeks, when it rapidly diminished, falling as low as 10 tons for one week's make. From this deplorable state it was made to produce 26 tons, and, after considerable delay, 110 tons; but with a large increase in the yield of materials over that at the other furnaces. When a furnace is first blown in it should be made to produce grey iron; but the tendency of forcing is to produce a white iron with a dark smothering cinder.

The quantity of air thrown into a blast furnace in full work is enormous, exceeding in weight the bulk of all the soiled materials used in smelting. A furnace working on ordinary iron of a capacity of 275 yards receives 3390 cubic feet of air per minute, which amounts weekly to 169½ tons; when working on white iron a larger volume of blast is employed, averaging 7870 cubic feet per minute, or 2315 tons per week.

The disorders to which blast furnaces are liable have a tendency to produce white cast iron. The colour of the slag or scoria is the surest test of these derangements, as it indicates the quality of the produce. If the furnace is yielding an iron proper for casting into moulds the slag has a greenish or buff verification and is slightly translucent. When the dose of lime is increased the slag becomes opaque, dull, and of a greenish yellow tint, with blue crystallized scales. Lastly, when the furnace is producing white metal, the slag are more or less black and glassy. The scoria from a coke are much more loaded with lime than those from a charcoal blast furnace. This excess of lime appears adapted to absorb and carry off the sulphur which would otherwise injure the quality of the iron. From numerous analyses we have made of blast furnace cinders we select the following as illustrating their general composition under different conditions of the furnace.

Analysis of Blast Furnace Cinders. (See No. 46.)

The following table exhibits the "yield" of blast iron per ton of the iron ore, as varied by the blast. During the month of July 1871, there were consumed in four furnaces at New Vale 1364 tons 14 cwt. of coke, 1779 tons of cast iron, 14 tons of charcoal iron, 1818 tons 10 cwt. of red iron, 1847 tons of cast iron cinders, and 1236 tons 7 cwt. of blast iron. The quantity of pig iron made was 1200 tons 7 cwt. —

The "cinders" mentioned in the foregoing table are not those from the blast furnace, but are derived from the cast iron during the process of "refining," "puddling," &c., by which the cast iron is converted into wrought iron. These cinders are very rich in iron, which exists in them principally in the form of a scale of the proxide. They often occur beautifully crystallized, particularly after they have been calcined, an operation which is always performed on them in well conducted works, and which has for its object the removal of the sulphur and the proxide of a portion of the iron. These cinders being very rich in iron, are always contaminated to a considerable extent with both sulphur and phosphorus, as might be expected, seeing that they are the results of operations which have for their object the removal of the foreign matters contained in the pig iron. The tendency of the former is to make the metal what is called "hot short," so that it cannot be worked while hot under the hammer; the tendency of the latter is to make the iron "cold short," so that it breaks when an attempt is made to bend it when cold. The separation of sulphur is very perfectly effected by the calcination of the cinder, and it is interesting to trace the progress of its gradual elimination. In some parts of the heap (which often contains several thousand tons of cinder) large masses of prismatic crystals of pure sulphur may be found, but usually nearly the entire surface of the heap is covered with a thin layer of sulphate of iron, sometimes crystallized, but generally in various stages of decomposition; lower down in the heap, where the heat is greater, the sulphate of iron disappears, and in its place red oxide of iron, without a trace of sulphur is found. In calcining a heap of cinder care is always taken not to allow the heat to rise too high, or increase so much as to cause the cinder to be fused, involving the necessity of blasting, which entails much expense. After the heap has been burning for some months, streams of water are directed over the surface, by

which much soluble sulphate of iron is removed. Unfortunately, the process of calcination does not remove any of the phosphoric acid, which enters a judicious complement of the cinders in the blast furnace. We have repeatedly submitted "forge cinders" to analysis, and give in the following table the average results of our experiments.

Hot blast — One of the greatest improvements ever made by simple means in any manufacture, is the employment of hot air instead of the ordinary blast of the atmosphere, in supplying the blast of furnaces for smelting and fusing iron. The discovery of the superior power of a hot over a cold blast in fusing refractory lumps of cast iron, was accidentally observed by Mr. James Beaumont Neilson, engineer to the Glasgow Gas Works, about the year 1827, at a smith's forge in that city, and it was made the subject of a patent in the month of September in the following year. No particular construction of apparatus was described by the inventor by which the air was to be heated, and conveyed to the furnace; but it was merely stated that the air may be heated in a chamber or closed vessel, having a fire under it, or in a vessel connected in any convenient manner with the forge or furnace. From this vessel the air is to be forced by means of a bellows into the furnace. The quantity of surface which a heating furnace is required to have for a forge, is about 1,260 cubic feet; for a cupola furnace, about 10,000 cubic inches. The vessel may be enclosed in brickwork, or fixed in any other manner that may be found desirable, the application of heated air in any way to furnaces or forges, for the purposes of working iron, being the subject claimed as constituting the invention.

Wherever a forced stream of air is employed for combustion, the resulting temperature must evidently be impaired by the coldness of the air injected upon the fuel. The heat developed in combustion is distributed to three portions; one is communicated to the remaining fuel; another is communicated to the atmosphere and to the volatile products of combustion; and a third to the iron and fluxes, or other surrounding matter, to be afterwards dissipated by wider diffusion. This inevitable distribution takes place in such a way, that there is a nearly equal temperature over the whole extent of a fire-place, in which an equal degree of combustion exists.

We thus perceive that if the air and the coal be very cold, the portions of heat absorbed by them might be very considerable, and sufficient to prevent the resulting temperature from rising to a proper pitch; but if they were very hot they would absorb less caloric, and would leave more to elevate the common temperature. Let us suppose two furnaces charged with burning fuel, into one of which cold air is blown, and into the other hot air, in the same quantity. In the same time, nearly equal quantities of fuel will be consumed with a nearly equal production of heat; but notwithstanding this, there will not be the same degree of heat in the two furnaces, for the one which receives the hot air will be hotter by all the excess of heat in its air above that of the other, since the former air adds to the heat while the latter abstracts from it. Nor are we to imagine that by injecting a little more cold air into the one furnace, we can raise its temperature to that of the other. With more air indeed we should burn more coals in the same time, and we should produce a greater quantity of heat, but this heat being diffused proportionally among more considerable masses of matter, would not produce a greater temperature; we should have a larger space heated, but not a greater intensity of heat in the same space.

Thus, according to the physical principles of the production and distribution of heat, fires fed with hot air should, with the same fuel, rise to a higher pitch of tem-

perature than fires fed with common cold air. This consequence is independent of the masses, being as true for a small stove which burns only an ounce of charcoal in a minute, as for a furnace which burns a hundred-weight; but the excess of temperature produced by hot air cannot be the same in small fires as in great, because the waste of heat is usually less the more fuel is burned.

This principle may be rendered still more evident by a numerical illustration. Let us take, for example, a blast furnace, into which 600 cubic feet of air are blown per minute; suppose it to contain no ore but merely coal or coke, and that it has been burning long enough to have arrived at the equilibrium of temperature, and let us see what excess of temperature it would have if blown with air of 300°C . (572°F .), instead of being blown with air at 0°C .

600 cubic feet of air, under the mean temperature and pressure, weigh a little more than 45 pounds avoirdupois; they contain 10½ pounds of oxygen, which would burn very nearly 4 pounds of carbon, and disengage 16,000 times as much heat as would raise by one degree per cent. the temperature of two pounds of water. These 16,000 portions of heat, produced every minute, will replace 16,000 other portions of heat, dissipated by the sides of the furnace, and employed in heating the gases which escape from its mouth. This must take place in order to establish the assumed equilibrium of caloric.

1002

If the 45 pounds of air be heated beforehand up to 300°C ., they will contain about the eighth part of the heat of the 16,000 disengaged by the combustion, and there will be therefore in the same space one-eighth of heat more, which

will be ready to operate upon any bodies within its range, and to heat them one-eighth more. Thus the blast of 300° C. gives a temperature which is nine-eighths of the blast at zero C., or at even the ordinary atmospheric temperature; and as we may reckon at from $2,300^{\circ}$ to $2,700^{\circ}$ F. (from $1,200^{\circ}$ to $1,500^{\circ}$ C.), the temperature of blast furnaces worked in the common way, we perceive that the hot-air blast produces an increase of temperature equal to from 270° to 360° F.

Now in order to appreciate the immense effects which this excess of temperature may produce in metallurgic operations, we must consider that often only a few degrees more temperature are required to modify the state of a fusible body, or to determine the play of affinities dominant at lower degrees of heat. Water is solid at 1° under 32° F.; it is liquid at 1° above. Every fusible body has a determinate melting point, a very few degrees above which it is quite fluid, though it may

be partly below it. The same observation applies to ordinary chemical affinities. Charcoal, for example, which reduces the greater part of metallic oxides, begins to do so only at a determinate pitch of temperature, under which it is inoperative, but a

few degrees above, it is in general lively and complete. It is unnecessary in this article to enter into any more details, to show the balance of a few degrees of heat more or less in a furnace upon chemical operations, or merely upon physical changes of state.

FIG. 1002, 1003, exhibit the apparatus of the hot blast as mounted at the Finner Park works, belonging to William Jessop, Esq. in every respect to detail. The drawings from which the wood cuts are minutely copied were kindly furnished for this work by Mr. Joseph Glyn, F.R.S., the distinguished engineer of the Railway Iron Works.

The resulting furnaces have now generally three systems, and three sets of air heating furnaces. The figures show two sets heat together; the third set being attached on account of peculiar local circumstances. The air enters the horizontal pipe A, in the ground plan, *see* 1002, on one side of the arched or siphon pipes, shown in upright section in *see* 1003, and passes through three pipes to the horizontal pipe B, on the other side, whence it proceeds to the blast furnace. These siphon pipes are flattened laterally, their section being a parabola, to give more heating surface, and also more depth of pipe (in the vertical plane), so as to make it stronger, and less liable to bend by its own weight, when exposed by the red heat. This system of arched pipe apparatus is set in a kind of oven, from which the flue is taken out at the top of it, but it there again descends, before it reaches the chimney, entering it nearly at the level of the fire grate, (as with coal gas retorts). By this arrangement, the pipes are kept in a bath of ignited air, and not exposed to the corroding influence of a current of flame. The places and directions of these oven flues are plainly marked in the drawing.

Fig. 1001 is a plan of the blast furnace, drawn to a smaller scale than that of the preceding figures.

The three sets of hot-blast apparatus all communicate with one line of conducting

pipes, A, which leads to the furnace. Thus in case of repairs being required in one set, the other two may be kept in full activity, capable of supplying abundance of hot air to the blast, though of a somewhat lower temperature. See SMELTING for constructions of different blast furnaces; also PUDLING.

During a visit which Dr. Hve made to Mr. Jessop, at Brierly, he found this eminent and very ingenious iron-master had made several improvements upon his hot-blast arrangements, whereby he prevented the alteration of form to which the angled pipes were subject at a high temperature, as also that he was about to employ five tuyères instead of three. For a drawing and explanation of his furnace-feeding apparatus, see SMELTING.

The experiments through which Mr. Nielson's important discovery was introduced into the iron manufacture, were made at the Clyde Iron Works, where the fuel generally made use of was coke, derived from splint coal; during its conversion into coke, this coal sustained a loss of 33 per cent. During the first six months of the year 1830, when all the cast iron in the Clyde Iron Works was made by means of the cold blast, a single ton of cast iron required for fuel to reduce it 8 tons $1\frac{1}{2}$ cwt. of coal, converted into coke. During the first six months of the following year, while the air was heated to near 300° F., 1 ton of cast iron required 3 tons $3\frac{1}{2}$ cwt. of coal converted into coke. The saving amounts to 3 tons 18 cwt. per ton of iron, from which must be deducted the coal used in heating the air, which was nearly 9 cwt. This great saving induced the Scotch iron-masters to try a higher temperature, and to substitute coke for coal; and during the first six months of the year 1833, the blast being heated to 600° F., 1 ton of cast iron was made with 2 tons $5\frac{1}{2}$ cwt. of coal. Add to this 8 cwt. of coal for heating, and we have 2 tons 13 $\frac{1}{2}$ cwt. of coal to make one ton of iron. An extraordinary impetus was given by this discovery to the iron manufacture in Scotland, where, from the peculiar nature of the coal, and from the circumstance that, with a heated blast, Mather's blackband ironstone could be exclusively used, its importance was more highly felt than in England and Wales. According to Mr. Finch's statement (Secretary's "History of the Iron Trade"), there were in 1830 only eight works in operation in Scotland, which made in that year 37,500 tons of pig iron; in 1838 there were eleven works, consisting of 41 furnaces, which made 147,500 tons, being an increase in eight years of 110,000 tons per annum; in 1839 there were 50 furnaces in blast, making 195,000 tons; in 1851, 750,000 tons of pig iron were made; and in 1856, with 137 furnaces in blast, the make rose to 860,500 tons. The influence of hot blast has likewise been felt in the anthracite district of South Wales, where that coal is now successfully used, and where several new furnaces have in consequence been erected. In short, notwithstanding the opposition with which the introduction of hot blast was met by engineers, as being destructive of the quality of the iron, so great have been the advantages derived from it, that at the present time more than nineteen-twentieths of the entire produce of the kingdom is made in furnaces blown with heated air.

Mr. Truran, in his recent work on the iron manufacture of Great Britain, gives it as his opinion that the effects of hot blast have been greatly exaggerated, and that it is to improvements in the preparation of fuel and ore in the furnaces, in blowing engines, and in the smelting process, far more than to the heating of the blast, that we must refer the great reduction in the yields of coal in recent times; he thinks that the comparatively large produce which has been obtained from the Scotch furnaces, is to be referred to the general use of carbonaceous ore, which melts at a low temperature; and which, from its comparative freedom from earthy matters, requires but a minimum dose of limestone for fluxing. Against this opinion of an English writer on iron smelting we may place that recorded by an American metallurgist, Mr. Overman, who has written a large and in many respects a valuable treatise on the manufacture of iron, as conducted in America. "The economical advantages arising from the application of hot blast, casting aside those cases in which cold blast will not work at all, are immense. The amount of fuel saved in anthracite and coke furnaces varies from 30 to 60 per cent. In addition to this, hot blast enables us to obtain nearly twice the quantity of iron within a given time that we should realise by cold blast. These advantages are far more striking with respect to anthracite coal than in relation to coke or to bituminous coal. By using hard charcoal, we can save 20 per cent. of fuel, and augment the product 50 per cent. From soft charcoal we shall derive but little benefit, at least where it is necessary to take the quality of the iron into consideration."

The following tables, embodying the general results of an extended series of experiments on the relative strength and other mechanical properties of cast iron, obtained by the hot and cold blasts, are extracted from a report presented to the British Association (1837) by Messrs. Eaton, Hodgkinson, and William Fairbairn.

Of the three columns of numbers, the first represents the strength or other quality

In the cold blast iron, the second that is the hot, the third is the ratio of the weight of the sample included in parentheses indicates the number of experiments from which the results have been deduced.

	Cold Blast.	Hot Blast.	Specific Gravity.
Carron Iron, No. 2.

These results contain nearly the whole of the information afforded by the investigation. From the numbers in the tables, it will be seen that in hot blast iron No. 1 cold blast somewhat surpasses hot blast in all the following particulars.—1, direct tensile strength; 2, compressive strength; 3, transverse strength; 4, power to resist impact; 5, modulus of elasticity or stiffness; 6, specific gravity; while the only numerical advantage possessed by the hot blast metal is that it bends a little more than the cold before it breaks. In No. 2 the advantages of the rival kinds are more nearly balanced, still rather in favour of the cold blast. No. 3 hot blast Carron iron resists both tension and compression better than cold blast of the same denomination; and No. 3 hot blast from the Devon works in Scotland is remarkably strong, while No. 3 cold blast is comparatively weak, notwithstanding its high specific gravity. On the whole it would appear from the experiments, that while the irons of No. 1 have been somewhat deteriorated in quality by the hot blast, those of No. 2 have been benefited by its molifying powers; while those of No. 3 have been but very slightly affected; and from the evidence brought forward, it is rendered highly probable that the introduction of a heated blast, whilst it has, perhaps, to a certain extent, injured the softer irons, has improved those of a harder nature; and considering the small deterioration that the irons of the quality No. 2 have sustained, and the apparent benefit of those of No. 3, together with the saving effected by the heated blast, there seems good reason for the process becoming so general as it has done.

The following general summary of results, as derived from the experiments of Messrs. Hodgkinson and Fairbairn on the transverse strength of hot and cold blast iron exhibits at one view the ultimatum of the whole investigation.

	Ratio of Strength that of Cast Iron being represented by 1000.	Ratio of Powers in static Impact: Cast Iron being 1000.

Dr. Thompson's chemical examination of several samples of hot and cold blast iron is appended to this report. According to the experiments of this distinguished chemist, iron smelted by hot blast contains a greater proportion of iron, and a smaller proportion of silicon, carbon, and aluminum, than when smelted by cold air. The mean specific gravity of 8 specimens of Scotch cold blast iron No. 1 was 7.074; the mean of 5 specimens of hot blast from the Carron and Clyde iron works was 7.0623, so that the density of cold blast iron is less than that of hot. The mean of 6 analyses of cold blast iron No. 1 gave 34 atoms of iron, 1 atom of carbon, silicon, and aluminum; the proportion of these three constituents being very nearly 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminum, consequently Scotch cold blast iron consists of 20 atoms of iron (with a little manganese), 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminum. The mean of 6 analyses of hot blast iron No. 1, gave 6 atoms of iron and manganese to 1 atom of carbon, silicon and aluminum, from which it would appear that cast iron smelted with a hot blast is purer than when the blast is cold. This however, is not the case, as the numerous analyses of both varieties that have been made during the last few years concur in proving. Hot blast grey iron smelted with mineral coal contains a much higher percentage of silicon than the same variety of cast iron smelted from the same ores by cold blast, in other respects, provided the process of reduction is complete, i.e. when little or no iron passes off with the slag, there is very little chemical difference between the two varieties, as will be seen in the following table, which contains the results of a series of analyses of hot and cold blast iron, which we have lately had occasion to make, under circumstances peculiarly favorable for instituting the comparison, the furnaces working with the same ores, and making the same class of iron, viz. good No. 3 grey pig.

The true reason of the frequent inferiority of hot blast iron has been correctly given by Mr. Blackwell. Furnaces blown with heated air exert greater reductive power

than those in which a cold blast is used. This has led, since the introduction of hot blast, to the employment in iron smelting of refractory coals so thoroughly selected, a large part of which have been ores of a composition calculated to produce soft iron, and is in fact the use of ores of this nature, far more than from any deterioration in quality, arising from a hot blast, that this inferiority of hot blast iron is to be ascribed.

Explanation of the waste gases given off from the furnace hear.—The agent in the blast furnace by which the oxide of iron is reduced is carbonous gas, the presence of which there is in great extent indispensable to the operation of the furnace. The flames rising from the heated hear, which make a blast furnace at night such an imposing object, are produced principally by the combustion of this gas, as resulting from contact with the oxygen of the atmosphere; the attention of practical men was first called to the enormous waste of heat which this carbon flame entailed by Messrs. Hansen and Moller, and the application of the gas to a useful purpose may be ranked next to that of the heated blast, as the most important of the recent improvements in the iron manufactory. The gases evolved from the furnace hear, when it is used as the fuel, contain the following constituents, viz. nitroge, ammonia, carbonous gas, carbonic oxide, light carburetted hydrogen, sulphur gas, carburetted hydrogen of carbonous composition, hydrogen, sulphuretted hydrogen, and aqueous vapour. The nature of the combustible gas stands in a relation so intimate to the changes suffered by the materials put into the furnace, that its different composition in the various regions of the furnace indicates the changes suffered by the materials introduced as they descend in their way to the entrance of the blast. Now as the examination of this column of air in its various heights in the furnace must be the key to the question upon which the theory and practice of the manufacture of iron depend, it was of the first importance to subject it to a rigid examination; this accordingly has been done by the above-named eminent chemists, and subsequently by Flebman. We shall return to a summary of the results they obtained presently, confining our attention at present to the composition of the gases at the mouth of the furnace, and to the methods which have been adopted to utilise them.

In order to arrive at a knowledge of the composition of these gases, M. Hansen first studied minutely the phenomena which would ensue were the furnace filled with fuel only: by a careful distillation of a known weight of coal, and analysing of the products, he obtained results embodied in the subjoined table:—

Carbon	68.925
Tar	13.254
Water	7.449
Light carburetted hydrogen	7.441
Carbonic oxide	1.135
Carbonic acid	1.073
Condensed hydrocarbon and olefiant gas	0.753
Sulphuretted hydrogen	0.549
Hydrogen	0.499
Ammonia	0.211
Nitrogen	0.035
	100.000

Now, in the furnace, the oxygen introduced by the blast is consumed in the immediate vicinity of the tuyère, being there converted into carbonic oxide, and the coal loses all its gaseous products of distillation much above the point at which its combustion commences, near in fact, the top of the furnace; the fuel with which the blast comes into contact is therefore coke, and upon calculating the amount of carbonic oxide produced by the combustion of 68.925 per cent. of carbon, and the nitrogen of the air expended in the combustion, we get as the composition by volume of the gases escaping from a furnace filled with Gasforth coal the following:—

Nitrogen	62.479
Carbonic oxide	13.173
Light carburetted hydrogen	2.527
Carbonic acid	0.139
Condensed hydrocarbon	0.151
Sulphuretted hydrogen	0.091
Hydrogen	1.431
Ammonia	0.070
	100.000

of the fuel is lost in the form of combustible matter still fit for use, and that only 1.46 per cent. of the whole fuel is retained in carrying out the process in the furnace.

The temperature which should be produced by the flame of the furnace gases when burnt with air, is found by dividing the units of heat, viz. 84374 arising from the combustion of 1 kilogramme of the gases by the number remaining when the quality of the products of combustion is multiplied by their specific heat (1.4625 + 0.0001) we thus get the number 57714 F., but this is below the truth, inasmuch as there is an accession of combustible gases at the mouth of the furnace, arising from the decomposition of the bluish products of the combustion of the coal in its passage over the red hot fuel. Making proper allowance for this, and using numbers derived from actual experiments, Messrs. Bunsen and Playfair calculated the temperature of the gases when generated under favourable conditions at 7814° F., and even this may be increased to 8000° F., a temperature far above that of most fires, by the using a blast sufficiently heated. In no long time, when gases can no longer be taken out to relieve them from the furnace till they really are waste, that is, until they have done their work in the furnace; it is obvious that no combustible matter could be removed from the lower regions of the furnace without seriously deranging the operations connected to the reduction and smelting of the ore. In order to remove the gases efficiently, and without injury to the working of the furnace, and in such a state as will permit their combustion to be effected with most advantage, the height of the furnace must be raised, the full width of the mouth being retained, and the gases must be withdrawn sufficiently far below the mouth for them to be obtained dry, and also beneath the point where they begin to enter into combustion from contact with the atmospheric air.

Various modes of collecting the gases have been tried; the best seems to be that adopted at Ebbw Vale, Sirhowy, and Cwm Celyn. A funnel-shaped casting, equal in its largest diameter to the throat of the furnace, projects into the interior a depth of 4 or 5 feet; the grid at the bottom, from 3 to 5 feet in diameter, is closed by a conical casting, the apex upwards, from which a chain proceeds to a lever having a counterpoise at the other end. (See fig 1000.) The materials are filled into the funnel-shaped receptacle, and are charged into the furnace with a uniform distribution, by lowering the cone by means of suitable machinery, which again returns it to its place when emptied. The circular space around the funnel, inside the furnace, forms a chamber

for the reception of the gases, from which they are conveyed by brick tunnels or iron piping to the place of combustion. The whole arrangement will be clearly understood

by an inspection of the accompanying plans, *Figs. 1005, 1006, 1007, 1008, 1009*, kindly furnished to the writer by the proprietor of the Cwm Celyn and Blaenau Iron Works.

Fig. 1007 shows the plan of extracting the gases which is adopted at the Brynbo Iron Works, near Wrexham, the same being the patent of C. E. Darby.

It consists of a large pipe or tube inserted into the middle of the top part of the furnace, which descends a short distance down into the materials, and is carried over the top of the side of the furnace in the form of a syphon, a continuation of which pipe is taken to the boilers, or hot air stoves, where the gas is burned in the usual way. The principal advantage claimed by this method, is that it puts no check on the free escape of the gases, by which the driving of the furnace is impeded, and the quality of the iron deteriorated. The patentee estimates the saving of fuel with two furnaces making 240 tons of iron per week, by applying the gas to the blast engine boilers and hot air stoves, at 1200 *l.* a year. *Tons* :—Consumption of fuel at engine and stoves equal to 7 cwt. of good coal per ton of iron, made at 3½ per cwt., is 24.00 *l.*, say 24. per ton on 12,480 tons, or 12480 *l.*

The causes of derangement in the working of blast furnaces when the gases are drawn off to be utilized elsewhere, have been diligently studied by Mr. George Parry, of Ebbw Vale; and he has kindly furnished me with the following resume of his observations, for insertion in this article.

The manner in which the waste gases were formerly collected, was by sinking an iron tube, 7 feet deep into the throat of the furnace, the diameter of the tube being

about 3 feet less than that of the throat, thus leaving an annular space of 18 inches between the walls of the furnace and the sides of the tube. From this space the gases were allowed to pass off by the pressure within the furnace, through a pipe which penetrated the ring and walls. When the tube was kept full of molten metal, about

only of the gas escaped into the open air, the rest passing into the annular chamber; and when this state of things was assumed, those troublesome adhesions of masses of semi-fused materials above and around the bushes, technically termed "seafish," occurred, with the usual accompaniments of black cinder and inferior iron. It is evident that when the tube was kept full of minerals, the contents acted as a loose stopper to the current of hot gases forced up by pressure from beneath, and diverted them towards the annular space where there was no such resistance, thus leaving the interior of the central parts of the furnace insufficiently supplied with the upward current, and consequently with heat; the minerals, on the other hand, surrounding this cold central core, were supplied with more than their usual quantity of heat, as was evidenced by the burning of tuyères, and by the destruction of the brickwork in their neighbourhood. In this state of things, the ores in the external portions of the furnace would become reduced and converted into grey metal; while those in the central portion would, according to the degree of deviation of the ascending current of heated gases from them, descend to the point of fusion either thoroughly deoxidized, and slightly carbonized, or possibly with a portion still in the state of oxide, and mixing there with the properly reduced ores, enter into fusion with them, producing a mixture of iron which must necessarily prove of inferior quality, and a black cinder from the unfused oxides. When the iron tube in the throat of the furnace was kept only partially filled with minerals, much more gas escaped into the open air, as might have been expected, and consequently more traversed the central parts of the furnace; and it was always observed that when that mode of filling was adopted, the furnace worked much better; but then the object, viz. that of economizing the gases, was not attained. Differently formed furnaces were found to be disturbed in different degrees by this system of drawing off the gases: the old conical narrow topped furnaces were affected very much less than the improved modern domed top furnaces of large capacity, from which all attempts to take off any useful portion of the gases proved absolute ruin. It might be argued, that as the same quantity of blast and fuel were used as heretofore, the ascending current of heated gases ought to produce the same deoxidizing and carbonizing effect on the superincumbent mass, whatever direction they might take in making their escape at the upper region of the furnace; for if the central part should not have been sufficiently acted upon, the external annulus would have more than its usual share of chemical influence. But when it is considered that iron is only capable of taking up a certain quantity of carbon, and no more, it follows that after having received this dose, its further exposure in the external parts of the furnace where the heated gases should can do nothing towards supplying the deficiency of carbon in the metal reduced in the central part. From these considerations it became evident, that no system of drawing off the gases around the sides, whether by the insertion of an iron tube into the throat, or by lateral openings through the walls into a chamber surrounding the top of the furnace, can be adopted without more or less injury to its action; and that the only unobjectionable mode would be to take the gases from a chamber above the surface of the minerals, thus equalizing the pressure on the whole sectional area of the mouth, and thereby allowing an equally free flow for the ascending current up the middle, as well as up the sides of the furnace. By this method the whole of the waste gases would become utilised, instead of a portion only, and the furnace would be restored to its original state, inasmuch as the direction of the flow of heated gases would not be interfered with by unequal resistance. To form this chamber, the furnace must be covered in, and fed through a hopper, a plan long adopted at the Codner Park Iron Works, with the supposed advantage of scattering the minerals around the sides of the furnace, and preventing their accumulating in the centre; a conical charger of this description, but fixed in the throat of the blast furnace, was in use at the Cyfartha Works more than half a century ago, the minerals being thrown by baskets to the centre of the cone, and allowed to roll down to the sides of the furnace, thus giving a cup form to the surface of the minerals, the larger lumps of course rolling to the centre, and affording a freer passage in that direction for the upward current. It was not, however, until January, 1851, that a trial was made, at the Ebbw Vale Works, of an apparatus of this description for collecting the gases. It was then supplied to one of the old forms of conical furnace with a narrow top, and the trial proved eminently successful, the furnace producing any quantity of iron required according to the burden, as usual. Several other furnaces were similarly furnished in and around the neighbourhood, and it was now thought that the principle of taking off the gases from a chamber above the surface of the minerals, together with the conical mode of charging, were the only indispensable conditions to success for all furnaces; and some even which were originally built too narrow at the mouth, were actually improved by the new method of charging, which did not allow of the sur-

form of the chimney rising higher than about 6 feet from the top; thus giving to the furnace a diminished height, and so a preponderance of its central charge a wider space. Further experiments, however, demonstrated the fallacy of this general conclusion.

A large lined furnace was furnished with the same kind of charging apparatus which proved so successful in former attempts, but to the advantage of all it turned out a complete failure, the same arrangements to measuring as in the former trials, where a portion of the gases only was retained, by adding a little hot blast to the top. Now the furnace could not be kindled without a 7 feet top, and as that depth the diameter was 18 ft. 6 in., owing to the steepness of the dome the actual width of the furnace was therefore 37 feet high, diameter of 44 feet, with a mouth 13 ft. 6 in., instead of 8 ft.; and at the same time raised by 30 feet above the ground, and of the walls as they are built, to each other in the same radial system of the furnace, a much freer draught of the gases up the furnace took place, and on boring a hole through the top of the furnace, in the neighbourhood of the furnace, it was found that 2 feet in, the ends and sides merely were of a white heat, but a little further on towards the centre, lumps of black burning coal were found, with iron ore which had not even at that a red heat. The charging apparatus had now raised with the furnace 3 feet, and the minerals drawn up an immense pile in the charging cup, thus enabling it to be kept full to within a short distance of the old mouth, after which the furnace worked as usual. That diminished height was not the cause of the bad working of the furnace was afterwards proved, the furnace having been blown out for repairs, and re-lined with brickwork, giving it that form and proportion demanded necessary, from the experience gained; the height being now only 37 feet instead of 44, and the diameter of the mouth 7 ft. 6 in., or one half of that of the former. The same charging apparatus which failed before, mounted 6 feet above the mouth, was used, and the furnace has now been working most successfully for 2 years, turning out as much as 160 tons of grey pig iron per week, or when the demand for white iron, 200 tons; economizing the waste of the gas, and at the same time the control of the manager as any furnace, either could it put out iron in readiness to be expected to be. It is clear, therefore, that the covering of the top has nothing whatever to do with the action of a furnace kept full to the mouth, and having the proper form and proportion as from that point downwards. The mouth must be understood to be that part of the furnace which represents the mean height of the surface of the minerals, and not the top of the masonry, and the proper arrangement should be that part in diameter to the bottom or widest part, and when the latter should be with reference to height in order to secure a uniform downward effect on the quality of the iron made, and on the yield of fuel. The case of perfectness can exist only when the isothermal lines in the furnace are parallel to the horizon. The temperature of the minerals at any given height above the tuyeres being the same through the whole horizontal sectional area at that height, and consequently arriving at the zone of fusion in an equally prepared state. If the mouth of the furnace be too wide, the heated gases have a greater tendency to pass up the sides than through the centre, thus destroying the horizontality of the lines of equal temperature, and giving them a curved form with the cooler side downwards; hence ores at different temperatures, and of various stages of preparation, will occupy any given horizontal sectional area of the furnace; these descending together and mixing in the zone of fusion, will produce evils in proportion to the extent of the deviation of the curves from a horizontal line. On the contrary, if the mouth of the furnace be too narrow in proportion to the other parts, we may expect an undue portion of the gases to pass up the centre, leaving the minerals around the sides comparatively unacted upon. It is easy to see that evils of the same kind as before must exist here, the isothermal lines becoming now concave downwards, instead of convex, giving as before, through any horizontal section of the furnace, ores at various temperatures, and at different stages of preparation or carburization, according to the depth which they may have attained in the furnace. There are several instances of furnaces originally built with too narrow tops, being greatly improved by widening them; this may conveniently be done by feeding them through a conical charger, which by lowering the surface of the minerals virtually increases the width of the mouth: on the other hand, furnaces having the opposite defect of being too wide at the top, may be better fitted in some extent, provided the walls are nearly perpendicular, or do not widen too rapidly downwards, by employing as large a cone as it is possible to work in the throat; for by the use of this feeder, the minerals must fall close to the sides, and the larger lumps roll to the axis of the furnace, and so facilitate the passage of the gases in that direction, broadening the surface a concave or cup form, and consequently a diminished height and resistance to the upward current in the middle. This principle of improving the

charging of such a blast-furnace is easily carried out to some extent in the open top furnaces where the gases are wasted. The charging plate is so placed as to prevent the nose of the barrow from passing any distance into the furnace; the minerals are thus discharged close to the side, the larger lumps have a tendency to roll over towards the centre, leaving the smaller at the rim walls, to check the upward current in that direction.

The above remarks will generally assist in furnishing an answer to the oft-repeated and very important question, "What form and proportions should a blast-furnace have to produce the best results in quality of iron, and in economy of fuel, whether worked on the open-top principle, or enclosed for the purpose of utilizing the waste gases?" Experience has proved that when the mouth of the furnace is one-half the diameter of the widest part, good work is obtained, and that any deviation from that proportion, if in excess, has been productive of great derangement in its action. The height of the furnace should also bear a certain proportion to the greatest diameter, in order to secure an uniform flow of the ascending current through all its parts; for if the widest part bear too great a relation to the height, the bushes must necessarily be of a low make, and consequently the minerals around the sides near their top be at too great a distance out of the direct line of passage of the ascending current, and consequently remain only partially prepared for fusion.

The proportions recommended by Mr. Parry, and which have been practically found most satisfactory in several instances, are as shown in fig. 1011. The mouth 1011 must be at a less depth than its own diameter. The shape of the furnace to this depth should be formed slightly *cambré* (cambered), for the purpose of giving to that region a larger capacity than would be obtained by a conical form. The radius of the curve should be at right angles to the axis of the furnace, and formed by a prolongation of the line representing the greatest diameter. When the radius is set at a great angle with this line, which is often done to give greater capacity to the widest part, the distortion produced by the obliqueness of the curve may leave a segment of the internal surface upon which the gases in their passage to the mouth, encounter greater evils than would be compensated for by increase of capacity. The curve is continued below the widest part of the furnace till it meets the top of the bushes *dd*, the angle of which should not be less than 70° , and start from the point of the tuyeres *ff*. The depth also from the widest part to the tuyeres should not be less than its own diameter plus half the diameter of the tuyeres. These proportions give a blast-furnace, of any determinate height fixed upon, the largest possible capacity it is capable of receiving, while remaining free from any distortion of form, likely to give a place for minerals to lie out of the way of the action of the upward gaseous current; when the height exceeds the proportion to its greatest diameter indicated in the figure, an unnecessary sacrifice in its capacity is the only loss entailed. The height above the mouth must be regulated by the kind of hopper used for charging, where it is intended to carry off the gases.

Doubtless when the true principle of collecting these gases without injury to the blast-furnace becomes more generally known, attention will be directed to the easiest and most convenient mode of introducing the minerals. The conical charger has only one disadvantage, that namely of allowing a great waste of gas during the charging; probably some kind of revolving hopper may be contrived to remedy this defect. It is of course assumed that the furnace is supplied with a proper quantity of blast, and of a density proportionable to the diameter across the tuyeres, so as to maintain a *convective* combination of the fuel to the very centre of the hearth, the top of which is indicated by the letters *ee*, for unless this is attained, a cold cone of mineral will remain in the centre, and produce derangements which no degree of perfection in the form of the furnace in the higher region can remove.

Theory of the blast-furnace.—Analyses of the gases from a furnace at Alfreton in Derbyshire, at various depths below the surface, gave to Messrs. Henson and Playfair the results embodied in the subjoined table. The furnace was supplied with 80 charges in the course of 24 hours, each charge consisting of 390 lbs. of coal, 420 lbs. of calcined ironstone, and 170 lbs. of limestone, the product being 140 lbs. of pig-iron. The gases were collected through a system of tubes of malleable iron, 1 inch in

diameter, and were removed in glass tubes 4 inches long, and $\frac{1}{2}$ of an inch in diameter. This was known to M. Bunsen as a gas analyst is a guarantee of the accuracy of the determinations.

Composition of the Gases taken from different depths in the Furnace.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.
	1 R.	1 R.	11 R.	11 R.	17 R.	22 R.	28 R.	33 R.	34 R.
Nitrogen	20.85	44.77	29.47	26.5	26.46	26.46	26.78	27.71	26.54
Carbonic acid	7.77	2.42	2.41	1.35	11.43	10.78	6.77	10.74	10.74
Carbonic oxide	34.5	47.34	47.14	14.2	19.17	17.43	27.01	21.48	27.03
Light carburetted hydrogen	2.73	9.23	4.76	7.13	9.36	6.46	1.64	2.11	2.11
Hydrogen	0.73	0.69	9.94	1.01	7.75	1.84	4.96	5.47	5.73
Olefiant gas	0.47	0.46	5.73	17	2.48	2.27	2.27	1.72	1.72
Cyanogen	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	1.34

From these analyses it appears —

1. That at a depth of 34 feet from the top, with a 2 feet 9 inches of the layer, the gas was entirely free from carbonic acid, but contained an appreciable quantity of cyanogen.

2. That the nitrogen is at a minimum at 14 feet.

3. That carburetted hydrogen is found so low as 24 feet, indicating that at that depth, coal must be undergoing the process of coking.

4. That hydrogen and olefiant gases are at a maximum at 14 feet.

5. That the proportions between the carbonic acid and carbonic oxide are irregular, which is probably to be explained by the fact that water is decomposed as its vapour passes through the layers of hot coal.

The average composition of the gas collected from the main shaft work in the blast furnace is somewhere between the two following numbers:

Nitrogen	20.85	27.71
Carbonic acid	7.77	6.77
Carbonic oxide	34.5	27.01
Light carburetted hydrogen	2.73	2.11
Hydrogen	0.73	5.47
Olefiant gas	0.47	1.72
Sulphuretted hydrogen	0.00	0.00
Ammonia	0.00	0.113
	100.000	100.000

The proportion of nitrogen to oxygen as an average deduced from these analyses is 79.2 to 20.8. The product of the combustion of coal gives the same proportions as those existing in atmospheric air, viz. 79.2 : 20.8. The excess of oxygen must therefore depend upon the carbonic acid of the limestone, and the oxygen of the ore given to carbon during the process of reduction. Now, so at a depth of 24 feet the gas collected contained 27.6 and 26.5 oxygen to 79.2 nitrogen, it is seen that at this depth the gas must already have accumulated all the oxygen of the ore, and the carbonic acid of the limestone; and the conclusion is drawn that in hot blast furnaces fed with coal, the reduction of the iron and the expulsion of the carbonic acid from the limestone takes place in the bosom of the furnace. The exact region of the furnace in which the melting of the iron and the formation of slag are effected is not exactly defined, but it is assumed that the point of fusion is at the top of the hearth. The region of reduction in a furnace smelting with coal must be much lower than when the fuel is coke or charcoal, because a large portion of the body of the furnace must be taken up in the process of coking, and the temperature is thereby so depressed, that it is sufficient neither for the reduction of the ore, nor for the expulsion of carbonic acid from the limestone.

The mean general results obtained by M. Edelman from a charcoal furnace at Cleval are given below. The methods of analysis adopted by this chemist were altogether different from those employed by Messrs. Bunsen and Playfair. For details we refer to his memoir in the *Annales des Mines*, vol. xix. p. 89, 1851.

No. of analysis .	I.	II.	III.		IV.	V.	VI.	VII.

Totals	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00
Oxygen, per 100 nitrogen	47.5	49.0	32.7	32.7	29.3	29.3	30.7	30.0
Carbon vapour, per 100 nitrogen	0.0	31.7	25.6	29.0	29.0	29.0	30.7	30.0

I. Gas taken a short time after the introducing of the charge; II. the same taken a quarter of an hour after charging; III. gas collected through a cast iron tube four inches in diameter, it rushed out with a noise and gave a sheet of flame, carrying with it particles of charcoal and dust; IV. gas collected by boring the masonry; it rushed out violently, burning with a blue coloured flame; V. the same taken an hour after; VI. gas collected by boring the masonry at the back of the furnace about $\frac{1}{2}$ foot above the tuyère; it burnt with a white flame giving off fumes of oxide of zinc; it was collected through porcelain tubes; VII. gas collected through gun barrels lined with porcelain, it was evolved with sufficient force to project scoria and even cast iron.

The furnace was working with cold blast under a pressure of $\frac{1}{4}$ inch of mercury. The charges had the following composition:—Charcoal, 255 lbs.; minerals (various), 337 lbs.; limestone, 251 lbs. Thirty-two charges were driven in twenty-four hours; the furnace was stopped after every twenty charges; the produce being 3970 lbs. of black cast-iron; the daily yield being about 6175 lbs.

The experiments show that while the carbonic acid progressively diminishes downwards, the carbonic oxide progressively increases, the former altogether disappearing at a depth of 37 feet. On examining the numbers representing the oxygen and carbon referred to 100 nitrogen, it is seen that they diminish progressively to a depth of 19 feet, the oxygen combined varying from 47.5 to 29.2. The proportion of carbon in the same zone rises from 25.5 to 32.8; a result brought about as much by the carbonic acid disengaged from the minerals as from the gaseous products of the distillation of the charcoal. It is seen that the reduction of the mineral is already considerably advanced at the depth of 19 feet; and this, so to speak, without any consumption of charcoal, but through the conversion of carbonic acid into carbonic oxide. The hydrogen decreases as the carbonic oxide increases; showing that this gas exercises no influence in the reduction of the ore.

The results obtained by M. Ebelmen from a coke furnace at Seraing were as under:—

No. of experiment	I.		II.		IV.		V.	VI.

I. Gas obtained by plunging an iron tube, three centimetres in diameter, about one foot into the furnace; II. the same; the gas burnt spontaneously; IV. two consecutive analyses of the same gas; V. the gas was collected by an iron tube; VI. gas collected by piercing the masonry two feet above the tuyères; the gas was accompanied by fumes of cyanide of potassium, but no cyanogen could be detached.

The furnace was 50 feet high; the air was supplied through two tuyères, and was Vol. II.

found to be 212. It was driven at the rate of 15.84 gallons per minute under a pressure of 3 of mercury. The gases were composed of, uncombined minerals, 1434 lbs.; hydrogen, 1434 lbs.; methane, 91 lbs.; coke, 1763 lbs. The metal was run every twelve hours, and 17,500 lbs. of white crystalline cast-iron obtained, which was run in thin plates and taken directly to the pouring-ladle. The yield of the mineral was 40 per cent., and the consumption of coke 1400 per 1000 of cast-iron, rising from 1800 to 2000 per 1000 of iron when the furnace was working in ordinary iron.

The analyses show a rapid diminution of carbonic acid, and indicate that in the upper regions of the furnace an equilibrium relation of iron takes place by the escape of carbon under the influence of the high temperature of the ascending gases. Between one and nine feet the furnace is calcined. The reduction of the ore takes place at this region by the conversion of iron oxide into carbonic acid, without change of volume and without consumption of fuel. The action in the by-product is too small to induce a supposition that a great volume of hydrogen is evolved; any notable quantity of carbon. The gases collected at a depth of about 12 feet represent about the mean composition of the gaseous mixture; from that point to a depth of 45 feet, two-thirds of the total height of the furnace, the gases do not sensibly vary, and are composed almost entirely of carbonic oxide and nitrogen. At 12 feet the oxygen is to the nitrogen as 25.9 to 100; in atmospheric air it is as 26.3 to 100. The difference, .36, represents the oxygen arising from the reduction of the oxides of iron constituting the *burge cinders*, which then is seen to take place between the tuyere and a depth of 12 feet. These oxides are well known to be decomposed with difficulty, but they are reduced at the high temperature prevailing in that zone of the furnace, and their reduction gives rise to a corresponding quantity of carbonic oxide, to a consumption of fuel, and to a considerable absorption of latent heat. The other minor ores are reduced higher up in the furnace, and this is common to all coke furnaces, being due to the high temperature of the ascending gases, a temperature much higher than exists in charcoal furnaces, a far larger quantity of combustible being consumed. Hence it is that iron ores can be economically used in coke furnaces, while in charcoal furnaces the introduction of small quantities only alters the working of the furnace, makes the iron white, and corrodes rapidly the walls of the furnace in consequence of the imperfect reduction.

From his radiometric experiments on the gases from coke and charcoal furnaces, Elbelen deduces the following conclusions:—

1. That the amount of carbonated hydrogen is too small to exercise any influence over the chemical phenomena of the furnace.
2. That the atmospheric air thrown into the furnace by the *tuyère* produces successively carbonic acid and carbonic oxide, at a small distance from the opening. The first of these reactions gives rise to an exceedingly high temperature; the second, on the contrary, causes a great absorption of latent heat, and a corresponding lowering of the temperature of the gaseous current. The limits of the *zone of fusion* bear relation to the space in which the transformation of carbonic acid into carbonic oxide takes place.
3. That the ascending current consisting of carbonic oxide and nitrogen, with a little hydrogen, produces in ascending two distinct effects: it communicates one part of its sensible heat to the materials of the descending column; it becomes charged with all the volatile products disengaged at different heights, and it reduces the oxide of iron to the metallic state. Sometimes this transformation gives rise to an increase in the quantity of carbonic oxide; sometimes, on the contrary, it effects the conversion of carbonic oxide into carbonic acid without change of volume, and without consumption of fuel. Whenever the reduction of oxide of iron takes place with the production of carbonic oxide, there is a consumption of fuel, and an absorption of latent heat. It is essential, therefore, to the good working of the furnace, that the minerals should arrive completely reduced to that part where the temperature is sufficiently elevated for the conversion of carbonic acid into carbonic oxide by contact with carbon; this condition is nearly always realised when the oxide of iron is in a free state in the mineral. The reduction of the oxide when in combination with silica requires, on the other hand, a high temperature, and it can only take place in that zone of the furnace where the carbonic acid has completely disappeared.
4. That the zone where carbonic oxide exists alone is much more extended in coke than in charcoal furnaces, and is nearer the mouth in the former than in the latter; it falls lower, however, in the cylinder with hot blast, the quantity of heat remaining the same.
5. That the volatile gaseous matters from the distillation of the charcoal pass into the escape gases, and exert no influence on the reduction of the minerals.

The mutual relation of the carbonic acid and carbonic oxide, which is observable

In the analyses of Ebelmen, is not far from those of Bunsen and Playfair; this is attributed by Ebelmen to the circumstance that the latter chemists collected their gases through narrow iron tubes, which, becoming intensely heated and partially clogged by the fragments of ore and fuel introduced by the rapid stream of gas, so modified the composition of the gases, that the analysis, however carefully conducted, could not represent accurately their real composition. Ebelmen collected his gases through wide tubes, and from the lower parts of the furnace, by piercing the solid masonry. It is obvious, however, that none but very general conclusions can be drawn from the analyses of the furnace gases, in whatever way they may be collected, for their composition cannot be the same under all circumstances, the nature of the fuel, the pressure of the blast, and (as Mr. Parry's experiments prove) the shape of the furnace itself, must each exert an influence in modifying the circumstances which affect their composition. Although, therefore, it is impossible to fix the precise regions of the furnace where the reduction of the oxide of iron begins to take place, that is, to define precisely the limits of the "zone of reduction," we may in considering the theory of the production of crude iron divide the furnace into four zones. 1. The zone of reduction; 2. The zone of carburization; 3. The zone of fusion; 4. The zone of oxidation. The zone of reduction will vary in extent, according as the furnace is working with coal or with coke; with hot blast or with cold. The zone of carburization commences just below the top of the blast, the reduced metal in a soft and malleable state here acquires carbon, its rapid working being retarded by the contraction which the sides of the furnace begin to undergo from this point downwards. As the carbonized metal passes through the zone of fusion it melts, together with the earthy matters which serve to protect it from the oxidizing effects of the fourth zone, that of oxidation, through which it passes in its passage to the crucible. If the temperature of the zones of fusion and oxidation be not much higher than the melting point of specular iron, the metal in the crucible will be white, with little or no graphite; and if the iron remain sufficiently long in the zone of carburization to take up the maximum quantity of carbon, it will be bright iron. The reduction of silicon appears to take place at about the melting temperature of specular iron: it exists therefore in small quantity in white iron, and in greatest abundance in the grey iron melted from refractory ores, which require a high temperature.

The proportion of carbonic acid in the gases obtained from different heights in a furnace, has been studied by MM. F. Montefiore Levi and Dr. Paul Schmidt (*Zeitschrift des Ingenieurvereins*, 1892). They found that the zone from which this gas is entirely absent is of very limited extent, for although it is not met with at a height of 8 feet from the tuyère, it exists at 9 feet to the extent of 4.78 per cent., above which point it diminishes up to 15 feet, where it is 0. From this point it again increases, amounting at a height of 30 feet to 3.5 per cent. It then gradually diminishes, until, at a point from 37 to 38 feet above the tuyère, it amounts to only 1.80 or 1.91 per cent.; after which it goes on increasing with rapidity and regularity up to the furnace mouth. The carbonic acid existing in the furnace gases between 15 and 30 feet is referred by these chemists to the decomposition of the limestone used as a flux; and its gradual diminution above this point indicates a reaction of considerable importance, that namely of the carbonic acid upon the ignited coke carbon being taken up and carbonic oxide formed. Now, the quantity of carbon taken up by 875 parts of carbonic acid to convert it into carbonic oxide, amounts to 75 parts, and as in the furnace experimented with, 20,000 kilogrammes of limestone, containing about 8000 kilogrammes of carbonic acid were consumed every 24 hours, a loss of fuel equivalent to 2175 kilogrammes of carbon was daily occasioned by the conversion of the carbonic acid into carbonic oxide, and this may be considered equivalent to 2175 kilogrammes of coke with 11 per cent. of ash. The heat absorbed by the conversion of the carbonic acid of the limestone into a gaseous state is found by calculation, taking the specific heat of carbonic acid at 0.22, and the heating power of coke at 6000, to be equivalent to that developed by the combustion of 322 kilogrammes of coke. Now it was demonstrated by Dulong that the quantity of heat disengaged in the conversion of carbon into carbonic oxide is much less than that disengaged in the conversion of carbonic oxide into carbonic acid, although the same quantity of oxygen is required in both cases. The conversion of carbonic acid into carbonic oxide by passing over ignited carbon, is essentially a twofold action; a combination of carbon with oxygen, and a decomposition of carbonic acid into carbonic oxide and oxygen; the former is accompanied by development, the latter by absorption of heat; the latter preponderates to such an extent as to indicate a loss of temperature equivalent to the heat developed by the combustion of 1609 kilogrammes of coke.

These considerations led the authors to employ barut lime in working blast furnaces, and thus to obviate the loss of heat; the results were not at first satisfactory, the management of the furnace being very difficult, and the slags black and pasty; but

consequently the working was regular and good, and the saving of coke and the increase of production are stated to have been very evident; moreover the raw iron was of better quality, and all the interior parts of the furnace, especially the tuyé pipe, remained in a much better state of preservation than when limestone was used. The following table shows the quantity of coke consumed for every 100 kilogrammes of raw iron, and the production during six months. The figures in the first column refer to the furnace, in which limestone alone was used; the second column to the same furnace, in which burnt lime alone was used; and the third column to the furnace in which limestone was used for three months, and burnt lime for the next thirty months.

Average from July to September - - -	- -	- -	147½	- -	- -	518,000

The very regular and uniform results given in this table, show that by the use of burnt lime, the consumption of coke for every 100 kil. grammes of raw iron was reduced by 14 to 15½ kilogrammes, while at the same time the production of iron increased, within a certain period, as much as 23 to 24 per cent.

Hitherto the opinion of metallurgists, with regard to the use of burnt lime, was rather unfavourable than otherwise, but since the above experiments were made (at Ougrée), it has been employed with good results in England and Wales, and as much as 12 kilogrammes of coke have, it is stated, been saved for every 100 kilogrammes of limestone, which was replaced by 63 of burnt lime.

Varieties and chemical constitution of cast iron.—In commerce there are four principal varieties of cast iron, known respectively as Nos. 1, 2, 3, and 4, or *dark grey*, *bright grey*, *mottled*, and *white*; these terms, although convenient, do not, however, indicate the intrinsic value of the iron thus denominated, as the variable qualities of ore, fuel, and limestone may exercise such an influence on the resulting crude iron, as to render a low denomination of one manufacturer of greater commercial value than a higher denomination of other makers. The general characters of the four varieties are these:—No. 1. Colour, dark grey, in large rounded grains, obtained commonly near the commencement of the casting when the furnace is in good working order, and when an excess of carbon is present; in flowing it appears pasty, and throws out blue scintillations. It exhibits a surface where crystalline vegetations develop themselves rapidly in very fine branches; it congeals or fixes very slowly; its surface, when cold, is smooth, concave, and often charged with plumbago; it has but a moderate tenacity, is tender under the file, and susceptible of a dull polish. When melted over again, it passes into No. 2, and forms the best castings. No. 2, colour bright grey, of small-grained structure, and interspersed only with small graphite lamina; possesses great tenacity, is easily filed, turned, and bored; may even be hammered to a certain extent; does not readily crack from change of temperature. No. 3 is a mixture of white and grey iron. On *strongly mottled* iron, little stars and spots of grey iron are found, interspersed in bright or flowery iron; *weakly mottled* iron exhibits white specks on a grey ground. In *streaked* iron, grey iron is found above and below, and bright iron in the middle, with strong demarcations. No. 4. *White* iron varies from tin white to greyish white; it is very brittle, cracking easily, even by change of temperature; it is extremely hard, sometimes even more so than

hardened steel, so that it will resist the strongest file, and scratches glass easily. Fracture sometimes laminar, sometimes lamino-radiating, sometimes finely splintered, sometimes dense and conchoidal. As the fracture changes from laminar to conchoidal, the colour likewise varies from white to greyish. Mean specific gravity, 7.5. Expands less than grey cast iron when heated, cannot be welded, because it becomes pasty at the very lowest welding heat. When heated to the melting point it does not suddenly pass into the fused state like grey pig iron, but is converted before fusing into a soft pasty mass. In this variety of pig iron the whole of the carbon is united to the iron; it is never used for casting, but always for conversion into malleable iron. The bright iron obtained from apathic iron ore contains the largest proportion of carbon (3.3 per cent. according to Karsten). A white iron is always the result of a derangement in the working of the furnace, though it by no means follows that when the iron is white the furnace must necessarily be in a deranged state, the presence of manganese, for example, has a tendency to make white cast iron; but the quality may be excellent. The white iron resulting from derangement flows imperfectly, and darts out in casting abundance of white scintillations; it fuses very quickly, and on cooling exhibits on its surface irregular asperities, which make it extremely rough; it is exceedingly hard, though it is easily broken, the fracture being radiated and lamellar; the bar iron it affords is of inferior description. This kind of iron is always produced when the furnace is carrying a heavy burden of large cinders containing sulphur and phosphorus.

Thus there are two distinct kinds of white cast iron: 1st. That obtained from ores containing a large proportion of manganese crystallising in large plates; this variety is highly prized for making steel. 2nd. That resulting from a heavy mineral burden, or from a general derangement of the furnace, or from the rapid cooling of fused grey iron crystallising in small plates; both are hard and brittle, the first more so than the last. Cast iron, which by slow cooling is grey, becomes white when it is cooled rapidly; on the other hand, when white iron is melted and allowed to cool very gradually, a portion of the carbon crystallises out as graphite, and grey cast iron is produced.

In some iron works six varieties of pig iron are recognised, which may be classified thus:—1. First foundry iron, large crystals; 2. Second foundry iron, large and small crystals mixed; 3. Dark grey, all small crystals; 4. Bright grey; 5. Mottled; 6. White, verging on mottled.

The subjoined table exhibits the composition of some different varieties of Continental, English, and American crude irons. The methods of determining the various elements which nearly always accompany cast iron, are given at the end of this article.

a. Very grey pig, from Leestach in the Harz, cold blast; b. Mottled iron, from the royal works in the Harz, cold blast; c. Normal grey pig, from the same works, hot blast; d. Grey charcoal pig, cold blast; e. White pig, from Farny, very short and brittle; f. American grey pig, charcoal; g. American mottled iron; h. American charcoal, white iron; i. German white charcoal iron, very crystalline; j. The same, but less crystalline; k. Grey Scotch coke pig, from the Calder Iron works; l. Scotch coke, No. 2 pig iron; m. Glenarries, No. 3 pig; n. Caubrookdale Lightstone best first foundry iron; o. Grey pig iron, from Dudley, Staffordshire; p. Ordinary Aberdare white pig; q. Grey slender pig; r. White crystalline pig iron, smelted from manganese ore; s. The same; t. The same; u. Ordinary white pig.

Besides the substances enumerated in the above table, other metals, such as copper, arsenic, chromium, titanium, cobalt, zinc, tin, aluminium, and the metals of the alkalis

and saline earths are occasionally found in crude iron, but very rarely in quantities that are at all affect the quality of the product. The nature of the quantities is composed of which has been given in the above analysis, &c. however, especially in the physical qualities of cast iron. We shall, therefore, offer a few observations on such.

1st. *Carbon*.—Iron may take up a very quantity of carbon up to a little over 3 per cent, at which point it becomes ductile; the amount that it should be able to dissolve in pig iron is equal to 1.5 (1.5) (1.5) (1.5) when a certain quantity of carbon is present in the iron, and 1.2 (1.2) is a certain limit, Fe^2C . The most highly carbonized iron which Faraday has obtained from pig iron, contained 1.5 per cent of carbon. There are some cases where the carbon content is even higher, but the extent of a pig-carbonized iron containing 1.5 per cent of carbon, is as iron containing under 6 per cent appears to be completely changed. The specific gravity of pure tetra-carbonized iron is 7.6; it is the same as that of all the varieties of iron, the melting point being 1400° (1400°) (1400°) (1400°). It is brittle and very white, and crystalline in oblique prisms, which are frequently tabular. According to Gault the carbon of iron existing in gray is the tetra-carbonized, Fe^2C , the crystals of which having a regular octahedral system, but they always appear in gray iron in the form of small octohedral groups. The specific gravity of pure tetra-carbonized iron, according to the same author is 7.1, and its composition is 97.1 iron and 2.9 carbon. As iron is iron gray, it is harder than steel, and is much less ductile than steel. The group of crystals which is found in cast iron is larger than those of the peculiar carbonized iron. Gault very ingeniously endeavours to show that in gray pig iron the carbon of the tetra-carbonized is partially replaced by sulphur, sulphur, and phosphorus, and the iron by manganese and other metals. In the case of the tetra-carbonized iron may be partially replaced by arsenic, phosphorus, or other, the diamond carbon appearing in the form of graphite the same decomposition is effected by heat, and specular iron, if exposed to a temperature considerably above its melting point, becomes gray; if cooled slowly, the graphite separates in large flakes, if rapidly, it remains in particles. Some metallurgists suppose that in gray cast iron, a portion only of the iron is chemically united with carbon, the rest of the metal being dissolved in the carbonized compound in the form of small particles. However to the opinion of Gault, that the whole mass of the iron is in a state of combination with the carbon-negative constituents, such as carbon, sulphur, phosphorus, and others. Thus in the white pig-iron of heavy burden (or) there is a deficiency of carbon, that is, some being replaced by sulphur and phosphorus.

Karsten gives as the mean of several analyses, 2.5 per cent as the quantity of carbon in cast-iron melted with charcoal from Spanish ore. He states that iron containing as little as 2.3 per cent. of carbon still retains the properties of cast-iron, particularly the faculty of separating graphite when allowed to cool slowly. With 2 per cent. of carbon iron is not forgeable, and scarcely so if it contains only 1.5 per cent. With this quantity of carbon it is steel, though not of the weldable kind (cast steel); even with so small a proportion of carbon as 1.75 per cent. it is weldable only in a slight degree; the latter property increases as the hardness of the iron decreases. An amount of from 1.4 to 1.5 per cent. of carbon in iron denotes the maximum of both hardness and strength. Iron containing 0.3 per cent. of carbon is a very soft steel, and forms the boundary between the steel (i.e. iron which may yet be hardened) and malleable or bar iron. These limits are perceptibly hindered if the iron be pure; and lower if it contain silicon, sulphur, and phosphorus.

The composition of the various carbonized iron, according to Karsten is as follows:—

	Fe^2C	Fe^2C	Fe^2C	Fe^2C	Fe^2C	Fe^2C
Iron	0.600	0.500	0.512	0.510	0.517	0.517
Carbon	0.400	0.510	0.513	0.511	0.517	0.517

In the blast furnace, the reduced iron may take up carbon in two different ways, 1. By immediate contact with the immediate fuel, and 2. By taking carbon from carbonic oxide; thus $\text{Fe} + 2\text{CO} = \text{Fe}^2\text{C} + \text{CO}_2$. That iron decomposes carbonic oxide is considered by Le Play and Laurent, to be proved by the following experiment: pure oxide of iron and charcoal were heated in two separate porcelain boats, placed in a glass tube; the air in the tube furnished oxygen to the carbon; carbonic oxide was formed, which was converted into carbonic acid, at the expense of the oxygen of the oxide of iron; the carbonic acid was again transformed into carbonic oxide, by taking up a fresh quantity of carbon, which was again converted into carbonic acid by taking oxygen from the oxide of iron, and this went on until the whole of the oxide of iron was reduced, the metallic iron then decomposed carbonic oxide, producing carbonic acid and carbide of iron; and this went on till a certain quantity of carbon had combined with the iron, when the action ceased. If the charcoal be very strongly ignited previous to the experiment, the carbonization of the

iron does not take place, neither does pure carbene oxide carbonise iron when passed over the metal at a red heat, the effect in the experiment above described may therefore be due to the carburised hydrogen evolved from the charcoal. Iron begins to take up carbon when heated only to the softening point, the carbon gradually penetrates the metal, converting it first into steel and then into cast-iron; conversely molten cast-iron gives up carbon to soft iron, which it converts into steel. When white iron (Fe^C) is heated with acids, nearly the whole of the carbon is eliminated in combination with hydrogen. Grey iron only gives up to hydrogen the carbon which was chemically combined with the iron, the uncombined carbon or graphite remains unacted upon; the dark spot produced upon grey iron by a drop of nitric acid arises from this separation of graphite. For the amounts of carbon in the different varieties of steel, see STEEL.

Phosphorus.—In very few specimens of crude iron is this element wholly absent; when it exists in small quantities only, it is said rather to improve the iron for castings, as it imparts to the metal the property of fusing tranquilly; in a larger proportion it weakens the iron. In like manner a very small quantity of phosphorus hardens bar iron without materially influencing the other properties, but when it exceeds 3 per cent. it renders the bar brittle, cold short, as it is termed. According to Schafhausen, both cast-iron and steel are improved by phosphorus and by arsenic; he found the latter in the celebrated Dannemora iron, and in the Lowmoor iron, and the former in the equally famous Rönneby (CCND) iron.

Sulphur. This element imparts to crude iron the property of becoming viscid, and of solidifying quickly with cavities and air-bubbles. It is not certain to what extent, or if at all, the presence of minute proportions of sulphur redacts either the tenacity or the toughness of cast-iron of given quality in other respects. It is stated in the Report of the Commission of Inquiry, as to the manufacture of iron in Sweden, on the authority of Schur and Muscherlich, that in certain Swedish works *pyrites* is thrown into the furnace with the other constituents of the charge, to produce the fine grey mottled iron required for gun founding, and it is added that the effect may be analogous to that of the oxidising flame in a reverberatory furnace. It is certain that sulphur possesses the property of concentrating carbon in iron; and as mottled iron is a mixture of white and grey iron, it is not difficult to see how the addition of pyrites may determine the formation of this variety of cast-iron in a furnace, which without it would produce grey iron only; but it is scarcely credible that any intelligent founder would resort to such a method of making iron for casting cannon, in which the highest possible degree of tenacity is required. The fine grey mottled iron, which from its tenacity is known to be best fitted for large castings, is said to be prepared without difficulty, by charging the furnace partly with roasted and partly with raw ore, and so regulating the blast that the yield shall be regular, and the slag nearly colourless; these two ores, having different degrees of fusibility, are reduced after different periods in the furnace, and hence afford one of them grey, and the other white iron, the result being, provided the minerals are properly proportioned, a mottled iron, harder and more tenacious than grey iron, obtained by mixing or by smelting in the cupola. It is desirable that the temperature of the furnace should be kept as low as possible, the production of dark grey graphitic iron resulting always from intensity of heat.

When sulphur is melted with iron containing the largest amount of chemically combined carbon, sulphuret of iron is formed on the surface; underneath a layer of graphite, and beneath that, a layer of iron with the maximum of carbon; and when grey iron containing 3.31 per cent. of graphite is melted with sulphur, white iron, containing iron 94.03, combined carbon 4.93, and no graphite, is formed. The tendency of sulphurous ores to produce white metal in their treatment in the blast furnace, has long been known; it was supposed that this was occasioned by the too great facility with which the sulphur gave to the cast iron, but ores containing large proportions of phosphoric acid will produce very grey iron, notwithstanding their fusibility, so that this explanation does not serve; these experiments above described point to the true reason. The sulphur present in the ore (if as sulphuric acid reduced in the furnace) enters into combination with the iron, displacing a corresponding proportion of carbon, which becomes concentrated in the remainder of the metal, forming white iron. To guard against this, and in order to obtain a metal which shall contain a minimum amount of sulphur, the slags should contain the maximum amount of lime, M. Berthier having shown that this earth decomposes sulphuret of iron at a high temperature, in the presence of carbon. M. Janoyer states, that the proportion of lime and silica in the slag may be as 54 to 56; it is doubtful whether such a highly basic cinder would be sufficiently fusible. Direct experiments, however, have shown that the amount of sulphur in cast-iron diminishes in proportion as the amount of lime in the slag increases. A still better flux is oxide of manganese, and it is found that when the

more iron than is required to constitute part of the burden of the furnace, may be lost, and may disappear from the crude iron. M. Jannoy believes that he has proved experimentally, that the whirling of cast iron around from a height of 10 to 15 feet, in part at least, is the cause of a portion of its carbon, and its volatility is due to the loss of sulphuret of carbon, by which the temperature of the furnace is lowered; but his experiments on this point require confirmation. The presence of a very small quantity of sulphur with very injuriously upon bar iron, an small proportion as it renders the metal "hot short," that is, incapable of being worked at a red-heat under the hammer. If the quantity of sulphur in the crude iron exceeds 0.4 per cent, it is scarcely possible to manufacture it into good wrought iron.

Silicon.—Like carbon this element enters into combination with iron in all proportions up to as high as 4 per cent. The largest quantity found by Karsten in cast-iron was 3.4 per cent., but in the above table a specimen (n) is quoted from the Brook Dale containing 4.08 per cent., and we have lately found it in a sample of Nova Scotia iron as high as 5.8 per cent. Generally speaking, grey cast-iron contains more silicon than white, and the greater the quantity of graphite in the metal, the larger the amount of silicon, because the higher the temperature of the furnace, but this again will depend materially on the quality of the coal, from the use of which the silicon is probably principally derived. A clean strong coal yielding a small percentage of ash furnishes a cast-iron with less silicon than an inferior coal, the inferior burden being the same. Pig-iron smelted with hot blast contains more silicon than when the blast is cold, because of the higher temperature which prevails in the furnace. Some analyses illustrating this fact have been already given. According to the experiments of MM. Jannoy and Gauthier the amount of silicon in hot blast cast-iron may be greatly influenced by varying the proportions of lime and silica in the furnace. Pig-iron obtained with a charge yielding a cinder in which the lime and alumina were to the silica as 7 to 10, had little strength, breaking readily, and analysis showed that it contained 8 per cent. of silicon. By increasing the amount of lime in the charge, so as to obtain a cinder in which the bases were to the silica as 8 to 10, and at the same time employing a blast of the highest attainable temperature, the iron produced had a much greater strength. When the proportions of lime to silica in the cinder was as 20 to 10, the iron contained only an insignificant amount of silicon, and the strength was increased in the proportions of 68 to 42. When the maximum quantity of lime was used the consumption of fuel was on the average increased to the extent of 4 per cent.

On reading the above account of the experiments of Messrs Jannoy and Gauthier, the writer of this article induced the furnace manager of the Moineau Works to increase the yields of lime on one of his furnaces to as great an extent as in his judgment it would bear, and when the furnace was under the full influence of the excess of flux to forward him samples of the grey pig for analysis. The following results show that, contrary to the statement of MM. Jannoy and Gauthier, no advantage as regards a diminution in the amount of silicon, was hereby obtained, the proportions of that element being not perceptibly altered, though there is a slight diminution observable in the percentage of sulphur.

	Grey pig. with normal burden of lime.	Grey pig. with extra burden of lime.
Sulphur	0.067	0.048
Silicon	2.900	2.930

As the presence of silicon in pig-iron affects to a remarkable degree the yield as well as the strength of puddled bars, it is of importance that this element should be removed as effectually as possible by a refining process before the crude iron is submitted to the puddling process. Pigs with 3 per cent. of silicon give about 6 per cent. of silica, and this requires somewhere about 12 per cent. of iron to form a cinder sufficiently fluid to allow the puddled iron to become aggregated into balls, this can of course be obtained only by burning that amount of iron in the puddling furnace after the expulsion of the carbon, and while the mass is in a powdery state. This powdery mass is composed of small granules of iron mixed up with a glazy infusible cinder. The puddler turns over this mass repeatedly to expose the iron to the oxidizing influence of the furnace; the silica now taking up sufficient oxide of iron to give it fluidity begins to separate from the iron, and forms a pool at the bottom. After some time the puddler, finding the mass of cinder accumulating pretty fast, makes the first attempt to "ball up." In order to save as much iron as possible, he keeps the damper down and works the powdery mass at as low a red heat as possible. The balls, even when made, will not bear much heat under the hammer without falling to pieces, hence an imperfect weld in the hammered mass and rolled bar is the result; and although the iron may be chemically pure it is deficient in strength. By protruding the process and wasting more iron, there is no doubt but that the iron might be im-

proved, for the cinder would become richer in oxide, more fluid, and consequently offer less resistance to a perfect weld. Iron, on the contrary, with a small percentage of silicon may be "killed up" directly it is "dried," and the short time required for that operation can be conducted at the best heat of the furnace. A good welding of the mass is the consequence, in which iron is strong, and the labour of the puddler in obtaining it is much less than in the former case. Every pound of silica must have twice its weight of iron to form a cinder sufficiently rich in oxide to allow the particles of iron to become properly agglutinated. Such being the influence of silicon on both the yield and the strength of wrought iron, and such being the waste attendant on its removal in the refinery, it becomes an object of much practical importance to prevent as far as possible the formation of a silicide of iron in the blast furnace, and the observations of MM. Janoyet and Gauthier on this point require careful verification.

Manganese.—The presence of this element in pig-iron does not appear to exert much influence either for good or for bad on the quality of the metal, and even when it exists in quantity amounting to 4 or 5 per cent. in the crude iron, it disappears almost entirely during the conversion of the cast-iron into wrought or malleable. It has already been observed that the cinder from iron smelted from manganese ores contains, generally speaking, more sulphur than slags or cinders from iron ores containing no manganese. We have had numerous opportunities of confirming this, and have therefore on this account alone attached much importance to the existence of manganese in iron ores; but our attention has more recently been directed to another point which we think especially worth notice of iron manufacturers, namely, to the almost perfect removal of phosphorus from pig-iron containing a very large proportion of that element, and at the same time a high percentage of manganese. As our experiments on this important point are still in progress, we shall merely here quote a few in illustration of the purifying action we have alluded to.

Iron made from a highly phosphorised ore containing no manganese:—

	Phosphorus per cent.
Pig	3.030
Puddled bar	0.838
Drawn down bar	0.572

The finished bar was cold short in the highest degree, it was in fact nearly worthless.

Iron made from a highly phosphorised ore containing a large per-centage of manganese.

	Phosphorus	Manganese
Pig	2.60	7.20
Puddled bar	0.20	0.20
Do.	0.20	
Finished bar	0.11	

The iron was carefully watched during the puddling process. It melted very thick, and took rather more work than usual; as soon as the boiling commenced it was very violent, the metal forcing itself out of the door hole until it was checked. When it "came to nature," as the workmen term it, it worked beautifully and stood any amount of heat, in fact the heat could with difficulty be raised to the requisite degree. The yield was 22 cwt. 2 qrs. 21 lbs. of pig to produce one ton (of 20 cwt.) of puddled bar; this is about the yield of good mine iron when properly puddled. The finished bar exhibited none of the cold short quality, it was exceedingly ductile, indeed excellent horseshoes were made from it. The puddling cinder had the following composition:—

Silica	8.240
Protoxide of iron	70.490
Oxide of manganese	12.500
Phosphoric acid	7.660
Sulphur335

99715

Other observations have shown that highly manganiferous pig (without phosphorus) is puddled with difficulty, and sometimes with considerable waste, so that the advantages of an alloy of manganese would seem to be confined to those varieties of crude iron into the composition of which phosphorus largely enters.

The Conversion of Crude or Carburised Iron into Malleable Iron.—This is effected by one or more operations, which are necessarily of an oxidising nature, the object being to eliminate from the cast iron the carbon in the form of carbonic oxide gas, and the silicon, sulphur, phosphorus, and other foreign bodies in the form of oxidised

products, which pass either partially or wholly to the hearth or elsewhere. The pig-iron is either admitted to a preliminary decarburization in the refining furnace, or is "refined," and the operation is then continued in a furnace equipped for the refining of cast-iron, or "puddling furnace," or the "puddling" operation of the crude metal is effected by the operation of the puddling furnace, by the process called "puddling." It is stated (*Howe*) that, at several works abroad, the attempt is even to progress of decarburization in the puddling or boiling furnace at that point in which the conversion has proceeded only so far as to leave the metal in the state of steel, or sub-martensite, but more commonly, and that a valuable product or puddled steel, not requiring remelting in the refining furnace, is thus obtained, but this is not the case.

Fig. 1012. Method of refining.—The refining furnace is composed of a body of brick-work, about 10 feet square, rising 10 feet above the surface of the ground. The hearth, the bottom of which is of refractory gneiss placed in the position of 11 feet deep, it is 10 feet wide, being in general 2 feet by 2, with the ground sloping parallel to the face of the tuyeres, and it is made of cast iron in four plates. On the side of the tuyeres there is a single brick wall, on the three other sides there is a brick wall, to prevent the external air from cooling the metal, which is always worked under an open shed or in the open air, but never in a space surrounded by walls. The chimney, from 15 to 18 feet high, is supported upon four columns of cast iron, and is placed about above the level of the hearth, in order that the labourers may work without restraint. The air is supplied by the blowing cylinders which supply the blast furnace, and enter the hearth through 6 tuyeres, so arranged that the current issuing from them on the opposite sides of the crucible are not disposed in the same place. These tuyeres, like those in the furnace in which cast iron is made, are provided with double rings, through which a current of cold water is constantly flowing, and each pipe is furnished with a suitable stop valve for regulating the velocity of the blast. The tuyeres are placed, at an angle of from 25° to 30°, so as to point upon the top of the metal as it flows. The quantity of air blown into the furnace is considerable, being nearly 400 cubic feet per minute for each finery. The ground plan of a finery is shown in Fig. 1012, A being the hearth, B the tapping hole, the chill mould, and C a view of the

valves of the tuyeres. The operation of refining crude iron is conducted as follows: A fire is lit in the centre of the hearth, which is first urged by a little coke, a charge of pig, about 2 tons, is then laid on, and the whole is covered up and covered with a heap of coke; the full power of the blast is then turned on, the cast iron melts, and the slag being gradually collects in the crucible, more coke being added as the first quantity burns away. The operation proceeds by itself, the melted metal is not stirred about as in some modes of refining, and the temperature is always kept high enough to preserve the metal liquid. During this stage the coals are observed continually heaving up, a movement due in part to the action of the blast, but in part to an expansion caused in the metal by the discharge of carbonic oxide gas. When all the pig-iron is collected at the bottom of the hearth, which happens in about two hours, it is blown vigorously for some time longer, the tap-hole is

opened, and the fine metal runs out with the slag into the chill mould, or pit, as it is called, which has been previously washed with a thin clay liquid, to prevent the refined metal from adhering to its surface. The chill mould is in a prolongation of the tapping hole; it is a heavy cast iron trough, about 10 feet long, 2 feet broad, and 2 to 2½ inches deep. The slag, from its inferior specific gravity, forms a crust on the surface of the metal: its separation is facilitated by throwing cold water in large quantities on the fluid mass immediately that the entire charge has left the refinery. This sudden chilling of the metal makes it exceedingly brittle, so that it can be broken into smaller pieces by heavy hammers, for the subsequent operation of puddling. The refined metal is very white, hard, and brittle, and possesses in general a fibrous radiated texture; or sometimes a cellular, including a considerable number of small spherical cavities, like a decomposed amygdaloid rock. The loss of iron in the refining process is very large, varying from 10 to 20 per cent. In the Welsh iron works, 1 ton of white iron takes from 1½ to 2 hours to refine, the consumption of coke being

from 6 to 8 cwts. and the loss about 3 cwts. Grey iron takes from 7 to 9 cwts. of coke per ton, the time required to produce being from 2½ to 3 hours, and the loss of iron per ton 4 cwt. The pig-iron is to be decarburised in the refinery, is frequently mixed with rich scrap-iron (for pig-iron), and occasionally with oxide of iron, the object being to protect the metal while in some degree from the oxidising effects of the blast, and to react on the carbon which it contains. The quantity employed depends on the degree to which the pig-iron is carburised. The crude iron, from which wrought iron of the best quality is produced, is that possessing a medium degree of carburisation, or what is generally termed grey pig-iron. White iron, which possesses an inferior degree of fluidity, is grey pig-iron, and which comes as it is termed more rapidly to nature, is that quality which is most generally employed in the manufacture of wrought iron, especially when the conversion is effected in the single operation of beating in the puddling furnace; but this species of pig-iron being the result of imperfect reaction in cooling, is always more impure than grey iron obtained from the same materials, and does not produce wrought iron of the best quality.

The coke employed in the refinery should be as free as possible from shale, and should contain only a low percentage of ash; it should especially be free from sulphuret of iron, which it often contains in considerable quantity, as it is found that nearly the whole of this sulphuret enters into combination with the metal, and does not pass off in the slag.

Refineries are sometimes worked on hot fluid iron, run direct from the hearth of the blast furnace, a considerable saving, both of time and fuel, being thereby effected. Various proposals have been patented for the employment of fluxes to assist in the removal of the impurities of pig-iron, both in the refining and puddling furnaces. Thus Mr. Hampton patented, in 1855, a flux, prepared by mixing quick lime with the carbonate of an alkali, or alkaline salt. MM. Du Maty and Fontaine proposed, in a patent secured in 1856, to purify and decarbonise iron in the refining and puddling furnaces, by the employment of fluxes prepared from the scoria of the puddling furnace, from oxide of iron and silicates or carbonates of alkalies, or other bases. Mr. Pope (1856) proposes to add the residue obtained by the distillation of kerosene or Torbane mineral, to such flux as is employed in the refining of iron. Mr. Sanderson, of Sheffield (1855), employed for the refining of iron such substances as sulphate of iron, capable of disengaging oxygen or other elements, which will act upon the silicium, aluminium, &c., contained in the metal. These and various other schemes have been suggested with the object of lessening the enormous waste which pig-iron undergoes on its passage through the refinery, for as the process is at present conducted, the partial elimination of the carbon, sulphur, phosphorus, &c., is only effected at the expense of a large quantity of iron, which is oxidised by the blast, and passes in the form of silicate into the slag; the desideratum is the recovery of some method of reducing the waste of iron, and substituting for it some other base, which will form with iron a sufficiently fusible silicate. Mr. Blackwell's proposal is that the decarburisation of pig-iron might be effected by melting it in a cupola furnace, either alone, or with minerals containing nearly pure oxide of iron; the oxide of iron would be reduced by the carbon of the pig-iron, while the silicates of the steel, with the silica, alumina, and other easily fusible alloys eliminated from the crude iron, would be separated in the form of fusible earthy glass. The employment of steam as a purifying agent for crude iron has been patented by several persons. Mr. Naumyth in 1854 obtained a patent for the treatment of iron in the puddling furnace with a current of steam, which being introduced into the lower part of the iron, passes upwards, and meeting with the highly heated metal undergoes decomposition, both elements acting as purifying agents. The steam employed is at a pressure of about 5 pounds per square inch, and passes into the metal through a species of blow-rabbit, the workman moving this about in the fused metal until the mass begins to thicken, which occurs in from five to eight minutes after the introduction of the steam; the steam pipe is then removed and the puddling finished as usual.

The advantages are said to consist in the time saved at each heat or puddling operation (from ten to fifteen minutes); the very effective purification of the metal; and the possibility of treating highly carbonised pig-iron at once in the puddling furnace, the preliminary refining being thus avoided. In October 1855, Mr. Bessemer patented a somewhat similar process for the conversion of iron into steel, the steam highly heated, or a mixture of air and steam, being forced through the liquid iron run from the furnace into a kille pot, steam being used only at an early stage of the process, and the treatment finished with heated air. In the early part of the same year Mr. Martien of New Jersey obtained a patent for a partial purification of crude iron, by causing air or steam to pass up through the liquid metal, as it flows along gutters from the top hole of the furnace or finery forge; and he subsequently proposed to include with the air or steam, other purifying agents, such as chlorine, hydrogen, and coal gas, oxides of manganese, and zinc, &c. Other methods of treating crude iron with air and

steam were made the subjects of patents by Mr. Bessemer in December 1856 and January 1857. In October a patent for the employment of steam in admixing with molten iron the smelting furnace and flaring flange, was obtained by Messrs. Armstrong and Co. of London, and in August a patent was obtained by Mr. George Parry, of the Elbow Vale Iron Works, for the purification of iron by means of highly heated steam. The fluid iron is allowed to run into a reverberatory furnace previously heated, and the steam is made to impinge upon it from several tuyeres or to pass through the metal. Steel is to be obtained by treating highly carburized iron with the steam, and then running it to water, and flaring it with the addition of purifying agents, or adding to it in the furnace a small quantity of clay, and afterwards about 1 or 15 per cent. of calcium spathose ore. Mr. Parry observing that when steam was sent through the molten iron, as in Mr. Nasmyth's process, the iron quickly oxidized, covered the lower of the furnace with a high degree of heat in the furnace by raising the steam pipe a couple of inches above the surface of the metal, so that it might be exposed to the intensely heated atmosphere of the furnace, and a small opening the jet at an angle of 45°, so as to give the molten mass a motion round the furnace while the pipe was maintained in the same position at a little distance beyond the centre; when this was done, in a few minutes the iron began to boil violently, the rotatory motion of the fluid being every part of it successively into contact with the highly heated atmosphere of steam and atmospheric air, and no oxidation taking place. Having thus ascertained the proper way of using steam as a refining agent, it occurred to Mr. Parry that, as the presence of silicon in the pigs for puddling affects in a remarkable degree the yield of iron, as well as its strength, it is a matter of consequence that this element should be removed as completely as possible previous to the puddling operation; the casting of the iron would probably therefore be more profitably applied in the refinery than in the puddling furnace. Pig iron containing 3 per cent. of silicon gives 6 per cent. of silica, which, to form a fluid sufficiently fluid to allow the balling up of the iron, would require from 10 to 12 per cent. of iron; and this case, if true, only be obtained by burning that amount of iron in the puddling furnace, after the expulsion of the carbon, and while the mass is in a powdery state. The superheated steam is injected on the surface of the iron in the refinery by water tuyeres, similar to those used for hot blast at smelting furnaces; they are inclined at an angle of about 45°; and are inserted at each side of the door of the furnace, and are pointed so as to cross each other, and give the iron a circulating motion in the furnace. The tuyeres are from 2 to 3 inches in diameter; a little oxide of iron or a little in a state of fusion on the surface of the iron accelerates the action, as in common refineries, and increases the yield of metal, but to a much greater extent than when blasts of air are used. The steam having been turned on, the mass of iron commences circulating around the inclined tuyeres, and soon begins to boil, and the action is kept uniform by regulating the flow of the steam. The most impure oxides of iron may be used in the process, such as tap cinder or hammer slag from puddling furnaces, without injury to the quality of the refined metal made; the large quantities of sulphur and phosphorus which they contain being effectually removed by the detergent action of the heated steam. When 4 cwt. of cinders are used to the ton of pig, 20 cwt. of metal may be drawn, the impurities in the pig being replaced by refined iron from the cinders.

We have had several opportunities of witnessing this beautiful refining process at the Elbow Vale Iron Works, and have made the following analysis of the cinders and metal which fully bear out the above statements:—

	Pig iron,	Refined metal,
Graphite	2.40	0.70
Silicon	2.68	0.72
Slag	0.65	0.10
Sulphur	0.22	0.14
Phosphorus	0.13	0.09
Manganese	0.26	0.24
	Large cinders thrown into the refinery.	Cinder run out of the refinery.
Sulphur	1.34	0.16
Phosphoric acid	2.06	0.120

A ton of grey iron may be refined by steam in half an hour, using seven jets of steam of an inch in diameter, and with a pressure of from 30 to 40 lbs.; the temperature of the steam being from 600° to 700° F., the orifices of the tuyeres being 2 or 3 inches above the surface of the iron. As the fluidity of the metal depends upon the heat which it is receiving from the combustion of the fuel in the grate, and not on any generated in it by the action of the steam, it is evident that the supply of the latter in a given time must not exceed a certain limit, or the temperature of the fluid iron will become reduced below that of the furnace. This however partly regulates itself,

and does not require much nicety in the management, for, if too much steam be given, the ebullition becomes so violent, as to cause the cinders to flow over the bridges, giving notice to the refiner to slack his blast. The "forge cinders" used in the steam refinery contain 66 per cent. of iron; the "run out" cinder contains only 26; 40 per cent. of iron, or thereabouts, have therefore been converted into refined metal, and the resulting cinder is as pure as the ordinary Welsh mine, with its yield of 25 per cent. of iron. The following is the result of one week's work of the steam refinery:—

		cwt.	qrs.	lbs.
Pigs used	- - - - -	396	0	15
Metal made	- - - - -	393	3	1
Loss	- - - - -	2	1	14
Yield	- - - - -	20	0	14

The quantity of cinder (puddling) used was $3\frac{1}{2}$ cwt. per ton of pig. When $1\frac{1}{2}$ cwt. of cinders were used to 1 ton of pig, the yield was invariably 20 cwt. over a make of about 100 tons.

Refining by gas (German method).—The most simple form of gas reverberatory furnace is that known as Eck's furnace, which is employed at the government works of Gleiwitz and Königshütte, for refining iron made on the spot. The following description and plan of this furnace is extracted from a report to the secretary of state for war, from the superintendent of the Royal Gun factories, Colonel Wilmot, R.F.A., and the chemist of the War Department, Professor Abel.

The gas generator (which replaces the fire-place of the ordinary reverberatory furnace) is an oblong chamber, the width of which is 3 feet 9 inches, and the height from the sole to the commencement of the sloping bridge 6 feet 4 inches. It tapers slightly towards the top, so as to facilitate the descent of the fuel, which is introduced through a lateral opening near the top of the generator. Its cubical contents are about 44 feet.

The air necessary for the production of the gas is supplied by a feeble blast, and enters the generator from the two openings or tuyères of a long air-chest of iron plate (figs. 1013, 1014, 1015) fixed at the back of the chamber, near the bottom. The space between the air chest and the sole of the chambers serves as a receptacle for the slag and ash from the fuel. There are openings on the other side of the chamber, opposite the tuyères, which are generally closed by iron plugs, but are required when the tuyères have to be cleaned out. There is an opening below the air-chest, through which fire is introduced into the chamber, when the furnace is set to work, and which is then bricked up, until at the expiration of about 14 days it becomes necessary to let the fire die out, when the slag and ash which have accumulated on the sole of the chamber are removed through this opening.

The hearth of the furnace is constructed of a somewhat loamy sand; its general thickness is about 6 inches, its form is that of a shallow dish, with a slight incline towards the top hole, the iron is prevented from penetrating through the hearth by the rapid circulation of cold air below the fire-bridge and the plate of the hearth.

Figs. 1016 and 1017, represent the upper oblong air-chest provided with a series of tuyères, which enter the top of the furnace just over the fire-bridge at an angle of 30°. The air forced into the furnace through these tuyères serves to inflame and burn the gases rushing out of the generator, and the direction of the blast throws the resulting flame down upon the metal on the hearth, in front of the bridge. This air-chest communicates, like the other one, by pipes, with the air accumulator of the neighbouring blast furnace. The amount of pressure employed is about 4 lbs.; but the supply of air, both to the generator and the inflammable gases, admits of accurate regulation by means of valves in the connecting pipes. There is an opening in the arch at both sides of the furnace, not far from the bridge, into which, at a certain stage of the operations tuyères are introduced (being placed at an angle of 25°) also connected with the blast apparatus and provided with regulating valves.

The refining process is conducted as follows:—The hearth of the furnace having been constructed or repaired, a brick coal-fire is kindled in the generator, through the opening at the bottom, which is afterwards bricked up. About 20 cubic feet of

cells are then lowered from above, and the necessary supply of air admitted to the furnace through the lower air chest. When these cells have been thoroughly heated, the generator is filled with iron, and a very abundant supply of air admitted through the tuyeres below (for the generation of the gas), and those over the bridge,

(for its combustion,) until the furnace is dried, when the supply of air at both places is increased, so as to raise the hearth to the temperature necessary for baking it thoroughly, upon which, about 40 cwt. of iron are introduced; the metal being distributed over the whole hearth as uniformly as possible, and the size of the pieces

being selected with the view to expose as much surface as possible to the flame. The fusion of the charge of metal is effected in about three hours, the coal used amounting to about 3½ cubic feet per hour. The gas generator is always kept filled

with coal, and the supply of air admitted from below is diminished by a regulation of the valve, whenever fresh coal is supplied, as the latter, at first, always yields gas more freely. The arrangement of the upper row of tuyères effects the combustion

of gas just as they pass from the generator on to the hearth. The hottest portion of the furnace is of course near the fire-brick, i.e. where the blast first meets with the iron. During the melting process the iron is shelled occasionally, so that the outer portion near the fire may in its turn become melted without loss of time. When the iron is ascertained to be thoroughly fused, about 3 lbs. of crushed limestone are thrown over its surface for the purpose of converting the dross which has separated into fusible slag. The two side tuyeres are now introduced into the furnace through the openings above alluded to, the width of the nozzle employed depending upon the power of the blast used. The air rushing from these tuyeres imparts with violence upon the iron, and the two currents meeting an eddying motion is imparted to the fused metal. In a short time the motion produced in the mass is considerable; the permanent slag is blown aside by the blast, and the surface of the iron thus exposed undergoes refinement, while it changes continually, the temperature of the whole mass being raised to a full white heat, by the action of the air. The iron is stirred continually, in order to insure a proper change in the metal exposed to the action of the blast. A shovelful of limestone is occasionally thrown in (the total quantity used being about 1 per cent. of the crude-iron employed). The slag produced is exceedingly fusible, and is allowed to remain in the furnace until the metal is tapped, and on cooling it separates from it completely.

The duration of the treatment in this furnace after the metal is fused, varies from two hours and a half to five hours, according to the product to be obtained. For the preparation of perfectly white iron, the treatment is carried on for five hours. A sample is tapped to examine its appearance, when it is believed to be sufficiently treated.

When the charge is to be withdrawn from the furnace, the side tuyere nearest the tap-hole is withdrawn, so that the blast from the opposite tuyere may turn the metal towards the hole. The final iron, as it flows from the tap-hole is fully white hot, and perfectly limpid; it chills, however, very rapidly, and when solidifies. A few pans of water are thrown upon those portions of the metal which are not covered with the slag, which flows out of the furnace, the object being to cool it rapidly, and thus prevent the oxidation of any quantity of iron. The loss of metal during the treatment is said not to exceed 5 per cent.

With regard to the purification which the iron undergoes in the gas reverberatory furnace, it appears to be confined chiefly to the elimination of carbon and silicon, the amount of sulphur and phosphorus undergoing but little variation, as appears from the following analysis (1867) —

	Pig iron.	Refined iron.
Silicium	4.66	0.42
Phosphorus . . .	0.56	0.30
Sulphur	0.04	0.03

Nevertheless the iron thus refined is highly esteemed for all castings which are required to possess unusual powers of resistance; some experiments made to ascertain the comparative strain borne by the refined metal, and the same metal as obtained from the blast furnace, showed the strength of the former to be greater by one half than that of the latter.

The operation of puddling.—In the year 1783 and 1784, Mr. Henry Cort of Gosport obtained two patents, one for the puddling, and the other for the rolling of iron, “discoveries,” says Mr. Scrivenor, “of so much importance in the manufacture, that it must be considered the era from which we may date the present extensive and flourishing state of the iron trade of this country.”

The object of Mr. Cort's processes was to convert into malleable iron, cast or pig iron, by means of the flame of pit-coal in a common air furnace, and to form the result into bar by the use of rollers in the place of hammers. The process was managed in the following manner:—“The pigs of cast iron produced by the smelting furnace are broken into pieces, and are mixed in such proportions according to the degree of carbonisation, that the result of the whole shall be a grey metal. The mixture is then speedily run into a blast furnace, where it remains a sufficient time to allow the greater part of the scoria to rise to the surface. The furnace is now tapped, and the metal runs into moulds of sand, by which it is formed into pigs, about half the size of those which are broken into pieces. A common reverberatory furnace heated by coal is now charged with about $2\frac{1}{2}$ cwt. of the half refined grey iron. In a little more than half an hour, the metal will be found to be nearly melted; at this period the flame is turned off, a little water is sprinkled over it, and a workman, by introducing an iron bar through a hole in the side of the furnace, begins to stir the half fluid mass, and divide it into small pieces. In the course of about 30 minutes from the commencement of the process, the iron will have been reduced by constant

stirring to the coarseness of small gravel, and will be considerably cooled. The flame is then turned on again, the workmen continuing to stir the metal, and in three minutes' time the work has become red and malleable, upon which the flame is then turned off. The hottest part of the iron now begins to leave and swell, and emit a deep lambent blue flame, which appearance is called *fermentation*; the heaving motion and accompanying flame soon spread over the whole, and the heat of the metal seems to be further increased than it finished for the next quarter of an hour; after this period the temperature again falls, the blue flame is less vigorous, and in a little more than a quarter of an hour the metal is cooled to a dull red, and the jets of flame are rare and faint. During the whole of the fermentation the stirring is continued, by which the iron is at length brought to the consistency of sand; it also approaches nearer to the malleable state, and in consequence adheres less than at first to the tool with which it is stirred. During the next half hour the flame is turned off and on several times, a stronger fermentation takes place, the lambent flame becomes of a clearer and lighter blue; the metal begins to clot, and becomes much less fusible and more tenacious than at first. The fermentation then by degrees subsides; the emission of blue flame nearly ceases; the iron is gathered into lumps and beaten with a heavy-headed tool. Finally, the tools are withdrawn, the apertures through which they were worked are closed, and the flame is again turned on in full force for six or eight minutes. The pieces being thus brought to a high welding heat are withdrawn and shingled; after this they are again heated and passed through grooved rollers, by which the bars are separated, and the bars thus forcibly compressed acquire a high degree of tenacity. But this mode of refining did not produce altogether the desired result. It was irregular; sometimes the loss of iron was small, but at others it was very considerable, and there were great variations in the quality of the iron, as well as in the quantity of fuel consumed. These difficulties were, however, removed by the introduction of the coke furnace by the late Mr. Samuel Homfray, of Penydarren, upon which the puddling and balling furnaces came immediately into general use, with the addition of rollers in lieu of hammers.

Mr. Cort's first patent, which is for "rolling," is dated 17th January, 1783; his second, that for "puddling," is dated 18th February, 1784. It has been attempted, though we think very unjustly, to detract from Cort's merits as an original inventor, by referring to the patents of John Payne, and Peter Onions, dated respectively 21st November, 1788, and 7th May, 1783. The first was to a certain extent, undoubtedly, a patent for "rolling;" for the bars rendered malleable by a process indicated, are "*in pino between the large metall rollers which have proper notches or furrows upon their surface.*" but there is no proof that any practical use was made of Payne's process, while that of Cort was almost immediately and universally adopted. It may be true therefore that Cort was the *discoverer* and not the actual *discoverer* of the process of rolling, but this in no way detracts from his merit, inasmuch as by his improvements, he was enabled to make available that which was previously useless. The same observation applies to the patent of Onions, which to a certain extent anticipated that of Cort for puddling. Onions employed two furnaces—a common smelting furnace, and a furnace of stone and brick, bound with iron work and well annealed, into which the fluid metal was received from the smelting furnace. When the liquid metal had been introduced into the second furnace by an aperture, it was closed up and subjected to the heat of fuel and blast from below, until the metal became less fluid, and thickened into a kind of paste; this the workman by opening a door turns and stirs with a bar of iron, and then closes the aperture again, after which blast and fire is applied until there is a *ferment* in the metal; the adherent particles of iron are collected into a mass, reheated to a white heat, and forged into malleable iron. That the process of puddling is here indicated there can be no doubt, but the actual operation was impracticable until Henry Cort invented the *furnace* in which it could be conducted.

Neither Mr. Cort nor his family appear to have derived much advantage from his important discoveries—discoveries which changed us at once from dependent importers of iron into vast exporters to every country of the world, and which may be considered to have founded the iron industry of Great Britain. So long ago as 1811, the chief representatives of the trade assembled at Gloucester unanimously acknowledged their indebtedness to Mr. Cort for the improvements of which he was the author, and this acknowledgment has been repeated within the last twelve months by Robert Stephenson, Fairbairn, Maudslay and Field, Cubitt, Rendel, Sir Charles Fox, Bidder, Cramphay, Hilly, and many others. In working out his inventions, Cort is said to have expended a fortune of 20,000*l.* and when his patents were completed, the leading iron masters of the country contracted to pay him 10*s.* a ton for their use, so that he would not only have been repaid, but munificently rewarded, had he not unfortunately connected himself with a man named Adam Sedgwick, chief clerk of the Navy Pay Office, who

proving to be a defective, unimproved machine, having previously destroyed the pattern and the agreement with the inventor, belonging to his partner, Henry Cort. Upon the death of Bessemer, the property, stock, and money effects of Cort went with the property passed on to the Navy Pay Office, and the unfortunate man was thus completely ruined.

The position of the furnace is of the most ordinary form. It is built generally with iron, as represented in the side view, *fig. 1004*, by means of horizontal and vertical bars,

with any joints, rivets and kind of welds, to prevent them from starting under. Very frequently, indeed, the reverse every furnace is covered with cast iron plates over their whole surface. These are retained by upright bars of cast iron applied to the side walls, and by horizontal bars of iron placed across the work at right angles. The furnace itself is divided internally into three parts; the hearth, the bridge, and the flue. The hearth varies from 14 to 44 feet long by from 2 feet 6 inches to 3 feet 4 inches wide. The door way, by which the coke is charged, is 8 inches square, and is levelled off towards the outside of the furnace. This opening consists entirely of cast iron, and has a quantity of cast-iron rivets in it. The bars of the fire grate are movable, to admit of more readily clearing down the flue.

Fig. 1005 is a longitudinal section referring to the elevation, *fig. 1004*, and *fig. 1006*

is a ground plan. When the furnace is a single one, a square hole is left in the side of the fireplace opposite to the door, through which the rakes are introduced, in order to be heated.

a is the fire-door; *b*, the grate; *c*, the fire-bridge; *d, d*, cast iron hearth-plates, resting upon cast iron beams *e, e*, which are bolted upon both sides to the cast iron binding plates of the furnace; *f* is the hearth covered with sand; *g*, is the main working door, which may be opened and shut by means of a lever *g'*, and chain to move it up and down. In this large door there is a hole 8 inches square, through which the iron may be worked with the paddles or rakes; it may also be closed airtight. There is a second working door *h*, near the flue, for introducing the cast iron.

on that it may soften slowly, till it be ready for drawing towards the bridge. *c*, is the chimney, from 30 to 50 feet high, which receives commonly the flues of two furnaces, each provided with a damper plate or register. *Fig. 1022*, shows the main damper for the top of the chimney, which may be opened or shut to any extent, by means of the lever and chain. *A*, *Fig. 1023*, is the tap or flow hole for running off the slag or cinder.

The sole is sometimes made of bricks, sometimes of cast iron. In the first case it is composed of fire-bricks set on edge, forming a species of flat vault. It rests immediately on a bed of brickwork either solid or arched below. When it is made of cast iron, which is now beginning to be the general practice, it may be made either of one piece or of several. It is commonly in a single piece, which, however, causes the inconvenience of restraining the furnace entirely when the sole is to be changed. In this case it is a little hollow, as is shown in the preceding vertical section; but if it consists of several pieces, it is usually made flat.

The hearths of cast iron rest upon hot iron pillars, to the number of four or five; which are supported on pillars of cast iron placed on large blocks of stone. Such an arrangement is shown in the furnace, where the square pillars, *Fig. 1023*, for heating the rakes, may be observed. The length of the hearth is usually 6 feet; and its breadth at the fire end part is another. Its greatest breadth, which is opposite the door, is 4 feet. In the furnace, where the horizontal plan is given above, and which produces good results, the sole exists in this part a species of ear, which opens into the mouth of the door. At its origin towards the fire place, it is 2 feet 10 inches wide; from the fire it is separated, moreover, by a low wall of bricks (the fire bridge) 10 inches thick, and from 3 inches to 5 high. At the other extremity its breadth is 2 feet. The current is governed by the sides of the hearth or hearth is not symmetrical; for sometimes it makes an advancement, as is observable in the plan. At the extremity of the sole farthest from the fire, there is a low rising in the bricks of 2½ inches, called the *stop*, for preventing the metal from running out at the *flow hole* when it begins to flow. Beyond the shelf the sole terminates in an inclined plane, which leads to the *flow*, or outlet of the slag from the furnace. This *flow* is a little below the level of the sole, and is led out of the basement of the chimney. The slag is prevented from converting here, by the fire being made to pass over it, in its way to the neck or try of the chimney; and there is also a plate of cast iron near this opening, in which a constant fire is kept up to preserve the fluidity of the *slag*, and to burn the gas that escapes from the furnace, as also to quicken the draught, and to keep the furnace end of the furnace warm. On the top of this iron plate, and at the bottom of the inclined plane, the cinder accumulates in a small cavity, whence it afterwards flows away; whenever it tends to congeal, the workman must clear it out with his rake.

The door is a cast iron frame filled up inside with fire-bricks; through a small hole in the bottom the workmen can observe the state of the furnace. This hole is at other times shut with a stopper. The chimney has an area of from 14 to 16 inches.

The *hearth* stands 3 feet above the ground. Its arched roof, only one brick thick, is raised 2 feet above the fire bridge, and above the level of the sole, taken at the mouth of the furnace. At its extreme point near the chimney, its elevation is only 5 inches, and the same height is given to the opening of the chimney. The sole is covered with a layer of finely powdered cinders from previous workings mixed with mill cinders; formerly the bottom was of sand, by which great loss of iron was occasioned, and the metal obtained of inferior quality.

The fine metal obtained by the coke is produced by a continuous operation, which calls for much care and skill on the part of the workmen. To charge the melting furnace, pieces of the wood are successively introduced with a shovel, and laid one over another on the sides of the hearth, in the form of piles rising to the roof; the middle being left open for pushing the metal, as it is successively fused. Indeed, the whole are kept as far separate as possible, to give free circulation to the air round the piles. The working down of the furnace is now closed, fuel is laid on the grate, and the mouth of the fireplace, as well as the side opening of the grate, are both filled up with coal, at the same time that the damper is entirely opened.

The fine metal in about twenty minutes comes to a white-red heat, and its thin edged fragments begin to melt and fall in drops on the sole of the furnace. At this period the workman opens the small hole of the furnace door, detaches with a rake the pieces of fine metal that began to melt, tries to expose new surfaces to the action of the heat, and in order to prevent the metal from running together as it softens, he

weary as, that of the latter. In the puddling furnace the distance between the bottom and top sillom exceeds twenty inches, while in the boiling furnace it varies from twenty to thirty. In puddling the furnace is charged with metal alone, but in boiling cinder is charged along with the metal, and the top rammer runs much higher. The bottom of the furnace is covered with broken cinders from previous workings, or with the tap cinder from the puddling furnace, which has been subjected to a process of calcination in kilns; this material, which constitutes an admirable protection to the iron plate of the furnace, is raised by the workmen "bull dog;" its preparation was patented by Mr. Hall in 1840. It is made in the following manner: the tap cinder from the puddling furnace is placed in layers in a kiln, and so arranged that a draught shall pass through from the fire holes on one side to those on the other; the kiln is filled up to the top with broken cinders, and over the whole is laid a layer of coke; about the third or fourth day, the more porous part of the cinder begins to run out of the bottom holes, leaving in the kiln a fine rich porous substance of iron, which is the substance used for lining the boiling furnace, the final portion being rejected. In 8 or 10 hours the "bull dog" is melted by the intense heat of the furnace, covering the bottom, and filling up all the interstices in the brickwork; the heat is now somewhat lowered by diminishing the draught, and the charge of pig (from 3½ to 4½ cwt.) is introduced in fragments of a convenient and uniform size, together with 30 or 40 lbs. of water; the doors of the furnace are now closed, and all access of cold atmospheric air prevented, throwing the cinder or hammer slag round the crucible, and stopping up the work hole with a piece of coal. In about a quarter of an hour the iron begins to melt out from the workman from a fire the same as to heat the whole to a state of uniformity as regards heat. In about half an hour the iron begins to melt; it is constantly turned over, and at intervals of a few minutes cinder is thrown on the surface of the mass so as to be covered with a blue flame; it soon begins to rise; a kind of fermentation takes place beneath the surface, and the mass, at first but 2 inches high, rises to a height of 10 or 12 inches, and enters into violent ebullition. During the time that this "fermentation" is taking place, constant stirring is required to prevent the iron from settling on the bottom. The boiling lasts about a quarter of an hour; after which the cinder gradually sinks, and the iron appears in the form of porous spongy masses of irregular size, which are constantly stirred to prevent their adhering together in large lumps, to facilitate the escape of the carbon, and to separate the cinder which, when the operation has been successfully completed, flows over the bottom apparently as liquid as water. The iron is now "halled up," as in the operation of puddling. The objects as to the boiling process are: the wear and tear in the furnace which occurs in treating gray pig iron, particularly that of the more fluid description, the slowness of the operation, and the amount of manual labour which it entails to produce good results. In some works the crude iron is run directly into the boiling furnace from the blast furnace, by which much saving of coal is effected, and a product of a more uniform quality obtained; but the labour of the workman becomes more oppressive from the additional heat to which he is subjected from the close proximity of the blast furnace. Iron masters are not agreed as to the respective merits of the "boiling" and "puddling" systems; some maintain that the former is more economical than the latter, which has been "refining;" others think that boiling iron has a tendency to communicate to it the "red short" quality. According to the observations of Mr. Truran, in several works where both methods are employed, the largest quantity of iron is first passed through the refinery.

Mr. Hall, the inventor of the boiling system, in descending on the merits of his process, describes how, with the same pig, the iron may be made weak and cold short; or tough, ductile, and malleable. For the first proceed thus:—Pass the pig through the refinery, then puddle agreeably to the old plan on the sand bottom; that is, melt it as cold as possible; drop the damper quite close before the iron is all melted, dry the iron as expeditiously as may be, with a large quantity of water; and, lastly, proceed to hall in a proper number of "yeen" halls; the result will be a very inferior quality of malleable iron. On the other hand, to produce a malleable iron of very superior quality, first charge the furnace with good large pig iron, adding, if required, a sufficiency of flux, increasing or diminishing the same in proportion to the quality and nature of the pig iron used. Secondly, melt the iron to a boiling consistency. Thirdly, clear the iron thoroughly before dropping down the damper. Fourthly, keep a plentiful supply of fire upon the grate. Fifthly, regulate the draft of the furnace by the damper. Sixthly, work the iron into one mass, before it is divided into balls; when thus in balls, take the whole to the hammer as quickly as possible, after which roll the same into bars. The bars are then cut into lengths, and piled to the desired weights, are then heated in the mill furnace, welded and consolidated by passing through the rolls, and thus finished for the market. In this way, from the pig to the finished mill bar, one entire process, that of the refinery, is saved. Mr. Hall

makes that, by his process, he can obtain malleable iron of any character (providing that the ore from which the pig is made are of good quality), from the softness of lead, the hardness of steel, and further that he can exhibit different qualities to the same bar and rod being crystalline, nearly as brittle as glass, the other end equal to the best iron that can be produced for fire and tenacity, while the middle exhibits a character approximating to both; and as a further illustration of the versatility of the iron that may be made by the "puddling" process, he refers to a specimen in the Geological Museum, J. Gwynne Street, London, labeled "specimens of two and a quarter inch round iron, rod and wire, manufactured at the Newcastle Iron Works, Tipton, Staffordshire." This specimen has been called a "steelball bar," it was made from a bar two inches and a quarter in diameter, and nearly seven inches in circumference, then to a "1 1/2 inch bar," half inch thick, then at its point for the cutting, becoming with a half inch gauge, and terminating with one end and a half, without exhibiting the slightest fracture.

Mr Hall was led to the discovery of the "puddling" principle, by seeing the extremely high fires which took place in the ordinary puddling furnace owing to a high degree of heat, and the expense of the fuel of iron produced by the combustion; it occurred to him, that if such good iron could be made from cheap iron, a very superior product might be obtained from puddling iron with equally good fluxes, and the result of experiment is fully answered by experience, though for a long time he was unable to make his discovery practically useful, on account of the difficulty of getting furnace linings and capable of enduring the intense heat required and the corrosive action of the fluxes. Puddling furnaces were then made of brick and clay, which had failed. He succeeded at last by lining the interior of the furnace with iron, and protecting them with a coating of prepared tap cinders.

In America, the "puddling" and "puddling" processes are both in use; the former gives preference to the latter as being the most profitable, but it can only be employed to a limited extent for lack of coal; in a rolling mill, therefore, half

1025

the furnaces are employed for boiling, and half for puddling, the latter supplying cinder for the former. In the eastern states where the fuel is anthracite, double

puddling furnaces are employed and a blast is used, the limited supply of the variety of coal rendering it impossible to get the requisite heat by merely the draught of the chimney. Fig 1128 represents an anthracite furnace heated vertically through the grate, hearth, and chimney. It differs from the ordinary puddling furnace chiefly in the greater depth of the grate, which is made to contain from twenty to twenty-five inches of coal,

and in the lesser height of the chimney, which, as a least is employed, need only be sufficiently high to carry the hot gases out of the furnace; the letters a, a, a, a, indicate the position of the iron cross binders, which serve to hold together the

cast iron plates of the enclosure, and to prevent the sinking of the roof from the expansion and contraction of the brickwork.

The blast machines are fans, the best form of which is shown in *fig. 1029*. (*Overman*.) The wings of this fan are encased in a separate box; a wheel is thus formed, which rotates in the outer box, the figure shows a horizontal section through the axis. The wings are thus connected, and form a closed wheel, in which the air is whirled round, and thrown out at the periphery. The inner case, which revolves with the wings, is fitted as closely as possible to the outer case, at the centre wear a, a, a, a. The speed of the wings is sometimes as much as 1500 revolutions per minute. The motion of the axis is produced by means of a leather or indiarubber belt and a pulley. This variety of fan is used at the puddling furnaces at Ebbw vale, where the fuel is small coal.

Fig. 1030 is a horizontal section of the double anthracite puddling furnace. The

grate measures 3 feet by 5. The width of the furnace externally is from 5½ to 6 feet. The hearth is usually 6 feet in length. It has two work doors, one directly opposite the other. Two sets of workmen are required therefore at the same time; double the quantity of metal is charged, and the yield is twice that of a single furnace; the economy is in the room, fuel, and labour: one good puddler only being required to manage the operation. Double puddling furnaces are also used in several works in England, but as Mr. Truran observes, the economical advantages attending them in point of fuel are lost if the puddlers do not work well to time: they must bring their heats to the respective stages simultaneously, for if one is kept waiting for a short period by the other, the loss in iron more than balances the reduced consumption of coal. This difficulty of obtaining men who will work well in concert has operated against the use of the double furnace, which would otherwise certainly supersede the single, as combined with the process of running the iron in liquid from the blast furnace, the consumption of fuel is under the one half of the quantity demanded with single furnaces working cold iron.

Puddling furnaces are sometimes constructed with what is called "water bosses," the hearth is surrounded with heavy cast iron plates, in which is formed a passage of an inch or an inch and a half bore, through which a current of cold water is caused to flow, the object being to protect the furnace from the destructive action of the heat and clinker. *Overman* found such furnaces to work well with fusible metal such as is produced from a heavy burden on the blast furnace, or from ores containing phosphorus; but with iron requiring a strong heat, such as results from a light burden on the blast furnace, or when it contains impurities firmly and intimately combined, puddling furnaces with cooled bosses failed to make good malleable iron.

We do not know whether the iron manufacturers in England will assent to the following proposition laid down by the American metallurgist, viz. "That the smaller the amount of coal consumed, or the lower the temperature of the hearth in the blast furnace, the better will be the quality of the metal; that is, the more fit it will become for improvement in the puddling furnace. The advantage of heavy burden in the blast furnace, is not only that it reduces the first cost of the metal, but makes a far superior article for subsequent operations. The worst cold short, or sulphurous metal, smelted by a low heat is quite as good as the best metal from the best ore smelted by a high temperature." Whatever may be thought of the latter part of this quotation, no iron manufacturer will deny that careful attention to the blast furnace is the best security of success in the puddling furnace, and that success in the one is in proportion to the economy observed in relation to the other; or that it is hopeless to attempt to improve in the puddling furnace pig iron made in a furnace that is constantly changing its burden and management, such iron is most advantageously disposed of by being worked up into coarse bar or railroad iron.

In the autumn of 1836 the attention of iron masters and of the public generally was powerfully excited by a proposal from Mr. Bessemer to manufacture iron and steel

from cupola iron, without any fuel at all. The views of Mr. Bessemer were first announced and set forth in a paper read by that gentleman at the meeting of the British Association held at Cambridge in August, 1856, from the paper the following extracts are taken, being part of the apparatus employed, and of the process of converting.

"The furnace is a cylindrical vessel of three feet in height, somewhat like an ordinary cupola furnace, the interior of which is lined with fire bricks; and at about two inches from the bottom are inserted five tuyeres, the position of which are formed of wrought iron, the orifices of each tuyere just below a set of three rings of an inch in diameter. These are so put into the brick lining from the center so as to admit of their removal or renewal in a few minutes when they are worn out. At one side of the vessel, about half way up from the bottom, there is a hole made for passing in the crude metal, and on the opposite side a tap hole stopped with loose, by means of which the iron is run out at the end of the process. The vessel is placed above the discharge hole of the blast furnace so to allow the iron to flow along a gutter into it. A small brass cylinder is required, capable of containing air at a pressure of 10 or 15 lbs. to the square inch. A communication having been made between it and the tuyeres, the converting vessel is in a condition to commence work. It remains, however, to supply the cupola for the first heat, it is at first well dried by holding a fire in the interior. The tuyeres are situated nearly close to the bottom of the vessel, the fluid metal rises, therefore, some 18 inches or two feet above them. It is necessary, in order to prevent the metal from entering the tuyere holes, to turn on the blast before allowing the crude iron to run into the vessel from the blast furnace. This being done, and the fluid iron run in, a rapid boil is up of the metal as hard as gun metal within the vessel, the metal being turned violently about, and dashed from side to side, shaking the vessel by the force with which it moves from the throat of the converting vessel. Flame will then immediately issue, accompanied by a few bright sparks. This state of things will continue for about 15 or 20 minutes, during which time the oxygen of the atmospheric air combines with the carbon contained in the iron producing carbonic acid gas, and at the same time evolving a powerful heat. Now as this heat is generated in the interior of, and is diminished in its escape through, the whole fluid mass, the metal about the greater part of it, and its temperature becomes immensely increased, and by the expiration of 15 or 20 minutes the mechanically mixed carbon or graphite has been entirely consumed. The temperature is, however, so high that the chemically combined carbon, now known to separate from the metal, as is at once indicated by an immense increase in the volume of the flame rushing out at the throat of the vessel. The metal now rises several inches above its natural level, and a light frothy slag makes its appearance, and is thrown out in large foam-like masses. This violent eruption of steam generally lasts 5 or 6 minutes, replacing the shower of sparks and cinder which always accompanies the boil.

"The rapid union of carbon and oxygen which thus takes place, adds still further to the temperature of the metal, while the diminished quantity of carbon present, allows a part of the oxygen to combine with the iron, which undergoes combustion, and is converted into oxide, at the excessive temperature that the metal has now acquired; the oxide, as soon as it is formed, undergoes fusion, and forms a powerful solvent of those earthy bases that are associated with the iron. The violent ebullition which goes on mixes most intimately the scoria and metal, every part of which is brought into contact with the fluid, which will thus wash and cleanse the metal most thoroughly from the silica and other earthy bases, while the sulphur and other volatile matters which cling so tenaciously to iron at ordinary temperatures, are drawn off, the sulphur combining with the oxygen and forming sulphurous acid gas. The loss in weight of crude iron during its conversion into an ingot of malleable iron was found on a mean of four experiments to be 12½ per cent., to which will have to be added the loss of metal in the finishing rolls. This will make the entire loss probably not less than 18 per cent., instead of about 28 per cent., which is the loss on the present system. A large portion of that metal is, however, recoverable, by treating with carbonaceous gases the rich oxides thrown out of the furnace during the boil. These slags are found to contain innumerable small grains of metallic iron, which are mechanically held in suspension in the slags, and may be easily recovered by opening the tap hole of the converting vessel, and allowing the fluid malleable iron to flow into the iron ingot moulds placed there to receive them.

"The masses of iron thus formed will be perfectly free from any admixture of cinder, oxide, or any other extraneous matters, and will be far more pure and in a considerable state of manufacture than a pile formed of ordinary puddled bars. And thus it will be seen that by a single process, requiring no manipulation or particular skill, and with only one workman, from 3 to 5 tons of crude iron passes into the condition of

several piles of malleable iron in from 30 to 35 minutes, with the expenditure of about $\frac{1}{2}$ of the blast now used in a fluey furnace, with an equal charge of iron, and with the consumption of no other fuel than is contained in the crude iron. . . .

"One of the most important facts connected with this new system of manufacturing malleable iron, is that all the iron so prepared will be of that quality known as *charcoal iron*, because the whole of the processes being conducted without the use of mineral fuel, the iron will be free from those injurious properties which that description of fuel never fails to impart to iron that is brought under its influence.

"At that stage of the process immediately following the boil the whole of the crude iron has passed into the condition of *cast steel* of ordinary quality. By the continuation of the process the steel so produced gradually loses its small remaining portion of carbon, and passes successively from hard to soft steel, and from soft steel to *swely iron*, and eventually to very soft iron: hence at a certain period of the process any quality of metal can be obtained."

The phenomena attending this novel process of iron making are very well described in the above extract, and if we substitute for the words "a few bright sparks," the words "showers of bright sparks, poured out in enormous quantities, projected thirty or forty feet into the air, and falling on all sides in a thick shower," a good idea may be formed of the gorgeous display of pyrotechny which is exhibited. We must demur, however, to the statement that "the sulphur and other volatile matters present in the crude iron are drawn off;" the fact being that the sulphur and phosphorus appear to have retained little if any diminution, notwithstanding the excessive temperature and the powerful oxidising action to which the iron has been subjected. Thus Mr. Alsford, in a specimen of Mr. Bessemer's product from 0.4 to 0.5 per cent of phosphorus, and from 0.1 to 0.06 per cent of sulphur; the Hibernian pig, from which it was stated to have been prepared, containing 0.5 of the former and 0.06 of the latter, and in a sample, broken off from an ingot cast at Blaenau House, Sept. 1st, 1856, on which occasion we were present, and witnessed the whole process, we obtained 0.6 per cent of phosphorus and 0.08 per cent of sulphur; similar results have been obtained by other chemists. The carbon and silicon, on the other hand, are eliminated, the latter wholly so, while the quantity of the former is reduced to a few hundredths per cent; we think also that Mr. Bessemer is mistaken in stating that the iron produced by his method contains "an admixture of oxide," for the specimens which we have had an opportunity of examining presented unmistakable evidence of partial oxidation in the very centre of the ingot, nor do we see how it could well be otherwise.

It will easily be imagined that a process which, if successful, must have revolutionised the whole iron manufacture, was speedily subjected to a most careful and sifting investigation; and, for some months after its announcement, the papers were filled with communications from all parts of the country, detailing experiments made on the large scale to test its value; the results, unfortunately for the ingenious projector, were unanimously unfavourable. We quote first from the "Mining Journal" of Nov. 29, 1856.

"The Dinas Company appear to have thoroughly and impartially tested Mr. Bessemer's process, and the results obtained can only be regarded as a total failure. . . . A Bessemer furnace was erected, and acted excellently as far as the process was concerned, but failed to produce anything like malleable iron. The iron used was from clay-ironstone, Whitehaven hematite, and small portions of forge cinders, in the proportions usually employed in Wales for rails and merchant iron. After the metal had been subjected to a blast of 8 lbs. pressure it was withdrawn and taken to the 'squeezer,' as is usual with puddled blooms, in take out the dross and unite the particles of metal. Instead of acting like puddled iron Mr. Bessemer's bloom under the squeezer was a mere mass of red-hot friable matter, and, from its crumbling and non-cohesion, was with difficulty formed into an ingot: when passed through the rolls it broke on the drawing side as easily as very 'red short' iron, to the infinite gratification of the men, who greeted each failure with hearty cheers. By mixing slag with the metal a slight improvement was effected, but, on being submittted to a similar manipulation, it was found to be no better than 'cold short' iron."

From the "Cobdenian," 10th Jan. 1857:—

"On December 31st the Briton Ferry Iron Company received two of Bessemer's finest ingots of iron to test its value after passing through the rolls. Notwithstanding every care that was bestowed on the process, it was found impossible to do anything with it to the purpose, and the manager informs us that cold short iron, after passing through the same process, is worth by at least 2*l*. per ton more than that tried on this occasion."

At a meeting of the Polytechnic Society at Liverpool, Monday, Sept. 16, 1856, the chairman, Edward Jones Eyre, is reported ("Daily News") to have said that a

iron retains the last portion of carbon with its ordinary tenacity, and that it can only be made to yield it up by the action of a great temperature and oxygen; it then passes into a state of what is called white iron, which is described, vol. v. p. 3. *It is said that the only variety of bar iron that is free from carbon*. It is not clearly the case, however, that the iron is free from carbon; it is stated, however, that by proper treatment any residual quantity of carbon may be retained, and it remains to be proved how far this will be practicable on a large scale, and whether those variations of chemical composition in the iron can really be produced.

The main driving shaft is carried at the end of a large iron wheel, which is connected to the different machines through smaller toothed wheels. (1) three there are six, four of which drive four different systems of cylinders, and the two others work the hammer and the shears. The different cylinders of the work are never to be placed on the same arbor, because they are not to be together, and they must have different velocities according to the diameter. In order to save time and labour, care is taken to place the cylinders of the same size on the same line the hammer, the shears, and the rolling cylinders, and on the other side, to place the several systems of cylinders for drawing out the iron into bars. For the same reason the rolling furnaces ought to be grouped on the side of the hammer; and the reheating furnaces on the other side of the works.

The hammers, fig. 1031, are made entirely of cast iron; they are nearly 10 feet long, and consist usually of two parts, the helve *c*, and the head or pane *d*. The latter

enters with friction into the hammer, and is retained in its place by wedges of iron or wood. The great masses of several hammers running from each other, for the purpose of giving different forms to the bar, &c. A ring of cast iron is fitted to the main-shaft, bearing movable cams *a* & *b*, which drive the hammers *d*, by lifting a wedge round its fulcrum *f*, and then letting it fall vertically. In one iron work, this ring was found to be 3 feet in diameter, 18 inches thick, and to weigh 4 tons. The weight of the belve (hammer) of the corresponding hammer was 3 tons and a half, and that of the head of the hammer a hundred weight.

The anvil consists of two parts: the one upon the point of the iron, is the counterpart of the plane of the hammer; it shows weight a hundred weight. The second, named the neck of the anvil, weighs 4 tons. It forms a parallelogram, with the edges rounded. The hammer is raised from the point of the anvil, and is turned about upon it, by means of a rod of iron welded to each of them, called a power. Some the weight of these powers is very great, and the strokes very considerable, the utmost precautions must be taken in setting the hammer and the anvil upon a substantial mass of masonry, as shown in the figure, *g* & *h*, which is built a level, or even quite above flooring of wood, formed of beams placed in transverse levers that rest upon such beams placed on other beams, and so on by gradually adding the superincumbent weight of the blocks. In some works, a six feet diameter cast iron ball is placed in the axis *i*.

Three hammers are very frequently mounted on levers of the first kind, with the centre of motion about one third or one fourth of the length of the belve from the iron wheel. The principle of this construction will be understood by inspection of fig. 1192. The short end of the lever, which is struck down by the hammer, is fixed upon the end of an elastic beam *a*, and transiently releases causing the long end to strike a handle *f* that upon the anvil *a*.

Fig. 1192 is the diagram of a hammer; to the left of 1, is the axis of the primary

cam, 2, 3, consisting of 8 wheels, each formed of a circular bar of cast iron, which are joined together to make the cam-work wheel. 4, 5, 6, are put on the driving cam or hinge made fast by wooden wedges; *b*, *b*, are standards of the frame with *c*, *d*, *m*, in which the belve of the large hammer has its fulcrum, and *u*, *h*, the side part of the frame. Another part of the frame or side is shown at *m*. *n* is a strong stay, to strengthen the frame work. At *r* two parallel hammers are placed, with cast-

iron heads and wooden belves. *s* is the anvil, a very massive piece of cast iron. *t* is the end of a vibrating beam, for throwing back the hammer from it forcibly by recoil. *x* *y* is the outline of the water-wheel which drives the whole. The cams or tappets are shown mounted upon the wheel *g*, *g*, *g*.

Squeezers are machines which condense a ball by pressure. They are either single or double, their construction will be readily understood from fig. 1193, which represents

a single level squeezer of the simplest construction; the bed plate *a* is cast in one piece; it is 6 feet long, 15 inches wide, and 12 inches high. The whole is screwed down on a solid foundation of stone, brick, or timber. *b* is the movable part, which

makes from 90 to 90 m. per minut. The motion is imparted by the crank *c*, which in turn is driven by means of a strap and pulley by the elementary power. The diameter of the fly wheel is from 3 to 4 ft. The anvil *d* is about two feet in length and from 12 to 14 inches in width; it is a movable plate, at least 3 inches thick, which if injured can be replaced by another; the face of the working part of the lever exactly fits the anvil, and consists of plates attached by means of screws. It is desirable to have all these face plates in small parts of 6 or 10 inches in width, by this means they are secured against breaking by expansion and contraction. The whole machine, including the crank and everything, is made of cast iron, and weighs from 4 to 5 tons. A working 100 tons the machine is both cheap and durable, and will make an 100 tons of iron per week.

Fig. 1034 represents the double squeezer, employed at many English iron works. The drawing is taken from a machine at the Dowlais Iron works, figured in Mr. Truran's work. Many other forms are in use.

Fig. 1035 represents Brown's patent bloom squeezer. The heated ball of puddled iron *x*, thrown on the top is gradually pressed between the revolving rollers as it

descends, and at last emerges at the bottom, where it is thrown on to a movable "Jacob's ladder," by which it is elevated to the rolls. This machine effects a considerable saving of time, will do the work of 12 or 14 furnaces, and may be constantly going as a feeder to one or two pairs of rolls. There are two distinct forms of this machine; in the one figured the bloom receives only two compressions; in another, which is much more effective it is squeezed four times before it leaves the rolls and falls upon the Jacob's ladder. Another form of squeezer is shown in fig. 1036.

A table *A* with a ledge rising up from it to a height of about 2 feet, so as to form an open box, is firmly imbedded in masonry; within this is a revolving box, *c*, of similar character, much smaller than the last, and placed eccentrically in regard to

11. The ball or bloom is placed between the innermost revolving bar *c* and the outer case *a* where the space between them is greatest, and is moved round all its circumference *a*, compressed and fit for the rolls.

Cylinders.—The compression between cylinders new iron, in a few seconds, that subsiding and disappearance of the fibres, which 40 years ago could not be accomplished till after many hours in the furnace, and many thousands of hammers. The cylinders may be constructed but two kinds: 1, those which serve to draw out the bar, called pulling rolls; 2, rolling mills, and which are, in fact, massive cylinders. 2, the cylinders of cast iron, called rollers, for drawing into bars the masses iron after it has received a welding, is more to make available. This second kind of cylinders is made of cast iron, several varieties according to the purpose of the iron that are required. Their diameter varies from 2 inches square to less than one inch of an inch.

Hence the cylinders there is a heavy frame, in which the rollers and the rollers roll when the iron is compressed. The rollers are made of iron, and are supported by a body of cast iron, capable of supporting the enormous load of the cylinders. The axis of each roller is made of the best of the iron, which cylinders may be made fast, by securing them with screws and bolts. The rollers of cast iron are found to be better, than of steel, but because the upper rights and bearings may be more easily fixed to them, but because the lower part of heavy metal is more liable to chatter or rattle, an axle, which supports frequently to the wheels. A mill of water is supplied by a pipe to each pair of cylinders, to hinder them from getting hot; as also to prevent the iron from adhering to the cylinder, by cooling its surface, and perhaps producing a slight degree of oxidation.

The shafts are 1 foot in diameter for the hammer and the rollers, and 6 inches where they connect with motion to the cylinders, and to draw the iron into bars.

The rollers are employed either to work out the lump or ball immediately after it leaves the puddling furnace, as in the Welsh process, or to draw out the piece, after it has been shaped under the hammer, as is practised by most of the Scotch fire establishments. These rolling cylinders are generally 7 feet long, including the trunnions, or 5 feet between the bearings, and 1 foot in diameter, weighing in the whole from 4 to 4½ tons. They contain from 5 to 7 grooves, each of an elliptical form, one smaller than another in regular progression, as is seen in fig. 1037. The small axis of each ellipse, as formed by the union of the upper and lower grooves, is always placed in the vertical direction, and is equal to the great axis, or horizontal axis of the succeeding groove; so that in transferring the bar from one groove to another, it must receive a quarter of a revolution, whereby the iron gets elongated in every direction. Sometimes the rolling rolls serve as preparatory cylinders, in which case they bear towards one extremity regular grooves, as the figure exhibits. Several of these large grooves are bevelled with small angles, analogous to the teeth of files, for lifting the lump of iron, and preventing its sliding. On a level with the under side of the grooves of the lower cylinder, there is a plate of cast iron with notches in its edge equal to the grooves. The piece, called the apron, rests on these rods, and serves to support the ball and bars raised on the bottom of the rollers, and to receive the fragments of solid metal, which fall off during the drawing. The frames in which the rollers are supported and revolve, are made of great strength. Their height is 5 feet; their thickness is 1 foot in the side perpendicular to the axis of the cylinders, and 10 inches in the other. Each pair of bearings is connected at their upper ends by two iron rods, on which the workmen rest their toes or pliers for passing the lump or bar from one side of the cylinders to the other.

The ends or bushes are each composed of two pieces; the one of hard iron, which presents a cylindrical notch, is framed into the other which is made of cast iron, as is clearly seen in fig. 1037.

The iron bar delivered from the square grooves, is cut by the shears into short lengths, which are collected in a bundle in order to be welded together. When this bundle of bars has become hot enough in the furnace, it is conveyed to the rollers, which differ in their arrangement according as they are meant to draw iron from a large or small piece. The first, fig. 1037, possess both elliptical and rectangular grooves; are 1 foot in diameter and 3 feet long between the bearings. The bar is not

finished under these cylinders, but is transferred to another pair, whose grooves have the dimensions proper for the bar, with a round, triangular, rectangular, or fillet form. The triangular grooves made use of for square iron, have for their profile an isosceles triangle slightly obtuse, so that the space left by the two grooves together may be a rhombus, differing little from a square, and whose smaller diagonal is vertical. When the bar is to be passed successively through several grooves of this kind, the larger or horizontal diagonal of each following groove is made equal to the smaller or upright of the preceding one, whereby the iron must be turned one-fourth round at each successive draught, and thus receive pressure in opposite directions. Indeed the bar is often turned in succession through the triangular and rectangular grooves, that its fibres may be more accurately worked together. The decrement in the capacity of the grooves follows the proportion of 15 to 11.

When it is intended to reduce the iron to a small rod, the cylinders have each a diameter, that three may be set in the same housing frame. The lower and middle cylinders are employed as roughing rollers, while the upper and middle ones are made to draw out the rod. When a rod or bar is to be drawn with a channel or gutter in its form, the grooves of the rollers are suitably formed.

To draw out square rods of a very small size, as nail-rods, a system of small rollers is employed, called *slitters*. Their ridges are sharp-edged, and enter into the opposite grooves $\frac{1}{2}$ inches deep; so that the flat bar in passing between such rollers is instantaneously divided into several strips. For this purpose the rollers represented in fig. 1038, may be put on and removed from the shaft at pleasure.

The velocity of the cylinders varies with their dimensions. In one work, cylinders for drawing out iron of from one-third to two-thirds of an inch thick, make 140 revolutions per minute; while those for iron of from two-thirds of an inch to 3 inches, make only 65. In another work, the cylinders for two inch iron, make 95 revolutions per minute; those for iron from two-thirds of an inch to an inch and a third, make 120; and those for bars from one-third to two-thirds of an inch, 150. The roughing rollers move with only one-third the velocity of the drawing cylinders.

The shingling and plate rolling mill is represented in fig. 1037. The shingling mill, for converting the blooms from the balling furnace into bars, consists of two sets of grooved cylinders, the first being called *puddling rolls* or *roughing rolls*; the second are for reducing or drawing the iron into mill-bars, and are called simply *rolls*.

a, a, a, a, are the powerful uprights or standards called *housing frames*, of cast iron, in which the gudgeons of the rolls are set to revolve; b, b, b, b, are bolt rods for hind-

ing three frames, *r, r, r*, and *r, r*, or the rollers *r, r*, having each a series of triangular grooves, such that the work done by the upper and lower rollers is equal, or nearly so, in all parts in the operation, with nearly equal force. The end given to the plate of *r, r*, should be somewhat like a rough saw, in order to take the better hold of the bloom, so to hit the metal in the work, and give it the proper taper, by changing the angle of the rollers, through the revolving power, till it comes to the square end, where it becomes a cylinder, *d, d*, are the smooth cylinders, horizontal up to the square end, and as it is made, revolving, that it may be made for rolling iron in plates or bars. *e, e, e, e*, are strong square cast-iron rollers for the ends, which work by means of a worm-hesher, and the ends *e, e, e, e*, fixed in the standards, they serve to regulate the height of the finished bars, of beams, &c. of the rollers, and thereby the distance between the upper and lower cylinders. *f, f*, is a narrow shaft, *f, f, f*, are small coupling bars, which connect the two square ends of the rollers, and make them turn together. *A, A*, are jointed joints, whereby motion is communicated from the driving shaft *f*, through the under pinion to the upper cone, and from to both upper and lower cones of cones. *i, i*, are the pinion standards in which their shafts rest; they are made of cast-iron, of the rigidity of the rolls. *A, A*, are screws for fastening the lower pinion to the top of the pinion standards. All the standards are provided with rollers *a, a*, whereby they are screwed to the foundations, beams of wood, or preferably iron, as shown by the dotted lines; *b, b*, are the leading screw bolts. Each pair of rolls at work is kept cool by a small stream of water let down upon it from a pipe and stop-cock.

In the cylinder drawing, the workman who holds the ball in large pieces, is the first of the elliptical grooves, and a second workman, on the other side of the cylinders, receives this lump and hands it over to the first, who repeats it between the rollers after bringing them somewhat close to each other by giving a turn to the adjust or pressure screws. After the lump has passed five or six times through the same grooves it has got an elliptical form, and is rolled in England a wire. It is next passed through a second groove of less size, which stretches the iron bar. In this state it is subjected to a second pair of cylinders, by which the iron is drawn into flat bars four inches broad and half an inch thick. From the end of the ball or lump fall round about the cylinders, which are afterwards added to the puddling charge. In a minute and a half the rude lump is transformed into bars with a precision and rapidity which the inexperienced eye can hardly follow. A steam engine of forty horse power can crush down in a week 200 tons of puddle iron.

This iron, called mill-bar iron, is however of too inferior a quality to be employed in any machinery, and it is subjected to another operation, which consists in welding several pieces together, and working them into a mass of the best quality. The iron bars, while still hot, are cut by the shears into a length proportioned to the use of the iron bar that is wanted, and four rows of these are usually laid over each other into a heap or pile which is placed in the re-heating furnace, and exposed to a free circulation of heat, one pile being set on fire while another. In a half or three quarters of an hour the iron is hot enough, and the pieces now sticking together are carried in successive piles to the bar drawing cylinders to be converted into iron bars, which are reckoned of middle quality. When a very tough iron is wanted, as for anchors, another welding and rolling must be given. In the re-heating ovens the loss is from 8 to 10 per cent. on the large bar, and from 10 to 12 in smaller work. The consumption of coals in heating the large pile averages 7 cwt. to the ton of iron charged; in the smaller sizes 10 cwt.; and in heating the mild rolled iron 15 cwt.

The re-heating furnace is shown in section in fig. 187. It differs but little from a puddling furnace. The whole interior, with the exception of the hearth, is made of

109

from 6 to 12 inch, resting on fire-brick; it generally requires no making after time or three heats. The height of the fire-brick arch, or its distance from the end

of the furnace, is made of sand. For this purpose a pure siliceous sand is required, the coarser the better. The hearth slopes considerably towards the fire, the object of which is to keep the hearth dry and hard. The iron is welded in re-heating ovens with the aid of the sand, forming a very fine powder, which flows off through the opening at *A*, at which there is a small fire to keep the sand liquid. The thickness of the sand is from

bottom is from 8 to 12 inches. The area of the fire place averages 12 feet, and the width of the furnace varies from 4 to 8 feet. When the pigs are completed in the furnace the door is shut, and the heat is directed around the pig, so that the heat of the furnace is raised to the highest intensity as quickly as possible, and the workmen turn the pigs over frequently so that they may be brought to a uniform welding heat in the shortest possible time.

It is thought by many that a purer iron is obtained by subjecting the pigs so they come out of the puddling furnace to the action of the hammer at first rather than to the working rollers, as by the latter process various impurities remain in the metal, which the hammer expels. Hence in some works the balls are first worked under the large hammer, and then the puddling being afterwards heated in the form of pigs or cakes, passed over each roller, are passed through the roughing mill.

Iron intended for boiler or tin plates are made from the best coal blast iron. The raw pig is refined in the usual manner with coke, the iron amounting to from 2½ to 3 cwt. per ton. It is then refined a second time with charcoal, the iron amounting again to from 2½ to 3 cwt. per ton. After this second refining the iron is rolled into flat plates white hot by the tilt hammer and the waste is removed by water, the rollers being run at it more easily when it is small cakes. The plates are passed over rollers, and welded in the hollow fire, each being the full thickness of the plate, and do not come into contact with the fuel; the blast is thrown under the fuel, and the heat is increased, when the plates are nearly at the rolling point, they are withdrawn and passed under the rollers; they are now reheated in the lower fire, then drawn out and heated a third time in the ordinary reverberatory furnace, after which they are drawn out into flat bars for boiler plates, or for the plates for tin. These plates amount to from 3 to 4 cwt. per ton. About 9 hours are employed in 12 hours, each heat amounting to ½ cwt. of refined metal, and consuming 3 baskets of charcoal.

The bars intended for tin plates are repeatedly heated and rolled until of the required thickness, the plates are then cut into squares, and annealed by exposing them for several hours to heat in covered iron boxes, being allowed to cool very slowly, this gives the plates the proper degree of pliancy. The next operation is that of pickling; the plates are immersed in dilute sulphuric acid for the purpose of removing from their surface all oxide and dirt; after remaining in it a short time for the requisite time, they are thoroughly washed in successive troughs of water, and then dried in saw dust, finally the surfaces of the metal are prepared for the reception of the tin, by rubbing them with leather upon cushions of sheepskin. The spent sulphuric acid is run out into evaporating pans, and the sulphate of iron crystallized out. In order to tin the plates, they are immersed in a bath of molten tin, the surface of which is covered with tallow or plum oil; when sufficiently covered, they are transferred to the *brusher* in the left hand side of the trough; he passes a rough brush rapidly over each side of the plate, whereby the superfluous tin is removed. He then passes the plate again into the tin bath, and passes it out to his left hand neighbour, who gives it a washing. The plate passes through several hands being dried. Great skill is required in the tinning process; nevertheless in a well conducted work the wastage does not amount to more than 10 per cent.; a small percentage of which are washed as to require to be reworked. Great care is taken to avoid waste, the bath being worth 150*l*. per ton. A box of 225 sheets of tin plates 10 inches by 14 inches contains about ½ lb. of tin. See TIN PLATE.

The processes pursued in the smelting works of the Continent have frequently been viewed to obtain from the ore malleable iron directly, in a pure or nearly pure state. The furnaces used for this purpose are of two kinds, called in French, 1. *Four à l'acier*, or *Forges Catalanes*; and 2. *Fourneau àacier*, or *Forges Allemandes*.

In the Catalan, or French method, the ore previously roasted in a kiln is afterwards strongly torrefied in the forge before the smelting begins; operation which is performed in successive stages. Iron treated in this way should be very fusible and very malleable, such as black oxide of iron, hematite, and certain spathose ores. From this part of the work, 50 of metallic iron have been procured, but the average product is 10. The furnaces employed are rectangular hearths, Nos. 1040 and 1041, the water-lifting machine being employed to give the blast. See METALLURGY. There are three varieties of this forge; the Catalan, the Navarrese, and the Hungarian. The dimensions of the first, the one most generally employed, are as follows: 21 inches long in the direction of the fire, 1041; 18½ broad, at the bottom of the hearth or crucible, in the direction of the fire, 1042. The tuyere, &c., is placed 2½ inches above the bottom, so that its axis is directed towards the opposite side, about 2 inches above the bottom. But it must be movable, as its inclination needs to be changed, according to the stage of the operation, or the quantity of the ore. It is then raised or lowered with poles of clay; and even with a graduated circle, for the workmen make a great mystery of

this matter. The hearth is lined with a layer of *lutum* (clay) and charcoal dust work together, and the ore after it is roasted is a mass of small powder being set down to be used in the course of the operation. The tuyere is placed on the left opposite to the blast in a sharp saddle ridge, and it occupies one-third of the furnace. In the remaining space of two-thirds, the charcoal is put. To supply the small ore in the hearth, it is covered with *man* (manure) mixed with clay.

The fire is urged with more force during the first two hours, the workmen being constantly employed in pushing down more charcoal as the former is going lower away, so as to keep the space full, and prevent the ore from crumbling down. By a blast so tempered at the beginning, the ore gets well calcined, and partially reduced in the way of cementation. But after two hours, the full force of the air is given; at which period the furnace ought to be covered. It is easy to see whether the temperature be sufficiently advanced, by the aspect of the flame, as well as of the ore, which becomes spongy or cavernous; and the workmen now improve the furnace by detaching the pieces of iron from the bottom, and placing them in front of the tuyere. When the fine stuff is afterwards thrown upon the top, they must be watched, to prevent their being blown away, and to keep them evenly spread over the whole surface of the light fuel. They increase the quantity of the products, and give a proper facility to the action. When the scoriae are void, the quantity of charcoal must be diminished; but if then, they must be increased. The excess of fuel is allowed to run off by the *cho* or flame hole. The process lasts from five to six hours, after which the party mass is taken out, and placed under a hammer to be cut into lumps, which are afterwards forged into bars.

Each mass presents a mixed variety of iron and steel; in proportions which may be modified at pleasure; for by using much of the charcoal, and making the tuyere dip towards the sole of the hearth, iron is the chief product; but if the operation be conducted slowly, with a small quantity of stuffings, and an upraised tuyere, the quantity of steel is more considerable. This primitive process is favourably spoken of by M. Brongniart. The weight of the lump of metal varies from 200 to 400 pounds. As the consumption of charcoal is very great, amounting in the Palatinate or Rheinhessen to seven times the weight of iron obtained, though in the Pyrenees it is only thrice, the Catalan forge can be profitably employed only where wood is exceedingly cheap and abundant.

The *Furnace à piece* of the French, or *Stuck-ofen* of the Germans, resembles fig. 573 (Copper), the tuyere (not shown there) having a dip towards the bottom of the hearth, where the melted matter collects. When the operation is finished, that is at least once in every 24 hours, one of the sides of the hearth must be demolished, to take out the pasty mass of iron, more or less pure. This furnace holds a middle place in the treatment of iron, between the Catalan forge and the cast iron *fluo-ofen*, or high-blast furnaces. The *stuck-ofen* are from 10 to 15 feet high, and about 3 feet in diameter at the hearth. Most commonly there is only one aperture for the tuyere and for working; with a small one for the escape of the slag; on which account, the bellows are removed to make way for the lifting out of the lump of metal, which is done through an opening left on a level with the sole, temporarily closed with bricks and potter's clay, while the furnace is in action.

This outlet being closed, and the furnace filled with charcoal, fire is kindled at the bottom. Whenever the whole is in combustion, the roasted ore is introduced at the top in alternate charges with charcoal, till the proper quantity has been introduced. The ore falls down; and whenever it comes opposite to the tuyere the slag begins to flow, and the iron drops down and collects at the bottom of the hearth into the *cho* or *stuck*; and in proportion as this mass increases, the *fluo hole* for the slag and the tuyere is raised higher. When the quantity of iron accumulated in the hearth is judged to be sufficient, the bellows are stopped, the scoriae are raked off, the little brick wall is taken down, and the mass of iron is removed by rakes and tines. This mass is then flattened under the hammer into a cake from 3 to 4 inches thick, and is put into two

lumps which are submitted to a new operation, where it is treated in a peculiar refinery, lined with charcoal *braguer*, and exposed to a nearly horizontal blast. The above mass seized in the jaws of powerful tongs, is heated before the tuyere; a portion of the metal flows down to the bottom of the hearth, loses its carbon in a mass of rich slags or fused oxides, and forms thereby a mass of iron thoroughly refined. The portion that remains in the tongs forms *bessemer steel*, which is drawn out into bars.

This process is employed in Canada for making a granular grade of iron. The mass of steel amounts to from 15 to 20 hundred-weight at the close of a run of 24 hours. Eight strong men are required to lift it out, a dolly carry it under a large hammer, where it is cut into pieces of about 1 cwt. each. These are afterwards rolled, and drawn into bars as above described. These furnaces are now almost generally abandoned in the Continent, in favour of *charcoal high or blast furnaces*.

Fig. 1042 represents a *schockofen* (but without the tuyere, which may be supposed to be in the usual place), and is, like all the continental *Häute Fourneaux*, remarkable for the excessive thickness of its masonry. The charge is put in at the throat, near the summit of the octagonal or square cone, *as they are made of both forms*. At the bottom of the hearth there is a dam-stone with its plate, for permitting the overflow of the slag, while it retains the solid fluid metal, as well as a type stone with its plate, which forms the key to the front of the hearth; the bushes are a wide funnel, almost flat, to contract the easy descent of the charges, whereby the smelting with charcoal would proceed too rapidly. The bottom of the hearth is constructed of two large stones, and the hinder part of one great stone, called in German *schlackstein* (black stone), which the French have corrupted into *rustine*. In other countries of the Continent, the bushes are frequently a good deal more tapered downwards, and the hearth is larger than here represented. The refractory nature of the Häute iron ores is the reason assigned for this peculiarity.

In Sweden there are blast-furnaces, *schockofen*, 35 feet in height, measured from the bushes above the line of the hearth, or *crucet*. Their cavity has the form of an elongated ellipse, whose small diameter is 6 feet across, at a height of 14 feet above the bottom of the hearth; hence, at this part, the interior space constitutes a belly corresponding with the upper part of the bushes. In other respects the details of the construction of the Swedish furnaces resemble the one figured above. Marcher has found that a furnace of that kind when height was only 30 feet, in which brown hematite of iron (*hematite*) was smelted, yielded 47 per cent in cast iron, at the rate of 5 hundred weight a day, or 36 hundred-weight one week after another; and that in the production of 100 pounds of cast iron, 170 pounds of charcoal were consumed. That furnace was worked with four bellows, mounted with leather.

The decarburization of cast iron is merely a restoration of the carbon to the surface in tracing inversely the same progressive steps as had carried it into the interior during the smelting of the ore. The oxygen of the air, acting first at the surface of the cast metal upon the carbon which it finds there, burns it; fresh charcoal, coming from the interior, comes then to occupy the place of what had been dissipated; this, finally, the whole carbon is transferred from the centre to the surface, and is there converted into either carbonic acid gas or oxide of carbon; for so direct experiment has hitherto proved which of these is the precise product of this combustion.

The diffusibility of carbon through the whole mass of iron constitutes a movement by means of which cast iron may be refined even without undergoing fusion, as is proved by a multitude of phenomena. Every workman has observed that steel loses a portion of its easily proper iron every time it is heated in contact with air.

On the above principle, cast iron may be refined at once operation. Three kinds of iron are susceptible of this continuous process:—1. The speckled cast-iron, which contains such a proportion of oxygen and carbon as with the oxygen of the air and the carbon of the fuel may produce sufficient and complete saturation, but nothing in excess. 2. The dark grey cast iron. 3. The white cast-iron. The nature of the crude metal requires variations both in the form of the furnaces, and in the manipulations.

Indeed malleable iron may be obtained directly from the ores by one fusion. This mode of working is practised in the Pyrenees to a considerable extent. All the ores of iron are not adapted for this operation. Those in which the metallic oxide is mixed with much earthy matter, do not answer well; but those composed of the pure

black oxide, red oxide, and carburets, cannot break loose. To extract the metal from this mass, it is sufficient to expose (them to a high temperature, in contact with charcoal, or with other reducing gases; the metallic mass is separated, and that which covers it falls as powder, being thus completely detached from the metal, and when they melt, or run in a fluid vitreous mass, the metallic mass is separated. When such matters are as soft and friable, to be put into the low furnace called *Coulée*, the ore with the charcoal passes with great facility, and in which the contact with the fuel is easily maintained, there would be found in the practice of blast-furnaces a rule not to place masses of a lump of metal.

In roasting and reducing by air, the operation is performed in three different stages for distinction. 1. The roasting of the ore to expel the sulphur, which would be lost easily if roasted afterwards. The roasting is performed also the water, the carbonaceous matter, and any other volatile substance, which the minerals may contain. 2. The reduction and reduction to a mass by exposure to charcoal or other reducing agents. 3. The fusion, or melting, and reduction of the metal into a form for the heavy hammer where it is a nerve. There are several stages in which these three operations will be repeated, and in a single step, because, although each operation is repeated at a single stage, as a general rule. In other stages, the operations are performed in two, or more steps between each stage of the work. Three varieties of the kind are known to exist: 1. The *Coulée* method, 2. The *Coulée* with wood charcoal, and 3. The *Coulée* with water.

The furnace of *Coulée* are a kind of semi-circular furnace, 14 inches in diameter, and 6 inches deep. They are excavated in an area, or a small elevation of country, 5 or 10 feet long by 4 or 6 broad, and covered in with a chimney. This area is quite similar to that of the ordinary hearth of our blast-furnaces.

The tuyère stands 5 or 6 inches above the basin, and has a slight inclination downwards. In *Coulée*, and the whole portion of Italy, as far as the Molise, the iron ore is an oxide similar to the specular ore of the Lake. This ore contains a little water, some carbonic acid, and a small quantity of pyrites, but in small quantity. Before deoxidizing the ore, it is requisite to expel the water and carbonic acid combined with the oxide, as well as the sulphur of the pyrites.

The operations of roasting, reduction, fusion, and agglutination are executed in the same furnace. These are indeed divided into two stages, but the one is a continuation of the other. In the first, the two primary operations are performed at once—the reduction of a portion of the roasted ore is begun at the same time that a portion of the raw ore is roasted; these two substances are afterwards separated. In the second stage, the deoxidation of the metal is continued, which had begun in the first stage; it is then melted and agglutinated, so as to form a ball to be submitted to the heavy hammer.

The roasted pieces are broken down to the size of nuts, to make the reduction of the metal easier. In executing the first step, the basin and area of the furnace must be lined with a *brasque* of charcoal dust, 3, 4, or even 5 inches thick over the *brasque* a mound is raised with lumps of charcoal, very hard, and 4 or 5 inches high. A semicircle is framed round the tuyère, the inner radius of which is 5 or 6 inches. This mass of charcoal is next surrounded with another pile of the roasted and broken ore, which must be covered with charcoal dust. The whole is sustained with large blocks of the raw ore, which form externally a third wall.

These three piles of charcoal, with roasted and unroasted ore, are raised in three successive beds, each 7 inches thick; they are separated from each other by a layer of charcoal dust of about an inch, which makes the whole 24 inches high. This is afterwards covered over with a thick coat of pounded charcoal.

The blocks of raw ore which compose the outward wall form a slope, the larger and stronger pieces are at the bottom, and the smaller in the upper part. The large blocks are sunk very firmly into the charcoal dust, to enable them better to resist the pressure from within.

On the bottom of the semicircular well framed within the charcoal lumps, kindled pieces are thrown, and over these, pieces of black charcoal; after which the blast of a water-blowing machine (*trappe*) is given. The fire is kept up by constantly throwing charcoal into the central well. At the beginning of the operation it is thrust down with wooden rods, lest it should affect the building; but when the heat becomes too intense for the workmen to come so near the hearth, a long iron rake is employed for the purpose. At the end of about 3 hours, the two processes of roasting and reduction are completely finished: then the raw ore no longer exhales any fumes, and the roasted ore, being softened, unites into lumps more or less coherent.

The workman now removes the blocks of roasted ore which form the outer casing, rolls them to the spot where they are to be broken into small pieces, and pulls down the *brasque* (small charcoal) which surrounds the mass of roasted ore.

The second operation is executed by cleaning the basin, removing the slag covering the basin above with 2 or 3 *brasques* (coats of pounded charcoal), and pulling up to

the right and the left two heaps of charcoal dust. Into the interval between these two heaps two or three baskets of charcoal are cast, and on the top some cakes of the reduced cruds are laid, and the blast is renewed. The cakes, as they heat, undergo a sort of ignition, or swelling, by the action of the partly gaseous and the unreduced black oxide present. Very fusible slags flow down through the mass, and the iron, reduced and melted, passes freely through the cones, and falls into the basin below. To the first parcel of cakes others are added in succession. In proportion as the slags proceed from the cones run down, and the melted iron falls to the bottom, the thin slag is run off by an upper overflow or *cho hol*, and the reduced iron kept by the heat of the partly oxidation, remains in the basin: all its parts are agglutinated, forming a soft mass, which is removed by means of a hooked pole in order to be forged. Each lump or bloom of malleable iron requires 2 hours and a half for its production.

The iron obtained by this process is in general soft, very malleable, and but little steely. In Cornica four workmen are employed at one forge. The product of their labour is only about 4 cwt. of iron from 10 cwt. of ore and 20 of charcoal, mixed with wood of beech and chestnut. Though there are remains on an average 65 per cent. of iron, only about 40 parts are extracted, evincing a prodigious waste, which remains in the slag.

The difference between the Cornish and the Catalonian methods consists in the latter roasting the ore at a distinct operation, and employing a second one in the reduction, agglutination, and refining of the metal. In the Catalonian forges, 100 pounds of iron are obtained from 300 pounds of ore and 310 pounds of charcoal, being a produce of only 33 per cent. It may be concluded that there is a notable loss, since the sparry iron ores, which are those principally used, contain on an average from 54 to 56 per cent. of iron. The same ores smelted in the ordinary blast furnace produce about 45 per cent. of cast iron.

On the Continent, iron is frequently refined from the cast metal of the blast furnaces by three operations, in three different ways. In one, the pig being melted, with a portion of water, a cake is obtained, which is again melted in order to form a second cake. This being treated in the refinery fire, is then worked into a bloom. In another system, the pig iron is melted and cast into plates: these are melted anew in order to obtain crude balls, which are finally worked into blooms. In a third mode of manufacture, the pig iron is melted and cast into plates, which are roasted, and then strongly heated, to form a bloom.

The French fusible ores, such as the silicates of iron, are very apt to smelt into white cast iron. An excess of fluxes, light charcoals, too strong a blast, produce the same results. A surcharge of ores which deranges the furnace and affords more slag mixed with much iron, too rapid a slope in the bushes, too low a degree of heat, and too great condensation of the materials in the upper part of the furnace, all tend also to produce a white cast iron. In its state of perfection, white cast iron has a silver colour, and a bright metallic lustre. It is employed frequently in Germany for the manufacture of steel, and is then called *steel steel*, or *lamellar steel*, a title which it still retains, though it be hardly silver white, and has ceased to be foliated. When its colour takes a bluish grey tinge, and its fracture appears striated or splintery, or when it exhibits grey spots, it is then styled *flower steel*. In a third species of white cast iron we observe still much lustre, but its colour verges upon grey, and its texture is variable. Its fracture has been sometimes compared to that of a broken cheese. This variety occurs very frequently. It is a white cast iron, made by a surcharge of ore in the furnace. If the white colour becomes less clear and turns black, if its fracture be contorted, and contains a great many empty spaces or air-cells, the metal takes the name of *carcrans steel*, or *timber steel*. The whitest metal cannot be employed for casting. When the white is mixed with the grey cast iron, it becomes *riband* or *trout cast iron*.

The German refining forge.—Figs. 1043, 1044, represent one of the numerous refinery furnaces so common in the Harz. The example is taken from the *Mansfeld* works, in the neighbourhood of Ellingerode. Fig. 1044 is an elevation of this forge. It is the refinery hearth, provided with two pairs of bellows. Fig. 1043 is a vertical section, showing particularly the construction of the crucible or hearth in the refinery forge. It is an overshot water wheel, which gives an alternate impulsion to the two bellows *b* by means of the revolving shaft *c*, and the cams or tappets *d* & *e* *g*.

n, the hearth, is lined with cast-iron plates. Through the pipe *l*, cold water may be introduced, under the bottom plate *m*, in order to keep down, when necessary, the temperature of the crucible, and facilitate the solidification of the *knops* or blooms. An orifice *n*, figs. 1043, 1044, called the *cho* (flow hole), shows the melted slag or cinder to flow off from the surface of the melted metal. A copper pipe or nose piece conducts the blast of both bellows into the hearth, as shown at *b* & *c*, fig. 1044.

The train was followed to this point of railway by a grey car containing coal men, from the works of Reichardt. The train is, being full and heaped over with iron

Next, open the side opposite to the tuy re *s.* *f.* 11, 12, 13, 14, long pipe of iron or
steel with a tapering spigot downwards, and be drawn upwards successively
to the hearth by a bell-poker, so that the extremity which may be placed in
the middle of the fire, at a distance of 6 or 8 inches from the mouth of the tuy re.
The working process in this way will be hastened, if a mass of metal to be raised
from the furnace, e. g. *fa* and *re* in drops to the bottom of the hearth, being
carried by the fluid and more vitreous matters more or less heated with it.
After raising them off by the crane, be then works the last iron by powerful air
blast with the *sa* bellows, till it is converted into mass of a past.

If this is correct, a portion of the carbon released in the east flows westward, and is absorbed by the belt, and is put out in the form of carbon monoxide and carbon acid. When the lump is completed, finally, the workmen turn it over to the earth, from where the heat so as to melt it afresh, and which explains all that is in the blast, and let it come the remainder of the carbon, that is, the iron has been oxidized, or reduced. If we found a proof independent to this effect, two are given. If for the first time, the workman runs off a good stream of viscous slag, but at a higher level, so that some of it may remain upon the metal.

The weight of each *pu* or bloom is about 2 cwts., being the weight of 4 cwt. and $\frac{1}{2}$ of pig iron; the loss of weight is therefore about 26 per cent. 149 pounds of charcoal are consumed for every 100 pounds of bar iron obtained. The whole operation lasts about 2 hours. The bellows are stopped as soon as the bloom is ready; this is immediately transferred to a force hammer, the cast iron head of which weighs 8 or 9 cwts. The bloom is greatly condensed thereby, and discharges a considerable quantity of semi-fluid cinder. The lump is then divided by the hammer and a chisel into 4 or 6 pieces, which are re-heated, one after another, in the refinery fire, in order to be forged into bars, whilst another pig of cast iron is laid on its place, to prepare for the formation of a new bloom. The above process is called by the Germans *Alump-frischen*, or lump refining. It differs from the *durch bruch-frischen*, because in the latter the lump is not turned over in mass, but is broken up, and exposed in separate pieces, solely to the refining power of the blast near the tuyes. The French call this *affinage par morceaux*, it is less laborious work than the

The quality of the iron is tried in various ways; as, first, by raising a bar by the anvil, with the two hands over one's head, and bringing it forcibly down to strike across a narrow anvil at its centre of percussion, or, one-third from the other extremity of the bar; after which it may be bent backwards and forwards at the place of percussion several times; 2, a heavy bar may be laid obliquely over the anvil's end, and struck strongly with a hammer with a narrow pane, so as to curve it in two opposite directions; or while heated to redness, they may be kneaded backwards and forwards at the anvil's point, to the edge of the anvil. This is a severe trial, which the best Swedish iron, bears surprisingly, emitting as it is hammered a pleasant odour, peculiar to it, and to the bar iron of Ulverstone, which also resembles it in furnishing a good steel. The forging of a horse-shoe is reckoned a good criterion of the quality of iron. Its freedom from flaws is detected by the above modes; and its linear strength may be determined by suspending a scale to the lower end of a hard-drawn wire, of a given size, and adding weights till the wire breaks. The tests of Harlow, Tredguld, Houghton, and Vair, may be resorted to with advantage.

on the mode of proving the strength of different kinds of iron, in a great variety of circumstances.

Dry assay of iron ore.—The object of a dry assay of an iron ore is to ascertain by an experiment on a small scale the amount of iron which the ore should yield when smelted on the large scale in the blast furnace. For this purpose the metal must be dissolved, and a heat of fusion produced as to melt the metal and the earths associated with it in the former, and the latter may be smelted as a slag, but at the bottom of the furnace, and the latter in a lighter slag or slag above it. Such a temperature may only be obtained in a small furnace connected with a chimney at least 12 feet in height, and which may expressly for smelting the furnace, is generally built of such a size that four assays may be made at the same time, viz. about 14 inches square, and 12 feet in depth from the outer side of the cover to the movable bars of iron which form the grate. In order that the substance smelted with the iron in the ore should form a fusible compound, it is usually required to add a flux, the nature of which will depend upon the character of the ore and the exactness required. Berthier divides iron ores into five classes: 1. *Iron almost pure silica, such as the magnetic oxide, oligistic iron, and the hematite*; 2. *Ores containing silica, but free or nearly so from any other substance*; 3. *Ores containing silica and various bases, but little or no lime*; 4. *Ores containing one or more bases, and no lime*; 5. *Ores containing silica, oxide of titanium, oxide of chromium, or oxide of tungsten, but little or no lime*; 6. *Ores containing silica, lime, and a little iron, and which are fusible alone*. Ores of the first class may be reduced without any flux, but it is always better to employ one, as it greatly facilitates the formation of the button; borax may be used, or, better, a fusible earthy silicate, such as ordinary pot glass. Ores of the second class require some base to serve as a flux, such as carbonate of soda, a mixture of carbonate of lime and clay, or of carbonate of lime and dolomite; ores of the third class are mixed with carbonate of lime in the proportion of from one-half to three-fourths of the weight of the foreign matter present in the ore. Ores of the fourth class require as a flux silica in the form of powdered quartz, and generally also some lime; the magnesian spathic ores which belong to this class may be smelted with the addition of silica alone, but the magnesian spathic ores require lime. Ores of the fifth class require no flux.

Method of conducting the assay.—One hundred grains of the ore finely pulverised and passed through a silk sieve are well mixed with the flux, and the mixture introduced into the small concavity made in the centre of a crucible that has been lined with charcoal; the lining of the crucible is effected by partially filling it with coarsely powdered and slightly damped charcoal or *braque*, which is then rammed into a solid form by the use of a light wooden pestle. The mingled ore and flux must be covered with charcoal. The crucible thus filled is closed with an earthen lid (lined with fire clay) and it is then set on its base in the air furnace. The heat should be very slowly raised, the damper remaining closed during the first half-hour. In this way the water of the damp charcoal exhales slowly, and the distillation of the ore is completed before the fusion begins; if the heat were too high at first the luting would probably split, and moreover, the slag formed would disintegrate on cooling of iron, which would be lost to the button, and thus give an erroneous result. After half an hour the damper is gradually opened, and the furnace being filled with fresh coke, the temperature is raised progressively to a white heat, at which pitch it must be maintained for a quarter of an hour; the damper is then closed and the furnace allowed to cool. As soon as the temperature is sufficiently reduced, the crucible is removed and opened over a sheet of brown paper; the *braque* is carefully removed, and the button of cast iron taken out and weighed. If the experiment has been entirely successful the iron will be found at the bottom of the crucible in a small rounded button, and the slag will be entirely free from any adhering metallic matter, and will resemble in appearance green bottle glass; should, however, the crucible contain small metallic particles, the experiment is not necessarily a failure, as they may generally be recovered by washing and the magnet. But if on breaking the crucible, the reduced metal should be found in a partially melted state and not collected into a distinct mass, it indicates either too low a temperature or an improper selection of fluxes, and the experiment must be repeated. The iron obtained is not chemically pure, but contains carbon, and if the ore is manganesiferous, manganese; the result is therefore somewhat too high, though indicating with sufficient exactness for all manufacturing purposes the richness of the ore assayed.

Humid assay of iron ore.—The quantitative determination of the various substances that occur in iron ores, demands on the part of the operator a considerable amount of skill and patience, and can only be profitably undertaken by those who have acquired in the laboratory a thorough acquaintance with analytical operations. As, however, much attention has of late years been bestowed on the composition of

Iron ore, and all kinds of stones, viz. magnesian, siliceous, and phosphoric, are frequently present, which vary considerably in their economical value, we should endeavour to gain a detailed account of the circumstances to be performed in order to arrive at an accurate knowledge of the composition of any ore.

Looking for instance at a specimen of the most complicated composition, the subsequent analysis is to be looked for, and estimated, are oxide (ferrous and ferric), sulphate, carbonate, silicate, (all sulphate) acid, and all compounds of iron, phosphorus, and carbonic acid, siliceous acid, oxide of magnesia, alumina, lime, and silica; and also copper, and arsenic, are also occasionally met with. These metals are sought for when a specimen of their presence is ascertained by a special operation on a large quantity of ore.

Two great errors must be avoided in the sampling of ores intended for analysis; to procure so much time and labour as an perfect specimen (suitable for a special object) is worth the trouble; the sample operated upon should be selected from a large mass, which should be thoroughly pulverized and mixed; the pieces taken from different parts of the mass should be thoroughly powdered and mixed, and a small portion from the mass should be preserved in a well packed bottle for examination.

1. *Dissolution of iron ore in hydrochloric acid.*—About 10 grains of the ore are placed in the water over the test-tube, and a weight is expressed; the two ounces of the hydrochloric water, the residue is introduced into a tube of fixed glass, to which a weighed weight of the containing solution of iron; the powder is then gradually raised to a low red heat, the distilled water is thereby expelled, and a compact hydrate is formed by the increase in weight of the chloride of iron. From 100 parts the hydrate of iron ore contains as much as 12 per cent. of combined water.

2. *Sulphuric acid and sulphur.*—From 34 to 50 grains of the ore are weighed with hydrochloric acid, filtered and washed. The filtrate, concentrated if necessary by evaporation, is precipitated by great excess of chloride of barium. Every 100 parts of the solution of baryta produced indicate 74.57 parts of sulphuric acid. The insoluble residue on the filter is dried in a glass crucible with care and exposure of flame; the fused mass is dissolved in hydrochloric acid, evaporated to dryness, moistened with strong acid, dried, and filtered; from the filtrate the sulphuric acid is precipitated as sulphate of baryta, every 100 parts of which indicate 15.71 parts of sulphur, and 2.48 parts of chloride of iron.

In the analysis of hematite it is necessary to bear in mind that peroxide of iron is partially reduced when heated with finely divided iron pyrites and by sulphuric acid, sulphuric acid being formed.—*Ibid.*

3. *Phosphoric acid.*—From 50 to 75 grains of the ore are dissolved with hydrochloric acid and filtered; the clear solution, which should not be too acid, is mixed with sulphate of ammonia, which gradually in small quantities it either becomes colorless, or acquires a pale green colour, indicating that the peroxide of iron originally present has been reduced to protoxide; the solution is nearly neutralized with carbonate of ammonia, excess of acetate of ammonia added, and the liquid boiled; strong solution of perchloride of iron is then added drop by drop, until the precipitate which forms has a distinct red colour; this precipitate, which contains all the phosphoric acid originally present in the ore, is collected on a filter, washed, and redissolved in hydrochloric acid, tartaric acid added, and then ammonia. From this ammoniacal solution, the phosphoric acid is finally precipitated as ammonio-phosphate of magnesia, by the addition of chloride of ammonium, sulphate of magnesia, and ammonia. The precipitate is allowed 24 hours to subside, it is then collected on a filter, and if it has a yellow colour, which is almost invariably the case, it is redissolved in hydrochloric acid, and after tartaric acid being added, it is again precipitated by ammonia. 100 parts of the dried pyrophosphate of magnesia correspond to 64.3 parts of phosphoric acid.

4. *Alkali.*—It was ascertained by Mr. Dalk, that nearly the whole of the alkali present in an iron ore are contained in that portion which is insoluble in hydrochloric acid. The residue from about 50 grains of the ore is placed in a platinum capsule, moistened with ammonia, and exposed for several hours to the action of hydrofluoric acid gas in a closed leaden dish; it may be necessary to repeat the operation if much silica is present; it is then slowly heated to dull redness, and dissolved in dilute hydrochloric acid; the solution is mixed with excess of baryta water and filtered; the excess of baryta is removed by carbonate of ammonia, and the solution is evaporated to dryness and ignited; the residue is redissolved in a little hot water, and a few drops of oxalate of ammonia added. If no precipitate or cloudiness occurs, it may be once more evaporated to dryness and gently ignited; the residue is chloride of potassium, 100 parts of which indicate 63 parts of potash. Should oxalate of ammonia have occurred a precipitate, it must be filtered off, and the clear liquid evaporated. The search for potash is troublesome and lengthy; it may be altogether omitted in a tedious analysis.

Dissolution of the remaining iron salts — 25 or 30 grains of the finely powdered ore are dissolved in a test-tube with a few drops of hydrochloric acid, diluted with distilled water and filtered. The residue on the filter being thoroughly washed, the solution is peroxidised, if necessary, by the addition of chlorate of potash, and is neutralised by ammonia, boiled with excess of acetate of ammonia, and rapidly filtered while hot; the filtrate (which would be colourless) together with the washings, is removed in a flask, ammonia is added, and then a few drops of bromine, and the flask closed with a cork. In a few minutes, if manganese be present, the liquid acquires a dark colour; it is allowed to remain at rest for 24 hours, then warmed, and rapidly filtered and washed; the brown substance on the filter is hydrated oxide of manganese, it loses its water by ignition, and then becomes MnO_2 , 100 parts of which correspond to 67 parts of protoxide.

The liquid filtered from the manganese contains the lime and magnesia; the former is precipitated by oxalate of ammonia, and the oxalate of lime formed converted by ammonium carbonate, in which state it is either washed, having been previously evaporated with carbonate of ammonia, or it is converted into carbonate by the addition of a few drops of sulphuric acid, evaporated, and ignited. The lime being separated, the magnesia is thrown down as ammonium magnesia phosphate by phosphate of soda and ammonia, and after standing for 24 hours it is collected on a filter, washed with cold ammonia water, dried, ignited, and weighed; 100 parts of carbonate of lime correspond to 60 of lime; 100 parts of sulphate of lime to 40.1 of lime, and 100 parts of pyrophosphate of magnesia to 35.7 of magnesia.

The red precipitate collected on the filter after the boiling with acetate of ammonia, consists of the basic acetates of iron and alumina, together with the phosphoric acid. It is dissolved in a small quantity of hydrochloric acid, and then boiled in a silver or platinum basin with considerable excess of pure caustic potash; the alumina (with the phosphoric acid) is hereby dissolved, the insoluble portion is allowed to subside, and the clear liquid is then decanted, after which the residue is thrown on a filter and washed; the filtrate and washings are supersaturated with hydrochloric acid, nearly neutralised with ammonia, and the alumina finally precipitated by carbonate of ammonia. From the weight of the ignited precipitate, the corresponding amount of phosphoric acid determined by a separate operation is to be deducted, the remainder is calculated as alumina. The residue left after digesting the ore with hydrochloric acid, consists principally of silica, but it may also contain alumina, peroxide of iron, lime, manganese, and potash. For practical purposes it is rarely necessary to submit it to minute examination; should such be desired, it must be dried, ignited, and weighed, then fused in a platinum crucible with four times its weight of fused alkaline carbonates, the fused mass dissolved in dilute hydrochloric acid, and evaporated to dryness, the residue washed with strong hydrochloric acid, and after standing at rest for some hours, redissolved in hot water, filtered, and the acids on the filter washed and weighed. The alumina, lime, oxide of iron, and manganese in the filtrate are separated from each other according to the instructions given above; the potash is estimated by a standard process.

Carbon and loss — The coal, which constitutes a considerable part of the weight of that large and important class of ores the *clay iron-stones*, is estimated by noting the loss sustained after adding to a weighed portion of the ore sulphuric acid, and thus evolving the gas; or more roughly, by the loss sustained in the entire analysis. Another method is to fuse 20 or 25 grains of the ore with 60 or 80 grains of dry borax, and noting the loss, which consists of water and carbonic acid; by deducting the water obtained in a previous experiment, the quantity of carbonic acid is obtained. This method, however, can scarcely be recommended, on account of the contraction of the crucible, though the results are very accurate.

Determination of the iron — This is performed on a separate portion of the ore, either by the volumetric method of Marguerite, or by that of Dr. Penny; both give very exact results. Marguerite's method is based on the reciprocal action of the salts of protoxide of iron and permanganate of potash, whereby a quantity of the latter is decomposed exactly proportionate to the quantity of iron. The ore (about 10 or 15 grains) is dissolved in hydrochloric acid, and the metal brought to the minimum of oxidation by treating the solution with sulphate of soda (or better, sulphate of ammonia), and boiling to expel the excess of sulphurous acid; the solution of permanganate of potash is then cautiously added drop by drop, until the pink colour appears, and the number of divisions of the burette required for the purpose accurately noted. The solution should be considerably diluted, and there must be a sufficient quantity of free acid present to keep in solution the peroxide of iron formed and also the oxide of manganese. The whole of the iron must be at the minimum of oxidation, and the excess of sulphurous acid must be completely expelled; if the latter precaution be neglected an erroneous result will be obtained, as the sul-

plasma will will take oxygen from the peroxide, and thus form in the same manner as iron.

To prepare the peroxide of protoxi, 7 parts of carbonate of potash, 10 parts of hyposulphite of potash, and 5 parts of peroxide of manganese are commonly used. The carbonate must be in the finest possible powder, and the peroxide having been dissolved in water, is mixed with the other substances, and the whole formed in a very dilute solution for use. The fluid mass is dissolved with water, so as to obtain as concentrated a solution as possible, and about twice as much added for the usual quantity of a cubic foot of water, to be afterwards filtered through asbestos. The solution must be freed from the matters of organic matter, and kept in a glass stoppered bottle. If the solution be evaporated it yields beautiful red osmium crystals; it is better to employ the crystals in the preparation of the test liquor, as the solution keeps much better when no carbonate is present. To prepare the normal or test liquor, a certain quantity, say 10 grains, of pure iron wire are dissolved in part by osmium acid, after the decomposition of the liquor has ceased, and the solution is complete, the liquor is diluted with about a pint of water, and immediately divided by measurement into two equal parts, the number of drops of solution of the test liquor of peroxide is added to produce a pink colour is immediately formed, and this number is then multiplied by 1000, and the result is the result of the analysis of the ore. A small amount of iron is more by dissolving long grains of the crystallized peroxide in 1000 grains of water.

Pavy's method is based on the proportional action of chlorine and acid on a salt of iron, whereby a fraction of the iron takes place, the peroxide of iron forming a normal base, and the residue acid thus equivalent of chlorine. The process is conducted as follows:—A convenient quantity of the substance is reduced to coarse powder, and one half at least of this is reduced further powder, and it is no longer only before the furnace. The test solution of bichromate of potash is next prepared: 444 grains of the salt in one pint of water are weighed out, and put into a beared graduated into 100 equal parts, and when dissolved water is afterwards poured in until the structure is filled to 0. The plug of the flask is then loosely placed on the top, and the contents are stirred by repeatedly turning the flask until the solution is dissolved and the solution colored red of osmium, and the division of the solution thus prepared is 444 grains of bichromate, which Dr. Pavy ascertained to correspond to half a grain of metallic iron. The bichromate must be pure, and should be thoroughly dried by being heated in a glass bottle. 10 grains of the pulverized substance are now introduced into a Florence flask with 1½ oz. by measure of strong hydrochloric acid and 1 pint of distilled water. Heat is occasionally applied, and the mixture continuously agitated until the osmium is removed by the escape of carbonic acid gases, the heat is then removed, and the mixture made to boil and kept at moderate ebullition for an hour, or a quarter of an hour. About 6 oz. of water are next added and mixed with the contents of the flask, and the whole filtered into an evaporating basin. The flask is rinsed several times with water, to remove all adhering solution, and the residue on the filter is well washed. Several small portions of a weak solution of red prussiate of potash (containing 1 part of salt to 40 water) are now dropped upon a white porcelain slab, which is conveniently placed for testing, the solution in the basin during the heat operation. The prepared solution of bichromate of potash in the burette is then added very cautiously to the solution of iron, which must be repeatedly stirred, and as soon as it assumes a dark greenish shade it should be occasionally tested with the red prussiate of potash. This may be easily done by taking out a small quantity on the end of a glass rod, and mixing it with a drop of the solution in the porcelain slab. When it is found that the last drop runs out a distinct blue line, the operation is terminated, the burette is allowed to drain for a few minutes, and the number of divisions of the test liquor consumed read off. This number multiplied by 2 gives the amount of iron per cent. The necessary calculation for ascertaining the corresponding quantity of protoxide is obvious. If the specimen should contain iron in the form of peroxide, the hydrochloric solution is decolorised as before by solution of ammonia. The presence of peroxide of iron in an ore is easily detected by dissolving 50 or 60 grains in hydrochloric acid, diluting with water, and testing a portion of the solution with red prussiate of potash. If a decided blood-red colour is produced, peroxide of iron is present. If it be desired to ascertain the relative proportions of peroxide and protoxide of iron in an ore, two operations must be performed:—one on a quantity of the ore that has been dissolved in hydrochloric acid in a stout stoppered bottle; and another on a second quantity that has been dissolved as usual, and then decolorised by sulphite of ammonia or by metallic zinc. It is advisable to employ the solution of bichromate much weaker than proposed by Dr. Pavy, and to employ a burette graduated to cubic millimetres. A good strength is 1 grain of metallic iron in 10 cubic centimetres of test liquor.

Metals precipitable by sulphuric acid.—The hydrochloric acid is washed portion of the ore very finely divided, and is washed for a considerable time with hydrochloric acid; the amount of iron is determined for the red iron, which is necessary by sulphate of ammonia, and a current of sulphuretted hydrogen is passed through it. A small quantity of sulphuric acid is always added to the solution on a filter, and the thoroughly washed; it is then evaporated at us as a precipitate as possible. The residue (if any) is mixed with carbon, and blown off with a blowpipe; any portion of metal that may be obtained is removed and dried.

Analysis of pyrites.—The most important constituents to be determined are iron (combined and uncombined), arsenic, sulphur, phosphorus, traces of lead, copper, cobalt, nickel, tin, aluminium, calcium, magnesium, arsenic, zinc, chromium, lithium, and the salts of the alkalis.

1. *Determination of the total amount of carbon.*—About 1 grain of the iron is dissolved in 20 cc. of water and 2 cc. of concentrated hydrochloric acid. The solution is allowed to proceed until all, or nearly all the iron is dissolved. Carbon and copper are left insoluble; they are filtered on a filter, washed with dilute hydrochloric acid (to prevent the precipitation of copper), and with water. The washed carbon and copper are dried on the filter, from which they are removed by a hot blast, and are mixed with oxide of copper, and burned in a glass tube in the usual way, with a current of air, or, still better, of oxygen. The carbonic acid is collected in Liebig's apparatus, from which the amount of carbon is calculated.

2. *Graphite, or uncombined carbon.*—A weighed portion of the finely divided iron (flasks or borings may be used) is digested with moderately strong hydrochloric acid, the evolved carbon is evolved in combination with hydrogen, while the graphite is left undissolved. It is collected on a filter, washed, and then boiled with a solution of caustic potash, sp. gr. 1.37, in a silver dish; the solution which contains the iron in the form of silico-iron is thereby dissolved; the clear caustic solution is drawn off by a pipe or syphon, and the black residue repeatedly washed; it is dried at as high a temperature as it will bear, and weighed; it is then heated in a current of air, until the whole of the carbon is burnt off. A residue remains, which is weighed, and the weight deducted from that of the original black residue, the difference gives the amount of graphite.

3. *Silica.*—The amount of this element is determined by evaporating to dryness a hydrochloric solution of a weighed quantity of the metal. The dry residue is digested with hydrochloric acid, filtered with water, boiled and filtered; the residue on the filter is washed, dried, and ignited, and the whole of the residue is lost off; it is then weighed, after which, it is dissolved with solution of potash, and the residue, if any, washed, dried, ignited, and weighed; the difference between the two weights gives the amount of silica. 100 parts of which indicate 47 parts of silica.

4. *Phosphorus.*—A weighed portion of the metal is dissolved in nitric acid, and evaporated to dryness, and the residue redissolved with hydrochloric acid. The solution is treated precisely as recommended for the determination of phosphoric acid in ores; every 100 parts of pyrophosphate of magnesia indicate 25.36 parts of phosphorus.

5. *Sulphur.*—In pyrites the element is very conveniently and accurately estimated by allowing the gas evolved by the action of hydrochloric acid on a weighed quantity (about 100 grains) of the metal, to pass slowly through a solution of acetate of lead acidified by acetic acid. Sulphur, the whole of which takes the form of sulphuretted hydrogen, enters into combination with the lead, forming a black precipitate of sulphide of lead, which is collected, washed, and converted into sulphate of lead by digesting it with nitric acid, evaporating to dryness, and gently heating to 100 parts sulphate of lead = 10.55 sulphur. The most minute quantity of sulphur in iron is detected by this process. If, however, crude white iron is under examination, this method does not give satisfactory results, on account of the difficulty with which it is acted upon by hydrochloric acid; it is better, therefore, to treat the metal with nitro-hydrochloric acid, evaporate to dryness, re-digest with hydrochloric acid, and then precipitate the filtered solution with great excess of chloride of barium; or the finely divided metal may be fused in a gold crucible with an equal weight of pure nitrate of soda and twice its weight of pure alkaline carbonates; the fused mass is extracted with water acidified with hydrochloric acid, and finally precipitated by chloride of barium.

Manganese.—The metal is determined by the process described for its estimation in ores; the iron must exist in the solution in the form of sesquioxide.

Arsenic and copper.—The nitro-hydrochloric solution of the metal is evaporated to dryness, re-digested with hydrochloric acid, and filtered. The iron in the clear

residue is removed to prevent its being mixed with a sufficient quantity of sulphuric acid, the solution is heated till it has the appearance of castile soap. It is then separated with water, distilled water, and a new distillation is performed in a small vessel, the excess of gas is boiled off, and the precipitate, if any, removed on a small filter and well washed; it is then mixed with a small quantity of potassium which dissolves the sulphate of arsenic, leaving the sulphate of copper. The latter is decomposed by heating with nitric acid, and the presence of copper is proved by the addition of ammonia, which produces a blue color; the sulphate of arsenic is precipitated from the solution in the shape of potassium by dilute sulphuric acid; it may be redissolved in aqua regia, and the filtrate solid having been exposed by evaporation, the residue may be analyzed as Marsh's arsenic.

Antimony and tin.—These metals, if present, will be found in the residue from which the copper and arsenic have been precipitated by sulphuretted hydrogen. The solution is percolated, and the superoxide of iron precipitated by slight excess of carbonate of baryta, after which the solution is treated as just directed by sulphate of magnesia.

Chromium and manganum.—These metals which should be looked for in the carbonaceous residue obtained by dissolving a small quantity of the sample in dilute hydrochloric or sulphuric acid are dissolved as follows: *Water.*—The filtered residue is intimately mixed with one third of its weight of iron, and exposed to a strong fire in a crucible to a black point. When cool the mass is powdered and treated with water. The filtered solution is gradually mixed and well stirred with nitric acid, taking care that it may boil rapidly, slightly, a half hour, and that no nitrous acid is liberated which would reduce the vanadic and chromic acids. The solution is then mixed with an excess of solution of chloride of barium as long as any precipitate is produced. The precipitate, which consists of vanadate and chromate of baryta, is dissolved with slight excess of dilute sulphuric acid, and filtered. The filtrate is evaporated with ammonia, concentrated by evaporation, and a fragment of chloride of ammonium placed in it. In proportion as the solution becomes impregnated with soluble of potassium, manganate of ammonia is deposited as a white or yellow crystalline powder. To test for chromium only, the solution is treated with water, extracted with water, and then boiled with carbonate of ammonia; the solution is neutralized with acetic acid, and then acetate of lead added; the production of a yellow precipitate indicates chromium.

Iron.—The metal is best separated from iron, by first reducing the latter to the state of protoxyde by sulphate of ammonia, then neutralizing with carbonate of soda, and afterwards boiling with excess of caustic potash, until the precipitate is black and pulverulent. The solution is then filtered off, and is neutralized with hydrochloric acid, and the alumina precipitated by sulphate of ammonia.

Calcium and magnesium.—These metals are found in the solution from which the iron and aluminium have been separated; they both exist probably (together with the aluminium) in the cast iron in the form of slag, and are best detected in the black residue which is left on dissolving the iron in dilute sulphuric or hydrochloric acid. After digesting this residue with caustic potash, and burning away the graphite, a small quantity of a red powder is left, which is composed of chromic acid, oxide of iron, alumina, lime, and magnesia; if 300 grains of cast iron are operated upon, a sufficient quantity of insoluble residue will be obtained for a quantitative determination of its constituents.—H. M. N.

IRON BRIDGE. See TRUSS.

ISINGLASS (*Galle de Poisson*, Fr.; *Husenblase*, Germ.), *Ichthyocola*, *ἰχθυόcolla*, from *ἰχθ*, a fish, and *κόλλα*, glue, or Fish glue, is a whitish, dry, tough, semi-transparent substance, twisted into different shapes, often in the form of a lyre, and consisting of membranes rolled together. Good isinglass is unchangeable in the air, has a leathery aspect, and a marked tone, nearly insipid when steeped in cold water it swells, softens, and separates in membranous laminæ. At the boiling heat it dissolves in water, and the solution, on cooling, forms a white jelly, which is semi-transparent, soluble in weak acids, but is precipitated from them by alkalis. It is gelatinous, nearly pure; and if not brittle, like other glue, this depends on its fibrous and elastic texture. The whitest and finest is preferred in commerce. Isinglass is prepared from the air-bladders of sturgeons, and especially the great sturgeon, the *Acipenser huso*, which is fished on the shores of the Caspian Sea, and in the rivers flowing into it, for the sake chiefly of its swimming bladder. It is also obtained from the *A. stellatus*, and the *A. Goldensteinii*. We are informed that in Russia the *Siberian glanis* is also caught for the purpose of obtaining isinglass.

The preparation of isinglass in Russia, and particularly at Astracan, consists in steeping the swimming bladders in water, removing carefully their external coat, and the blood which often covers them, putting them into a dampen-bag, squeezing them, softening them between the hands, and twisting them into small cylinders. They are

ready for the market is made only after being dried in the sun, and washed with the juice of burning sulphur.

In some districts of Malavia, another process is followed. The skin, the stomach, the intestines and the swimming bladder of the eel are cut in small pieces, steeped in cold water, and then gently boiled. The jelly thus obtained is spread in thin layers to dry, when it assumes the appearance of parchment. This being softened in a little water, then rolled into cylinders, or extended into plates, constitutes an inferior article.

The swimming bladder of the eel and many other fishes, also furnishes a species of isinglass, but it is much more membranous, and less soluble than that of the sturgeon.

The properties of isinglass are the same as those of gelatine or pure glue, and its uses are very numerous. It is employed in considerable quantities to clarify ale, wine, liquors, and coffee. As an article of food to the luxurious in the preparation of creams and jellies, it is in great request. Four parts of it convert 100 of water into a transparent jelly, which is employed to enrich many soups and sauces. It is used along with gum as a dressing to give lustre to ribbons and other silk articles.

It is by covering thin silk with a coat of isinglass that court water is made. A solution of isinglass covered with carmine forms an excellent injection liquor to the anatomist. M. Roehen has made another pretty application of isinglass. He plunges into a liquid solution of it, made by means of a water-bath, sheets of wire gauze set in window or lamp frames, which, when cold, have the appearance of glass, and answer instead of it for shades and other purposes. If one dip be not sufficient to make a proper transparent plate of isinglass, several may be given in succession, all within such film to harden in the interval between the dips. The outer surface should be varnished to protect it from damp air. These panes of gelatine are now generally used for lamps instead of glass, in the maritime arsenals of France. — See GELATINE.

Isinglass is known commercially as *Leaf isinglass*, *Long and short staple*, and *Black isinglass*. Dr. Royle speaks of the *Simorey leaf*, *bush*, and *long and short staple*. In his paper on the *Production of Temphoo along the coasts of India*, which a *Notice of its Fisheries*. We receive from the *Brasil, Pipe, Lump, and Home-cumb Isinglass*.

Our importations of isinglass in 1856 and 1857, were

ISOMERISM, from *isos*, equal, and *meros*, part. Identity of elements and proportions with variations in physical properties. Thus, oil of turpentine and oil of citron are isomeric, each having the composition $C_{10}H_{16}$. The study of the laws of atomic constitution is one of the most important within the range of physico-chemical science, and beyond all others, it demands the highest powers of the philosopher, united with the mechanical care of the microscopic analyst. The tendency of science leads to the conviction that many of the bodies which we now regard as distinct elements are only isomeric; and such groups as chlorine, iodine, bromine, and fluorine, as sulphur, selenium, and boron, and as carbon and silicon, may with the advance of our knowledge be shown to be modified conditions of one form of matter. This subject will be fully treated in *Frost's Dictionary of Chemistry*.

ISOMORPHISM. M. Scherer was the first to observe that many groups of substances, simple or compound, having an analogous constitution, crystallise in forms of the same crystalline character, or differ but little in their angles. Thus, *alumina*, *red oxide of iron*, and *oxide of chrome* crystallise in forms of the rhombobedral system.

Carbonate of lime, *carbonate of magnesia*, *protosulphate of iron*, *protosulphate of manganese*, and *oxide of lime* are also isomorphous forms belonging to the rhombobedral system.

both hair and fur, is derived from an animal deriving sustenance from the leaves and branches of trees, which grow as low as the black berries of north latitude. Some of the ivory of commerce is, instead of being derived from the tusk of this animal, taken from the jawbone of the walrus.

The ivory of the tusk of the African elephant is most esteemed by the manufacturer for its density and whiteness.

The outside of the tusk of the elephant is covered by the cortical part, which is softer and less compact than the interior substance, with the exception of the two sides that meet there, being the hardest cavity. The hardest, toughest, whitest, and most translucent ivory has the preference in the market; for many purposes the horn of the narwhal being considered the best. The horn of the narwhal is sometimes used for the same purposes as ivory.

The ivory of the humpback is preferred by dentists; it is much harder than that of the elephant, its surface is a pearly white, and it is almost free from grain. The teeth of the walrus, sometimes called the walrus-ivory, which being perforated from the upper jaw, are also used for the same purposes. The most common kind of ivory of the human animal are occasionally used as ivory; those of the sperm whale are of a pearly oval section, and resemble ivory in appearance, but they are dark coloured towards the centre, and surrounded by an oval band of white ivory.

Ivory has been used for ornamental works from the earliest periods. It has been used to have been found for his works only in ivory combined with gold, and attributed to the Egyptians. The ivory statues of the ancients appear to have been painted upon, and not carved out of ivory, and covered with gold or ivory.

In our days ivory has been extensively employed by the miniature painter; it is used by the carver in the manufacture of numerous useful and ornamental articles; the carver makes the bone handle from it, and the philosophical instrument maker constructs his scales from this material.

When ivory shows cracks or fissures, it is a substance, and when a splinter broken off by a dull aspect, it is reckoned of inferior value. Ivory is distinguished from bone by a peculiar semi-transparent rhomboidal net-work, which may be readily seen in a piece of ivory cut transversely.

Ivory is very apt to take a yellow brown tint by exposure to air. It may be whitened or bleached, by rubbing it first with pounded pumice-stone and water, then placing it under a glass shade luted to the side at the bottom, and exposing it to sunlight. The substance without the shade would be apt to become discoloured in the ivory. The most rubbing and exposure may be repeated several times.

For etching ivory a ground mass by the following recipe is to be applied to the polished surface.—Take of pure white wax, and the purest tears of asphalt, each two ounces, asphalt, half an ounce. The mass, and asphalt having been separately reduced to fine powder, and the wax being melted in an earthenware vessel over the fire, the asphalt is to be added and stirred in and dissolved by stirring; and then the asphalt in like manner. The composition is to be poured out into lukewarm water well kneaded, and then by the hand, into balls about an inch in diameter. These should be kept wrapped round with oiled paper. If white resin be substituted for the asphalt, a clearer composition will be obtained, which answers nearly as well; 2 oz. asphalt, 1 oz. resin, 3 oz. white wax, being good proportions. The etching ground is made by dissolving with heat 4 oz. of resin in 1 oz. of very fine linseed oil, filtering the varnish through a rag, and bottling it in a glass.

Either of these grounds being applied to the ivory, the figured design is to be traced through it in the usual way, a ledge of wax is to be applied, and the surface is to be then covered with strong sulphuric acid. The effect comes better out with the aid of a little heat; and by replacing the acid, as it becomes diluted, by a fresh portion of moisture, with concentrated oil of vitriol. Simple wax may be employed instead of the copperplate engravers' ground; and strong muriatic acid instead of sulphuric. If an acid solution of silver or gold be used for etching, the design will become purple or black on exposure to sunshine. The wax may be washed away with oil of turpentine. Acid nitrate of silver affords the easiest means of tracing; transient black lines upon ivory.

Ivory may be dyed by using the following prescriptions:—

1. *Black dye*.—If the ivory be laid for several hours in a dilute solution of neutral nitrate of pure silver, with access of light, it will assume a black colour, having a slightly green cast. A still finer and deeper black may be obtained by boiling the ivory for some time in a strained decoction of logwood, and then steeping it in a solution of red sulphate or red acetate of iron.

2. *Blue dye*.—When ivory is kept immersed for a longer or shorter time in a dilute solution of sulphate of indigo (partly saturated with potash), it assumes a blue tint of greater or less intensity.

2. *Crossing*.—This is generally done by dipping about every four or five inches into a solution of nitric acid of the right strength, and drawing it out.

4. *Yeast dressing*.—is given by dipping in the yeast, and then drawing it out. The yeast dressing is used when the ivory is to be polished. The dressing is made by taking a pound of yeast, and adding to it a quart of water. A very fine cloth is used to wipe the ivory, and the dressing is then applied by dipping it in it. The dressing is then drawn out, and the ivory is then polished.

5. *Red dress*.—may be given by dipping the ivory first with the red dress, then drawing it out, and then dipping it in the red dress, and drawing it out. The red dress is made by taking a pound of red dress, and adding to it a quart of water. The red dress is then applied by dipping the ivory in it, and drawing it out.

6. *Final dress*.—is given by dipping the ivory in the final dress, and drawing it out. The final dress is made by taking a pound of final dress, and adding to it a quart of water. The final dress is then applied by dipping the ivory in it, and drawing it out.

With regard to the use of the ivory, it may be observed that the ivory is generally used for the purpose of making the surface of the ivory, and for the purpose of making the surface of the ivory. The ivory is then used for the purpose of making the surface of the ivory, and for the purpose of making the surface of the ivory.

If the ivory is to be used for the purpose of making the surface of the ivory, it may be observed that the ivory is generally used for the purpose of making the surface of the ivory, and for the purpose of making the surface of the ivory.

Ivory waste.—Ivory articles may be made of ivory, and may be made of ivory. The ivory is then used for the purpose of making the surface of the ivory, and for the purpose of making the surface of the ivory.

It is not our intention to enter into the details of the method of preparing the ivory, but a short account of the method of preparing the ivory, and of the method of preparing the ivory, will be of use.

"On account of the great value of ivory, it requires considerable skill and judgment to be employed in its preparation. The first step is to select the ivory, and then to select the ivory. The ivory is then used for the purpose of making the surface of the ivory, and for the purpose of making the surface of the ivory.

"The methods of dividing the tooth, either into rectangular pieces or into a circular figure required for turning, are alike in their early stages, until the tooth is resorted to. The ivory saw is stretched in a steel frame to keep it very true; the blade generally measures from fifteen to thirty inches long, from one and a half to three inches wide, and about the fortieth of an inch thick; the teeth are rounder course, namely, about five or six to the inch, and they are shaped a little from that is, between the angle of the common hand-saw tooth and the true circular tooth. The instrument should be very sharp, and but slightly set. It requires to be ground very correctly in cutting, and with no more pressure than the weight of the arm, finger, and is commonly lubricated with a little lard, tallow, or other good fat.

"The cutter begins generally at the hollow, and having fixed that accurately, parallel with the vice, with the curvature upwards, he saws off that piece which is too thin for his purpose, and then two or three parallel pieces to the depth of some particular width, for which the thickness of the tooth at that part is the most suitable; he will then saw off the very wide firm piece, and afterwards two or three more parallel blades.

"In setting out the length of every section, he is guided by the gradually increasing thickness of the tooth; having before him the patterns or images of his various works, he will in all cases employ the hollow for the thickest work it will make. As the tooth approaches the solid form, the considerations of the ivory gradually cease, and then the blocks are cut off to any required measure, with only a general reference to the direction of the *heel*, or the *curve* arising from the curved nature of the tooth, the sets being in general directed as nearly as may be to the imaginary centre of curvature. The greater waste occurs in cutting up very long pieces, owing to the differ-

ence between the straight line and the curve of the tooth, on which account the blocks are rarely cut more than five or six inches long, unless for some special object.

Mr. P. L. Simmonds has given the following as the weights of large elephants' tusks:—

Mr. Gordon Cumming had one weighing	-	-	-	174 lbs.
Mr. Caswood, of Graham's Town, had a pair weighing	-	-	-	330 lbs.
From Camaroon, shipped to Liverpool	-	-	-	184 lbs.
A tusk imported at Rangoon	-	-	-	147 lbs.
At the Great Exhibition of 1851, tusk	-	-	-	102 lbs.

IVORY BLACK (*Nuit d'ivoire*, Fr.; *Kohle von Elfenbein*, Germ.) is prepared from ivory dust, by calcination, in the very same way as is described under **BLACK**. The calcined matter being ground and levigated on a porphyry slab affords a beautiful velvety black, much used in copperplate printing.

IVORY, FICTILE, is plaster of Paris which has been made to absorb, after drying, melted spermaceti, by capillary action, or it may be prepared according to Mr. Franchi's process as follows:—Master and coloring matter are employed in the proportions of a pound of super-fine plaster of Paris to half an ounce of Indian yellow color. They are intimately mixed by passing them through a fine silk sieve, and a plaster cast is made in the usual way. It is first allowed to dry in the open air, and is then carefully heated in an oven; the plaster cast, when thoroughly dry is soaked for a quarter of an hour in a bath containing equal parts of white wax, spermaceti, and stramon, heated just a little beyond the melting point. The cast on removal is set on edge, that the superfluous composition may drain off, and before it cools, the surface is brushed, with a brush like that known by house painters as a sash tool, to remove any wax which may have settled in the crevices; and finally when the plaster is quite cold, its surface is polished by rubbing it with a tuft of cotton wool.

IVORY-NUT. Corom, or vegetable ivory. A species of the green pine *Ficus* growing in Central America and Columbia. The *Phytolophus macrocarpa* produces these nuts, which have a structure somewhat resembling that of ivory; but it more nearly resembles white wax. The ivory nut is not used for any important work.

J.

JACK, called also *jack-in-a-box*, and *hand-jack*, is a portable, mechanical instrument, consisting of a rack and pinion, or a pair of claws and ratchet bar, moved by a wheel handle, for raising heavy weights a little way off the ground.

JACK and **JACK-SINKERS**, are parts of a stocking frame. See **HOSIERY**.

JACK-BAK, is the largest jack of the brewer.

JACK, BLACK. The miners' name for the sulphide (sulphuret) of zinc, or blende. See **ZINC**.

JACQUARD. A peculiar and most ingenious mechanism, invented by M. Jac-

quest of I voms to be adapted to work on such a loom for producing the regular series of draw-boys, or weaving figured cloth. Independence of the ordinary series of the warp threads for the formation of the ground of each a web, all those threads which

should rise simultaneously to produce the figure, have their appropriate levers, which a child formerly raised by means of cards, that grouped them together into a system, in the order, and at the time desired by the weaver. This plan evidently required no

little complication in the machine, when the design was richly figured; but the apparatus of Jacquard, which only adds this manoeuvre to a regular mechanical operation, and derives its motion from a simple pedal put in action by the weaver's foot, was generally adopted soon after its invention in 1801. Every common loom is susceptible of receiving this beautiful appendage. It costs in France 200 francs or 8*l*. sterling, and a little more in this country.

Fig. 1043 is a front elevation of this mechanism, supposed to be let down. *Fig. 1046* is a cross section, shown in its highest position. *Fig. 1047*, the same section as the preceding, but seen in its lower position.

A, is the fixed part of the frame, supposed to form a part of the ordinary loom; there are two uprights of wood, with two cross-bars uniting them at their upper ends, and leaving an interval *xy* between them, in place and with the movable frame *n*, vibrating round two fixed points *a*, placed laterally opposite each other, in the middle of the space *xy*, *fig. 1043*.

c is a piece of iron with a peculiar curvature, seen in front, *fig. 1043*, and in profile, *figs. 1046* and *1047*. It is fixed on one side upon the upper cross-bar of the frame *n*, and on the other, to the intermediate cross-bar *b* of the fixed frame, where it shows an inclined curvilinear space *c*, terminated below by a semi-circle.

v is a square wooden axis, movable upon itself round two brass pivots, fixed into its two ends; which axis occupies the bottom of the movable frame *n*. The four faces of this square axis are pierced with three round, equal, truly-bored holes arranged in a quincunx. The two at *a*, *fig. 1043*, are stuck into each face, and correspond to holes *o*, *fig. 1046*, made in the ends which have not their fellow there for the frame; so that in the successive application of the cords to each face of the square axis, the holes pierced in one cord may always fall opposite to those placed in the other.

The right-hand end of the square axis, of which a section is shown in double size, *fig. 1048*, carries two square plates of sheet iron *d*, kept parallel to each other and a little apart, by four spindles *e*, joined opposite to the corners. This is a kind of lantern, in whose spindles, the hooks of the levers *ff'*, turning round fixed points *yy'* beyond the right hand upright *A*, catch hold, either above or below at the pleasure of the weaver, according as he merely pulls or lets go the cord *z*, during the vibratory movement of the frame *n*.

1048

1049

n is a piece of wood shaped like a T, the stem of which, pointing upwards, passes freely through the cross-bar *b*, and through the upper cross-bar of the frame *n*, which serves as guides to it. The head of the T piece being applied successively against the two spindles *e*, placed above in horizontal position, first by its weight, and then by the spiral spring *k*, acting from above downwards, keeps the square axis in its position, while it permits it to turn upon itself in the two directions. The same press is given to the assemblage of all the pieces which compose the movable frame *n*.

r is a cross-bar made to move in a vertical direction by means of the lever *o*, in the notches or grooves *i*, formed within the fixed uprights *A*.

n is a piece of bent iron, fixed by one of its ends with a nut and screw, upon the cross-bar *r*, out of the vertical plane of the piece *c*. Its other end carries a friction roller *j*, which, working in the curvilinear space *c* of the piece *c*, forces the, and consequently the frame *n*, to recede from the perpendicular, or to return to it, according as the cross-bar *r* is in the top or bottom of its course, as shown in *figs. 1046* and *1047*.

k, cheeks of sheet iron attached on either side to the cross-bar *r*, which serve as a safe to a kind of claw *h*, composed here of eight small metallic bars, seen in section *figs. 1046* and *1047*, and on a greater scale in *fig. 1049*.

J, upright skewers of iron wire, whose tops bent down hookwise naturally place themselves over the little bars *h*. The bottom of these spindles likewise hooked in the same direction as the upper ones, embraces small wooden bars *l*, whose office is to keep them in their respective places, and to prevent them from twisting round, so that the uppermost hooks may be always directed towards the small metallic bars

space which they occupy. The three links from below are numbered *g*, *h*, and *i*, which after having revolved a fixed length may proceed with corresponding holes for the purpose, giving a text as to which to the inside of the cloth directed to fill the warp threads. As a horizontal square or square, arranged thus in eight several rows, so that each square corresponds both horizontally and vertically to each of the holes placed in the first line of the square *aa* &c. These are therefore so many of these squares as there are holes in one of the lines of the square.

Fig. 1010 represents one of these horizontal squares, *a* is an angle through which the corresponding vertical skewer passes, which is arranged with a thread which is a small fixed square, passes to *g*, *h*, and *i*, and a point, but which it is not longer if it is carried to *g*, *h*, and *i*, while the lower of the angle of the square is still at the upright position placed in each hole of the line *aa*, *Fig. 1011*. They were the purpose of bringing back to its position, position every corresponding square as soon as it comes to press upon it.

1010

1011

1012

Fig. 1011 represents the plan of the upper row of horizontal squares. *Fig. 1012* is a fragment of the middle chain, formed with perforated cards, which are made to revolve or travel by the motion of the loom. In this movement, all of the perforated series, whose position, form, and number, are determined by the operation of type up of the warp, comes to be applied in succession against the first line of the square as a or drum, leaving open the corresponding holes, and covering those upon the face of the axis which have no corresponding holes upon the card.

Now let us suppose that the press is let down into the vertical position, shown in *Fig. 1013*; then the card applied against the left face of the axis, being at this or untouched the whole of the horizontal squares, whose ends are raised to these holes, but pushes back those which are opposite to the unperforated part of the card; thereby the corresponding upright skewers, 3, 5, 6, and 8, for example, pushed out of the perpendicular, unhook themselves from above the bars of the claw, and remain in their place, when this claw comes to be raised by means of the lever *o*, and the skewers 1, 2, 4, and 7, which have remained hooked on, are raised along with the warp threads attached to them. Then by the passage across of a shot of the colour, as well as a shot of the common weft, and a stroke of the lay after shedding the warp and lowering the press, an element or point in the pattern is completed.

The following card, brought round by a quarter revolution of the axis, finds all the needles in their first position, and as it is necessarily perforated differently from the preceding card, it will lift another series of warp threads; and thus in succession for all the other cards, which compose a complete system of a figured pattern.

This machine, complicated in appearance, and which requires some points to be understood, acts however in a very simple manner. Its whole play is dependent upon the movement of the lever *o*, which the weaver himself causes to rise and fall, by means of a peculiar pedal; so that without the aid of any person, after the frame is properly read in and mounted, he can execute the most complex patterns as easily as he could weave plain goods; only attending to the order of his weft yarns, when these happen to be of different colours.

If some warp yarns should happen to break without the weaver observing them, or should be mistake his coloured shuttle yarns, which would so far destroy the pattern, he must undo his work. For this purpose, he makes use of the lower hooked lever *p*, whose purpose is to make the chain of the card go backwards, while working the loom as usual, withdrawing at each stroke the shot both of the ground and of the figure. The weaver is the more subject to make mistakes, as the figured side of the web is downwards, and it is only with the aid of a bit of looking-glass that he takes a peep of his work from time to time. The upper surface exhibits merely loose threads in dif-

fixed points, according as the pattern requires them to be upon the one side or the other.

It must be evident, that each a number of paste-boards are to be provided and mounted as equal the number of the warps of the shuttle loom in the beginning and end of any figure or design which is to be woven; the piercing of each paste-board individually will depend upon the arrangement of the lifting rods, and their connection with the warp, which is according to the design and option of the workman; great care must be taken that the holes come exactly opposite to the ends of the needles; for this purpose two large holes are made at the ends of the paste-boards, which fall upon central points, by which means they are made to register correctly.

It will be hence seen, that, according to the length of the figure, so must be the number of paste-boards, which may be readily displaced so as to remove and produce the figure in a few minutes, or remove it, or replace it, or preserve the figure for future use. The machine, of course, will be understood to consist of many sets of the lifting rods and needles, shown in the diagram, as will be perceived by observing the disposition of the holes in the paste-board; those holes in order that they may be accurately distributed, are to be pierced from a gauge, so that not the slightest variation shall take place.

To form these cards, an ingenious apparatus is employed, by which the proper steel punches required for the piercing of each distinct card, are placed in their relative stations preparatory to the operation of piercing, and also by its means a card may be punched with any number of holes at once. This disposition of the punches is effected by means of rods connected by cords disposed in a frame, in the nature of a false loom, on which the pattern of the work to be performed is first read in.

These improved pierced cards, or paste-boards, apply to a weaving apparatus, which is so arranged that a figure to be wrought can be extended to any distance along the loom, and by that means the loom is rendered capable of producing broad figured works; having the long lever *q* placed in such a situation that it affords power to the foot of the weaver, and by this means enables him to draw the heaviest monitures and figured works, without the assistance of a draw-boy.

The machinery for arranging the punches consists of a frame with four upright standards and cross-pieces, which contains a series of endless cords passing under a wooden roller at bottom, and over pulleys at the top. These pulleys are mounted on axles in two frames, placed equally over the top of the standard frame, which pulley-frames constitute the table commonly used by weavers.

In order better to explain this endless cord, *fig. 1* & *2* represent a single endless cord, *1 1*, which is here shown in operation, and part of another endless cord, *2 2*, shown stationary. There must be as many endless cords in this frame as needles in the weaving loom. *a* is the wooden cylinder, revolving upon its axis at the lower part of the standards; *b*, the two pulleys of the pulley-frames above, over which the individual endless cord passes; *c*, a small transverse rod. To each of these rods a weight is suspended by a single thread, for the purpose of giving tension to the endless cord. *d* is a board resembling a common comb-bar, which is supported by the cross-bars of the standard frame, and is pierced with holes, in situation and number corresponding with the perpendicular threads that pass through them; which board keeps the threads distinct from each other.

At *e*, the endless cord passes through the eyes of wires resembling needles, which are contained in a wooden box placed in front of the machine, and shown in this figure in section only. These wires are called the punch-projectors; they are guided and supported by horizontal rods and vertical pins, the latter of which pass through loops formed at the hinder part of the respective wires. At *f* are two horizontal rods extending the whole width of the machine, for the purpose of producing the cross in the cord; *g* is a thick brass plate, extending along in front of the machine, and lying close to the box which holds the punch-projectors; this plate *g*, shown also in section, is called the punch-holder; it contains the same number of apertures as there are punch-projectors, and disposed so as to correspond with each other. In each of these apertures, there is a punch for the purpose of piercing the cards, slips, or pasteboards

with holes. *A* is a thick metal plate of the same diameter, and shown in figure 1 in section, carrying long slots in its number of apertures, and their disposition, with the punch-receiver, and the punch-holder. The plate *A*, is called the punch-receiver.

The manner in which the machine is to transfer each of the patterns is now to be pointed out. The punch-receiver is divided into four parts, the punch-holder *A*, the punch-receiver *B*, where there will be properly secured, and ready for passing the individual card or slip, with a hole having an edge beveled in upon the machine, and are prepared for forming the way through in the hole, when the card is brought in front of the machine. The manner of securing the patterns to the punch-receiver will be effected in the following manner.

The punch-receiver is to be read in accordance to the primary cards, as in a slide rule, upon the machine. First, below the hole *f*, and punch-receiver the revolving working cylinder is to be rotated through for a given distance, in front of the machine, to reach the primary card. It then takes the upper portion of the primary card, the lower end drawn thus forward, as to be drawn a hole behind the punch-receiver, as shown by line, for the purpose of keeping the primary card in the position which is not intended to be printed upon. All the punch-receivers which are connected with the cards brought forward will be thus made to pass through the corresponding apertures of the punch-holder, and up the same will project the punch-receiver out of these apertures, the corresponding apertures of the punch-receiver *B*. The punch-receiver will now be properly arranged for passing the required hole in a card or slip, which is to be effected in the following manner.

Remove the punch-receiver from the front of the machine, and having placed one of the slips of card or parchment between the two sliding plates of metal, completely pierced with holes corresponding to the portions of the hole, by the punch-receiver upon these perforated plates; to which it must be made to fit by cutting and breaking the cutting parts of the punch-receiver down with a file. Upon the back of the punch-receiver is then to be placed a plate or block, coated with preparation of gum, corresponding to the new intended hole, upon which the punch will fall. The plates and the blocks thus laid together, are to be pushed under a press, by which means the part of the blocks will be made to pass through the apertures of the punch-receiver, and wherever the punch has been deposited in the receiver by the above process, the card or slip will be forced through the slip of parchment, and pierced with each letter as are required for producing the figured design in the lower.

With each of the primary, the punch-receiver is rotated in its place in front of the machine, and all the punch-receivers forced back into the apertures of the punch-holder as at first. The next set of cards is now drawn forward by the next hand, as above described, which sends out the punch-receiver, as before, and brings the punch-receiver in the punch-receiver, ready for the operation of passing the next card. The process being thus repeated, the whole pattern is, by a number of operations, transferred to the punch-receiver, and afterwards to the cards or slips, as above described.

JADE, *axe-stone* (*Nephrite*, *Ceramide*, Fr.; *Halstein*, Germ.) is a mineral of a greenish, bluish, or whitish colour, compact, and of a fatty luster. Spec. grav. 2.95; scratches glass; is very tough; fuses into a white enamel. It comes from China, and has been found in Australia; it is used among rude nations for making hatchets, and is susceptible of being cut into any form. In China the jade is greatly valued, especially the pure white varieties. These are worked into cups, and as ornaments for the Josses, or emblem of power.

The composition of Jade, as given by Klaproth and Rosenschlag, is —

Silica	-	-	-	-	50.50	-	-	54.00
Magnesia	-	-	-	-	31.00	-	-	2.00
Lime	-	-	-	-	-	-	-	1.00
Protoxide of iron	-	-	-	-	-	-	-	2.10
Peroxide of iron	-	-	-	-	5.50	-	-	-
Alumina	-	-	-	-	10.00	-	-	-
Chromium	-	-	-	-	0.05	-	-	-

H. W. R.

JAPAN EARTH; *Terra Japonica*. See GLAZING.

JAPANNING is a kind of varnishing or lacquering, practised with excellence by the Japanese, whence the name.

The only difference between varnishing and Japanning is that after the application of every coat of colour or varnish, the object so varnished is placed in an oven or stove at as high a temperature as can safely be employed without injuring the articles or causing the varnish to blister or rot.

For black japanned works, the ground is first prepared with a coating of black, made by mixing brown ivory black to a proper consistency with dark-colored oil varnish, as this gives a blacker surface than could be produced by Japan alone. If

the surface is required to be polished, five or six coats of japan are necessary to give sufficient body to prevent the japan from being rubbed through in polish.

Coloured japans are made by mixing with the hard varnishes the required colour, and proceeding as described. See VARNISH.

JARGOON, the name given to a variety of Zircon from Ceylon. It is seldom perfectly transparent, and is either colourless or grey, with tinge of green, blue, red, and yellow of various shades, but generally smoky and ill-defined. It occurs in worn angular pieces, or in small detached crystals, rarely exceeding 6 or 8 carats in weight, chiefly in the mud of a river in Ceylon. The surfaces of the crystals are smooth, and possess a lustre more nearly approaching that of the diamond than any other gem. At the present day, though out of fashion and in no request, it is still occasionally sold for inferior diamonds.

Davy says that the light grey varieties of the zircon are sold by the inhabitants of Ceylon as imperfect diamonds, the natives being altogether ignorant of the true nature of the mineral. It is most abundant in the district of Matara, whence it has its common name in Ceylon of *Matara diamond*. The colourless zircon is also cut and sold as a false diamond in the bazaars of India. — H. W. R.

JASPER (*Jaspe rubicundine*, Fr.; *Jasper*, Germ.) is a sub-species of quartz, of which there are five varieties. 1. The Egyptian red and brown, forming nodules with ring or tunnel-shaped depressures. 2. Striped jasper, or clay altered by heat, and differing from true jasper by being fusible on the edges, before the blowpipe. 3. Porcelain riband or jasper. 4. Common jasper. 5. Agate jasper. The prettiest specimens are cut for seals, and for the inferior kinds of jewellery ornaments. See LAPIDARY. — H. W. R.

JATROPHA MANIHOT. A plant belonging to the Euphorbiaceæ, from which the *Cassia meal* is prepared, and from the express juice of which is obtained *Cassia starch* and *Tapioca*. See **TAPIOCA**.

JEAN. A twisted cotton, usually striped. Satin-jans are woven so as to present a smooth glossy appearance. It is used for stays, &c.

JELLY, ANIMAL. See **GELATIN**, **GLUE**, and **ISINGLASS**.

JELLY, VEGETABLE. A great many vegetable productions yield upon infusion or decoction gelatinous solutions. These vary very much in character. The jelly of ripe currants and other berries, is a compound of mucilage and acid, which loses its power of gelatinising by prolonged ebullition.

JESSAMINE or **JASMINE**. A well-known family of plants. The *Jasminum fruticans*, a native of the southern parts of France, *J. odoratissimum*, a native of India, and *J. semibre*, a native of India and Arabia, are used to obtain the essential oil of jasmine. See **PERFUMERY**.

JET (*Jaiet*, or *jais*, Fr.) Jet occurs in the upper lias shale in the neighbourhood of Whitby, in Yorkshire, in which locality this very beautiful substance has been worked for many hundred years. The jet miner searches with great care the clayey rocks, and finding the jet spread out, often in extreme thinness between the laminations of the rock, he follows it with great care, and frequently he is rewarded by its thickening out to two or three inches.

The best jet is obtained from a lower bed of the upper lias formations. This bed has an average thickness of about 20 feet, and is known as jet rock. An inferior kind, known as soft jet, is obtained from the upper part of the upper lias, and from the sandstone and shale above it. The production of jet in this country appears to be limited to the coast of Yorkshire, from about nine miles south of Whitby to Honthly, about the same distance to the north; the estates of Lord Moulgrave being especially productive. There is a curious allusion to this in Drayton's *Polyolbion*.

- The rocks by Moulgrave, too, my glories forth in set,
Out of their crinated rocks can give you perfect jet.

Dr. Young, in his *Geology of the Yorkshire Coast*, writes—"Jet, which occurs here in considerable quantities in the aluminous bed, may be properly classed with fossil wood, as it appears to be wood in a high state of bituminisation. Pieces of wood impregnated with siliceous are often found completely crusted with a coat of jet about an inch thick. But the most common form in which the jet occurs is in compact masses of from half an inch to two inches thick, from three to eighteen inches broad, and of ten or twelve feet long. The outer surface is always marked with longitudinal striae, like the grain of wood, and the transverse fracture, which is conchoidal, and has a resinous lustre, displays the annual growth in compressed elliptical zones. Many have supposed this substance to be indurated *petroleum*, or *animal pitch*; but the facts now quoted are sufficient to prove its ligneous origin."

It does not appear to us that the "ligneous origin" of jet is by any means established; indeed we think the amount of evidence is against it. There is no example as far as we can learn, of any discovery of true jet having a strictly ligneous structure, or showing

a strong idea the conversion of wood into the coal-like substance. There is, indeed, however, in a few localities, evidence in the other veins of those who have written on the subject. Mr. Simpson, the talented curator of the Whity Museum, has been much attracted to the subject, and says, "Jet is generally considered to have been a wood, and in some cases it undoubtedly has been so; for the woody structure often remains, and it is not unlikely that fossilized vegetable matter may have been changed into jet. But it is evident that vegetable matter is not an essential part of jet, for we frequently find the bones, and the entire of fishes, and have been examined into jet. In the Whity Museum there is a large mass of bone, which had the external contour of a jet for a mass a quarter of an inch in thickness. The jetty matter appears to have first entered the pores of the bone, and there to have hardened; and during the subsequent process, the whole bony matter has been gradually deposited, and the place occupied by jet is not to preserve its original form." After an attentive examination of this specimen, we are not disposed to agree entirely with Mr. Simpson.

Jet certainly occurs in a mass which has undergone the conversion of a bone, but we think a chemical examination of such a mass, we think, however, rather, say it was bone. Wood without doubt has been found encrusted with jet, no fragments of animal matter may also have been. But this is not consistent with our knowledge of geological and chemical changes, to suppose that both a mineral and vegetable matter would undergo the change. By process of substitution, we know that silica will take the place occupied by carbon, or woody matter, as, for example, in the fossil palms of Triassic, and the fossil forests of Egypt, but we have no example within the entire range of the coal formations of the world of carbon taking the place of any of the earth.

Jet is found in plates, which are sometimes perforated by tubular pores. Mr. Ripley, of Whitby, has several curious examples, — two pieces of jet, in the one case having within quartz pebbles, and in another jet partially having an angular fragment of quartz rock. "This is the more remarkable," says Mr. Ripley, "no quartz rock, or, indeed, any other sort of rocky fragment, is rarely found in the upper jet."

The very fact that we find jet encrusting between some of the adjacent strata of stone, and invading wood, seems to show, that a liquid, or at all events, a gaseous condition, must at one time have prevailed. We have existing evidence of this. Dr. Yocum, in the work already quoted, says — "In the cavities of sculpins, and in the perfect ones, we sometimes meet with petrified wood, and of which first exposed, it is generally quite fluid and of a dark green color; but it soon becomes solid and black, and at last hardens into a kind of pitch, which gradually becomes with heat, and when ignited burns with a crackling noise, and emits a strong aromatic smell." One more example of evidence in favor of the view that jet has been formed from wood. It is cited (*Reed's Illustrated Guide to Whity*) that in front of the jet-work of Harburne Wyke existed a petrified stump of a tree, in an erect position, three feet high, and fifteen inches across, having the roots of coaly jet in a bed of sand; whilst the trunk in the sandstone was partly petrified, and partly of decayed woody wood. Even in this example it would appear, that after all, a coating of jet was all that really existed upon this example of the equisetum, which probably would have been it grew. Mr. Simpson, in a valuable little publication, "*The Plants of the Yorkshire Lias described from Nature, with a short Outline of the Geology of the Yorkshire Coast*," says — "From all we know respecting this beautiful mineral, it appears extremely probable that it has its origin in a certain lustrous matter, or petroleum, which abundantly impregnates the jet-rock; giving out a strong odour when it is exposed to the air. It is frequently found in a liquid state in the chambers of an ammonite and belemnites and other cavities, and, whilst the ammonite operator is breaking a liss nodule, it flies out and stains his garment. This petroleum, or mineral oil, also occurs in nodules which contain no organic remains, and I have been informed by an experienced jet miner that such nodules are often associated with a good store of jet, and are therefore regarded as an omen of success."

Jet is supposed to have been worked in this country long before the time of the Danes in England, for the Romans certainly used jet for ornamental purposes. Lionel Charlton, in the history of Whitby, says, that he found the ear-ring of a lady having the form of a heart, with a hole in the upper end for suspension from the ear, it was found in one of the Roman tumuli, lying close to the jaw bone. There exists no doubt that when the abbey of Whitby was the seat of learning and the resort of pilgrims, jet rosaries and crosses were common. The manufacture was carried on till the time of Elizabeth, when it seems to have ceased suddenly, and was not resumed till the year 1800, when Robert Jefferies, a painter, and John Carter made beads and crosses with files and knives — a neck guard, made in this manner, fetched one guinea. A stranger coming to Whitby saw them working in this rude way, and advised them to try to turn it; they followed his advice and found it answer; several more then joined them, and

the trade has been gradually increasing. Most of the best jet ornaments are sent to London, the inferior ones are mostly purchased for the American market.

The jet workers compose of the great variety of designs in jet. Several designs have been sent them, but the artists not being acquainted with the peculiarities of the material, their designs are not generally applicable, and the most successful is much more successful in the imitation of natural objects than any artificial ornamentation.

JEWELLERY. See GOLD and SILVER.

JIGGING, a mining term. Separating the ore with a griddle, or wire-worked sieve, the heavier substances passing through to the bottom or lower part of the sieve, the lighter substances remaining on the upper part.

JINTA WAN. A substance somewhat resembling gutta serena, imported from India.

JUJU BE. The fruit of the *J. papha vulgaris* and *J. jujuba*, about the size of and nearly resembling a small plum. The French confecturers prepare a marmalade from the juice of the fruit, but nearly all the jujubes sold by our druggists and confectioners are merely dried mucilage, flavoured and sweetened.

JUMPER, a mining term. A large borer, steaked at each end like chisel. It is worked by the hand.

JUNIPER. A genus of plants belonging to the order Conifera. About twenty species are known. This plant is cultivated mostly for its berries, which, when distilled with water, yield a valuable essential oil. The berries are largely employed in the manufacture of H. ands and gin. The French name of the plant is *Genévre*, and hence our French words "gin" and "p. -va."

The *Juniperus Berniana*, the Bermuda red cedar, is a large tree with soft and fragrant wood, and is what is used in making pencils, and by cabinet makers. See CEDAR.

JUTE consists of the fibres of two plants, called the clunch and rebound (*Corchorus olivaceus* and *Corchorus p. -ularis*), extensively cultivated in Bengal, and forming, in fact, the material of which gunny bags and gunny cloth are made. It is nearly, though not quite so high, a price as cotton. See COTTON. It comes into competition with flax, tow, and cordilla, in the manufacture of stair and other carpets, bagging for cotton and other goods, and such like fabrics, being extensively used for these purposes in Dundee. But it is unsuitable for cordage or other articles into which hemp is much required, from its snapping when twisted, and rotting in water. — M. C. C. C.

K.

KAHOK. A name for a clay ironstone in Ceylon. — *Sinimoda*.

KAL. "Will iron; a coarse, false kind of iron" (*He-haw*). A mining term. In the East, in Cornwall, a *Kal* is a hole containing much iron.

KALEIDOPHON. An instrument devised by Prof. Wheatstone. An elastic bar is fixed by one of its extremities, and at its free end it carries a silvered or polished plate; a ray of light is reflected from the plate, and when the plate is put in vibration, the free point of light describes various curves, corresponding with the musical notes produced by the vibrations.

KALEIDOSCOPE. A well-known instrument invented by Sir David Brewster. It has been much employed in arts of design. The leading conditions are that the angle at which the reflectors are placed is a submultiple of 360°, that the only positions in which a body can be placed to form perfectly symmetrical images are between the ends of the mirrors, or in contact with the ends, and the eye must be as near as possible to the angular point.

KALI. The Arabs gave this name to an annual plant which grows near the seashore; now known under the name of *Salicda soda*, and from whose ashes they extracted a substance, which they called *alkali*, for making soap. The term *alkali* is used by German chemists to denote caustic potash, and *kalium*, its metallic basis; instead of our potash and potassium.

KANGAROO. A marsupial animal, native of Australia. Its tail makes excellent soap, and its skin, when tanned, becomes a soft and durable leather.

KAO LIN. *Terra à porcelaine*, Fr.; *Porcellanerde*, Germ.) is the name given by the Chinese to the fine white clay with which they fabricate the biscuit of their porcelains. See CLAY and PORCELAIN CLAY.

KARABE, a name of amber, of Arabic origin, in use upon the Continent.

KARN. A Cornish miner's term, frequently, according to Borlase, used to signify the solid rock; — more commonly a pile of rocks.

KAHSTLITE. The name given by Haas to anhydrous sulphate of lime.

KATTIMUNDUO or CHITTEMUNDUO. A catichone like substance obtained from the *Euphorbia antiquorum* of Roxburgh. It was first exhibited in this country in the Great Exhibition of 1851, being sent by Mr. W. Elliott from Singapore.

It was of a dark brown colour, opaque except in thin pieces, hard and somewhat

The principal varieties of kermes are the *Coccus quercus*, the *Coccus palmarum*, the *Coccus fragarie*, and the *Coccus rosae*.

The *Coccus quercus* insect lives in the bark of the *Quercus* oak. The female lays an egg, is of the size of a small pea, of a brownish-red colour, and is covered with a white dust. From the middle of May to the middle of June the eggs are collected, and exposed to the vapour of vinegar, to prevent their incubation. A portion of time is left upon the tree for the incubation of the breed. In the department of the Landes, in France, one half of the kermes crop is dried.

The kermes of Poland, or *Coccus palmarum*, is found upon the roots of the *Scleranthus perennis* and the *Scleranthus aconitifolius*, in a sandy soil of that country and the Ukraine. This species has the same properties as the preceding; one pound of it according to Wolff being capable of dyeing 10 pounds of wool, but Hiermerstedt could not obtain a fine colour, although he employed 5 times as much of it as of cochineal. The Turks, Armenians, and Cossacks dye with kermes their Morocco leather, cloth, &c., as well as the houses and tents of their houses.

The kermes called *Coccus fragarie* is found principally in Sicily, upon the root of the strawberry.

The *Coccus rosae* was used by the Jews of the Polish kermes, and dyes with alum a fine red. It occurs in Russia.

Kermes is found not only upon the *Ilex aquifolium* in the Ukraine, but upon a great many other plants.

Several kermes is purplish, of a deep red colour, of an agreeable taste, and a rough and pungent touch. Its colouring matter is soluble in water and alcohol; it becomes yellowish or brownish with acids, and violet or crimson with alkalis. Sulphate of iron blackens it. With alum it dyes a bluish red, with copperas, an agreeable grey with sulphate of copper and tartar, an olive green; with tartar and oil of turpentine, a name yellow, with iron alum and tartar, a black with sulphate of zinc and tartar, a violet. Scarlet and crimson dyed with kermes were called *grain indians*. The red eggs for the Levant are dyed at Orleans with equal parts of kermes and madder, and occasionally with an addition of Brazil wood. Kermes is but little used in England at present as a dyeing substance.

KERMES MINERAL. Pure mineral kermes is regarded by Berzelius, Fuchs, and Rose, as an amorphous ternary phosphate of antimony. As the preparation has no use in the arts or manufactures, for its mode of preparation and its chemical constitution we refer to *Ure's Dictionary of Chemistry*.

KERSHAYITE. Red antimony ore, composed of oxygen, 57.1; antimony, 34.43; arsenic, 20.17.

KIRSEY. A coarse stuff woven from long wool, chiefly manufactured in the north of England.

KIRSEYMIERE. Coarsely spun cotton yarn. A fine fabric woven plain from the finest wool, a manufacture of the west of England principally.

KHAYA. One of the largest and handsomest trees growing on the western coast of Africa. The wood is of fine quality, and of a reddish colour like mahogany.

KIAHOCCA WOOD, called also *Amoyan wood*. This wood is said to be the extreme of hardness of the *Juniperus communis*, or of the *Juniperus drupacea* from the Malabar, the Island of Borneo, Amoyana, &c.

KIMBLIF is a mining term. A bucket usually made of iron, in which the ore is drawn to the surface from the depths of the mine.

KILN-AS. The name given by the Cornish miners to the *slaty slate* of that district. It varies very much in colour and character, being sometimes of a clay-white, and at other times gray or blue. It is in one district soft; in another, compact and hard. According to the character of this rock, the miner determines on the probability of the mineral veins which traverse it being metalliferous or the contrary.

KILN (*Furnace*, Fr.; *Ofen*, Germ.) is the name given to various kinds of furnaces and stores, by which an attenuated heat may be applied to bodies; thus there are brick-kilns, hop-kilns, lime-kilns, salt-kilns, pottery-kilns. See BRICK, LIMESTONE, MALT, POTTERY, for a description of their respective kilns.

KIMERIDGE CLAY. The strata which underlie the Portland Stone of Dorsetshire, and the south-west of England, are based upon a considerable thickness of dark brownish or bluish-gray clay, to which the term Kimeridge Clay has been given by geologists, from the circumstance of its being largely developed and well displayed in the neighbourhood of the village of that name.

Throughout the life of Purbeck, but especially in the part of it in question, the clay assumes a very shaly and laminous character, sometimes passing into more massive beds of brownish shaly coal, possessing a conchoidal fracture.

The Romans, and also the Celts who inhabited the country previously to its invasion by the former nation, appear to have manufactured the harder portions of the

shale was capped and below are layers of clay, chiefly of the fossiliferous, and thinning upwards, of which but few have been found in the neighbourhood of Wareham, the most likely and promising being that of *Ekmanella*.

Considerable quantities of shale about the size of a penny piece, have now been dug up in good quantities in this part of the Isle of Purbeck, as many as one being open and broken down, found locally perfect number.

Authorities have been much divided in opinion as to the origin and use of these conical pieces of shale, by some they are supposed to have passed current as money, or where where the name of Kimeridge is inscribed, by which they are commonly known, has been applied to them; but, the most probable supposition is, that they were the portions of the natural bed to the hollow, and left adhering to it after the strata or other elements in a similar disposition had been turned from their former circumstances, and that at some subsequent period these hollow pieces of the former were worn as *denarii* or charms by the superstitious.

The shale around Kimeridge contains animal and vegetable matter the former consisting of the shells of *nautilus*, *ammonites*, &c., together with the bones and teeth of large animals and fish; while the latter is in so easily divided a state as not to be distinguishable to the eye. Much carbonate of lime and pyrites are also present, especially in those portions in which animal remains are most abundant.

The variation in the external character of the shale is accompanied by a corresponding variation in the relative proportions of mineral and organic matter contained in it; thus portions which are the most fossiliferous and clayey contain a large proportion of mineral matter combined with a relatively small proportion of organic matter, while on the other hand, in the harder and more massive portions which break with a conchoidal fracture, the organic matter is greatly in excess of the mineral matter, as is shown by the following analysis.

	Analysis of the shale, determined by the following methods.		
	A	B	C
Amount of volatile matter	17.51	32.5	73.4
" " mineral matter	81.49	67.5	26.7
	100.00	100.0	100.0

When heated the shale gives off copious fumes of a dark greenish colour resembling that of petroleum; and when ignited, it burns of itself with a dull smoky flame, leaving, when freely exposed to the atmosphere, a reddish ash, which generally retains the form of the original fragment.

The shale has long been used for fuel by the people of the district where it occurs, and the ashes left after combustion have long been known to the farmers on the coast to exercise a beneficial influence upon their crops, especially turnips; but the unpleasant smell given out by it when burning has prevented it from being used except by the poorer inhabitants.

Within the last few years works were established at Wareham, for the purpose of extracting naphtha and other products from the shale by distillation; but the manufacture was abandoned in consequence of the impossibility of destroying the smell given out by the naphtha.

This defect having now, it is believed, been overcome, the works have lately been re-opened, and are now being carried on with every prospect of success.

The chemical composition and properties of the shale have been recently thoroughly investigated by Dr. Hofmann, of the Government School of Mines.

The following results were obtained by him from the distillation of the shale, at a high temperature, for the purpose of producing gas:—

Amount of gas, water, ammonia, &c.	63.5
Amount of coke	36.5—100.0

The shale distilled in a gas retort furnished a gas composed of—

Olefiant gas and congeners	8.4
Light carbonated hydrogen and hydrogen	60.3
Carbonic oxide	9.7
Carbonic acid	8.2
Sulphuretted hydrogen	7.0—100.0

The composition of this gas, freed from carbonic acid and sulphuretted hydrogen, by passing through an ordinary lime purifier, was as follows:—

Insolent gas and nitrogen	100
Light carbonated hydrogen and hydrogen	79.0
Carbonic oxide	11.0—100.0

The composition of the coke produced was:—

Carbon	73.4	72.8
Ash	24.8	20.3
	107.7	100.0

The excess above 100 arises from the presence of sulphides in the coal, which during the process of incineration absorb oxygen and are converted into sulphates.

A ton of shale furnished 11,200 cubic feet of this purified gas, the illuminating power of which, used in an argand burner, consuming 5 cubic feet per hour, equalled that of 20 sperm candles, while the percentage of coke remaining was 6.5.

The liquid and solid products obtained by the distillation of the shale at a low temperature, are an effluve, consisting, dark brown oil, suspended in an aqueous liquid, charged with sulphuretted hydrogen, carbonic acid, and ammonia.

This oil, purified and distilled with water, furnishes an oily liquid heavier than water; a tar-like residue being left in the retort.

The oily liquid which, when purified, gives out the colour of the finest varieties of coal-tar naphtha, is a mixture of several chemical substances.

When treated with concentrated nitric acid, this oily liquid is divided into two portions, one of which is dissolved by the acid, while the other insoluble portion floats on the surface of the solution in the form of a light colourless oily liquid, resembling in its general character the hydrocarbons of Boghead coal-tar oil, and of petroleum. The nitric solution which forms the larger portion of the oily liquid, when mixed with water, furnishes a dense, heavy, yellowish oil, with the odour of nitrobenzol.

Hence it appears that the oily liquid obtained by the distillation of the shale consists chiefly of benzol and its homologues, mixed with small quantities of petroleum hydrocarbons. When sufficiently purified it is applicable for all the purposes for which benzol is employed, for dissolving india-rubber and gutta-percha, for removing stains from fabrics, for preparing varnishes, for making artificial oil of almonds, &c.

On submitting to distillation without water, and at a rather high temperature, the only tar-like residue remaining in the retort after the crude volatile liquid obtained by heat from the shale had been distilled with water, other volatile products are obtained.

The first portion of the oil obtained during the distillation is of an amber colour when first distilled, and much less limpid than the oil produced by distillation with water. It also possesses an offensive sulphurous smell, which however is lost on exposure to the air, while the oil assumes a much darker colour. This oil is acted upon by sulphuric, nitric, and hydrochloric acids, by which, especially by the first, a portion of it is resinified.

The remaining portion of the oil, when washed with water and afterwards distilled with steam, furnishes a perfectly colourless oil with the properties of paraffine. This last oil, which forms but a small fraction of the original oil, behaves in all respects like the paraffine oil obtained from Boghead canal coal, and is applicable to the lubrication of machinery, and all the other purposes to which that liquid is applied.

The black, pitch-like, coky residue left in the retort resembles in general character the coke produced from coal in the manufacture of gas.

The ash of the incinerated coke contains nearly the same proportions of silica, alumina, and iron as Portland cement. The following is an analysis of the ash left by the shale which contains the larger amounts of mineral matter:—

	Ash of Kimberidge shale.	Portland cement.
Insoluble residue	22.01	
Peroxide of iron	7.10	5.30
Silica	21.73	23.23
Alumina	10.60	7.73
Lime	20.62	54.11
Carbonic acid	20.92	2.15

100.00

The composition of the shale at 4 for the manufacture, for the purpose of obtaining the liquid and solid products, furnished the following results:—

Analysis of A.

Coke	71.5	{	Mucous matter . . .	7.1
			Carbon	88.9
			Hydrogen	2.6
Oil and solid prod- ucts	14.5	{	Light oil (volatile) . .	3.7
			Heavy oil (residue) . .	10.8
			per cent. of paraffine .	9.3
			Residue of pitch . . .	7.4
Gas, water, am- monia, &c.	13.5	{	Gas, water, &c. . . .	13.5
	100.0			100.0

Analysis of B.

Coke	43.0	{	Mucous matter . . .	8.2
			Carbon	10.2
			Hydrogen	3.3
Oil and solid prod- ucts	5.0	{	Heavy oil, residue . .	1.9
			per cent. of paraffine .	7.1
			Gas, water, ammonia, &c.	18.0
Gas, water, &c.	18.0			18.0
	100.0			100.0

The manufacture of the shale at Westport, according to Mr John C. Shand, is conducted in the following manner:—

The retorts are charged with about 3 wt. of shale, previously broken down into about two inches square, and the temperature is maintained as nearly uniform as possible. In order to obtain the required uniform temperature the retorts are constructed so as to have banks of masonry built. The gas issued in the retorts is then conducted by means of a leaden pipe, and the product is a crude oil; there is a quantity of gas made during the operation, which is not condensed, but used for ordinary purposes. The crude oil is allowed to stand in long cisterns of lead for the purpose of letting the mineral water (of which there is a large quantity) settle. The oil is then put into a still, and rectified once or twice at the same temperature. The first product is a light oil, making over-proof 75; the next products are kerosene, containing paraffine, which is now in great request by manufacturers.

The shale, on being taken out of the retorts, is placed in chise vessels, and when cool is ground in a mill for manure. In its natural state the shale is not sufficiently rich in ammonia for this purpose; but at this stage the artificial manure is as valuable as Ichaboe guano, both having been recently analysed for the purpose of comparison. By keeping the temperature low in the retorts neither the phosphorus nor the organic matter are destroyed.

The name has been changed from Kimeridge shale to South Highland coal by the manufacturers, the failure of the late company (by whom the former designation was used) having, it was considered, rendered the statement expensive. The term South Highland coal was selected from the resemblance to the Highland coal of Scotland, now so extensively worked near Edinburgh.—H. W. R.

KING WOOD is imported from the Brazils, and is sometimes called violet wood. This is one of the most beautiful of the hard woods, and is used in small cabinet work.

KINIC ACID. A peculiar acid extracted by Vanquyen from cinchona.

KINO is an extract obtained most probably from the *Phenaxys mucronata*, which grows on the Malabar coast. In India, also it is used for dying cotton a nashken colour. It is of a reddish-brown colour, has a bitter styptic taste, and consists of tannin and extractive, 75 parts, and a red gum, 23 parts. It is used only as an astringent in medicine. Kino is often called a gum, but most improperly so.

KIP. A Malacca weight for tin, of 40 lbs. 11 oz. avoirdupois.—N. M. S.

KIPS. The tanners call the skins of young animals kips.

KIRSCHWASSER, is an alcoholol liquor obtained by fermenting and distilling bruised cherries, called *Acheren* in German. The cherry usually employed in Switzerland and Germany is a kind of *myrica*, which on maturation becomes black, and has a kernel very large in proportion to its pulp. When ripe, the fruit, being some to feel by switching the trees, is gathered by children, thrown promiscuously, unripe, ripe, and

rotten, and to be, and crushed either by hand, or with a wooden beater. The mashed materials are set to ferment, and when the process is complete, the whole is transferred to a still, and the spirit is removed by passing the put over the common fire.

The fermented mash is usually made before it is put in the still, the capital of which is fitted on with a mixture of wood and dung. The liquor has a strong, for the most part, a rank smell, and is most injurious to health, but is from its own medicinal qualities, but from the presence of a derivative from the fermentation of the cherry-stone.

There is a superior kind of kreosote made in the Black Forest, prepared with fewer herbs, from a better spirit, properly fermented, bottled, and distilled.

KIRWANITE. A mineral found in basalt on the north-eastern coast of Ireland, consisting of a silicate of iron, alumina, and protoxide of iron.

KNIFE-CLEANING MACHINES. Mr. Kent's machine for this purpose consists of a box or frame, containing a couple of wooden drums, fixed near to each other upon a horizontal iron rod or spindle, which passes through the frame and is caused to rotate by means of a wheel-handle. Each drum is, for about three-fourths of the area of its lower face, covered with alternate rows of bristles and strips of leather, and the remaining fourth part is covered with bristles only. The bristles to be cleaned are introduced through the openings in the frame, between the rubbing surfaces of the drums, and rotary motion being given to the drums by a wheel-handle, the knives are rapidly cleaned and polished.

Mr. Mason's improved knife-cleaning machine is on the same plan as the above; but the rubbing surface of each drum is formed of strips of buff leather, with only a narrow circle of bristles around the edge of each surface, to clean the shoulders of the knives. Small brushes are fixed beneath the bottom of the case, through which the blades of the knives are inserted, to prevent the dust of dust from the apparatus.

Mr. Price has also devised a machine for cleaning knives, and another for cleaning forks. The knife-cleaner consists of a horizontal drum, covered with pieces of leather or felt, and fixed within a frame or circular frame, lined with leather or felt. The knives are introduced through openings in a movable circular plate, at the front of the outer casing, and enter between the surfaces of the two drums. The plate is fixed upon a horizontal axis, which extends through the frame, and is revolved at the back with a handle, by turning which the drum is caused to rotate and carry round the knives between the surfaces of the drums. The fork-cleaner consists of a box, with a long rectangular opening in the side, behind which two brushes are fixed, face to face. Between the brushes the prongs of the forks are introduced, and the handles are secured in a carrier, which is made to advance and recede alternately by means of a screw-drunk, and thereby thrust the prongs into and draw them out of contact with the brushes. The carrier consists of two metal plates, the lower one carrying a cushion of vulcanized indiarubber for the fork handles to rest upon, and the upper one lined with leather; they are joined together at one end, and are connected at the other, when the handles have been placed between them, by a thumb-screw.

KNOLLS. A kind of tin in Germany for lead ore separated from the smaller parts.

KNOPPERS are cankers produced by the puncture of an insect upon the flower-buds of several species of oak. They are compressed or flat, irregularly pointed, generally prickly and hard when ripe. They abound in Syria, Croatia, Servonia, and Nassau; those from the latter country being the best. They contain a great deal of tannin, are much employed in Austria for tanning, and in Germany for dyeing fawn, grey, and black. See GALLA.

KOLMISS is the name of a liquor which the Calmucks make by fermenting mare's milk, and from which they distil a favourite intoxicating spirit, called *sack* or *rudak*.

The milk is kept in bottles made of hides till it becomes sour, is shaken till it casts up its cream, and is then set aside in earthen vessels, in a warm place to ferment, no yeast being required, though sometimes a little old kolmiss is added. 21 pounds of milk put into the still afford 14 ounces of low wines, from which 6 ounces of pretty strong alcohol, of an unpleasant flavour, are obtained by rectification.

KOURIE WOOD. The wood of the New Zealand pine *Dioscorea Australis*, one of the most magnificent of the gum-ferns. It is also called *roudie* and *lawie* wood. It is much used for the masts of ships.

KRAMERIA. A shrub, which is a native of Peru, yielding the well-known rhizany root, often used as a diuretic.

KREOSOTE, or CHLOSOTE. One of the many singular bodies discovered by Reichenbach in wood-tar. It derives its name from *kreos* and *oso*, I preserve, in allusion to its remarkable antiseptic properties. A great deal of confusion exists in the published accounts of wood-creosote, owing to the variable nature of the results obtained by the chemists who have examined it. This confusion is not found with that from coal, which undoubtedly contains two homologous bodies, C₁₀H₈O and C₁₁H₈O₂; the first being carbolic, and the second cresylic acid. The composition of carbolic acid has long been

LAC. (*Laque*, Fr.; *Lack*, *Lackforben*, Germ.) A resinous substance produced by the puncture of a peculiar female insect, called *Coccus lacca* or *ficus*, upon the branches of several plants, as the *Ficus religiosa*, the *Ficus Indica*, the *Rhusmannijuba*, the *Croton laciferum* or *hairy tree*, and the *Urtica frondosa* or the paper tree, which grow in Siam, Assam, Pegu, Bengal, and Malabar. The twig becomes thereby incrustated with a reddish mammillated resin, having a crystalline-looking fracture.

The female lac insect is of the size of a louse; red, round, flat, with 12 abdominal circles, a bifurcated tail, antennae, and 6 claws, half the length of the body. The male is twice the above size, and has 4 wings; there is one of them to 3000 females. In November or December the young brood makes its escape from the eggs, lying beneath the dead body of the mother; they crawl about a little way, and fasten themselves to the bark of the shrubs. About this period the branches often swarm to such a degree with this vermin, that they seem covered with a red dust; in this case, they are apt to dry up, by being exhausted of their juices. Many of these insects, however, become the prey of others, or are carried off by the feet of birds, in which they attach themselves, and are transplanted to other trees. They soon produce small nipple-like incrustations upon the twigs, their bodies being apparently glued, by means of a transparent liquor, which goes on increasing to the end of March, so as to form a cellular texture. At this time the animal resembles a small oval bag, without life, of the size of a chinkal. At the commencement, a beautiful red liquor only is perceived, afterwards eggs make their appearance; and in October or November, when the red liquor gets exhausted, 50 or 60 young ones bore a hole through the back of their mother, and come forth. The empty cells remain upon the branches. These are composed of the milky juice of the plant, which serves as nutriment to the insects, and which is afterwards transformed or elaborated into the red colouring matter that is found mixed with the resin, but in greater quantity in the bodies of the insects, in their eggs, and still more copiously in the red liquor excreted for feeding the young. After the brood escapes, the cells contain much less colouring matter. On this account, the branches should be broken off before this happens, and dried in the sun. In the East Indies this operation is performed twice in the year; the first time in March, the second in October. The twigs encrusted with the radiated cellular substance constitute the *stick-lac* of commerce. It is of a red colour more or less deep, nearly transparent, and hard, with a brilliant conchoidal fracture. The stick-lac of Siam is the best; it often forms an incrustation fully one quarter of an inch thick all round the twig. The stick-lac of Assam ranks next; and, last, that of Bengal, in which the resinous coat is scanty, thin, and irregular. There are three kinds of lac in commerce: stick-lac, which is the substance in its natural state, seed-lac, and shell-lac. According to the analysis of Dr. John, stick-lac consists, in 100 parts, of

An odorous common resin	- 80.00	Fatty matter, like wax	- 3.00
A resin insoluble in ether	- 20.00	Skins of the insects, and colour-	
Colouring matter analogous to		ing matter	- 2.50
of that of cochineal	- 4.50	Salts	- 1.25
Bitter balsamic matter	- 3.00	Earths	- 0.75
Dun yellow extract	- 0.50	Loss	- 4.75
Acid of the stick-lac (laccic acid)	0.75		130.00

According to Franke, the constituents of stick-lac are, resin, 65.7; substance of the lac, 24.3; colouring matter, 0.6.

Seed-lac.—When the resinous concretion is taken off the twigs, coarsely pounded, and triturated with water in a mortar, the greater part of the colouring matter is dissolved, and the granular portion which remains being dried in the sun, constitutes *seed-lac*. It contains of course less colouring matter than the stick-lac, and is much less soluble. Mr. Hatchett's analysis of seed-lac was as follows:—

Resin	- 68	Foreign bodies	- 6.5
Colouring matter	- 10	Loss	- 6
Wax	- 6		
Glass	- 5.5		100

John found in 100 parts of it, resin, 86.7; wax, 1.7; matter of the lac, 16.7; bitter balsamic matter, 2.5; colouring matter, 3.9; dun yellow extract, 0.4; envelopes of insects, 2.1; laccic acid, 0.0; salts of potash and lime, 1.0; earths, 6.6; loss, 4.2.

Shell-lac.—In India the *seed-lac* is put into oblong bags of cotton cloth, which are held over a charcoal fire by a man at each end, and, as soon as it begins to melt, the bag is twisted so as to strain the liquefied resin through its substance, and to make it drop upon smooth stems of the banyan tree (*Moro perulata*). In this way, the resin spreads into thin plates, and constitutes the substance known in commerce by the name of *shell-lac*.

The Pegu stick-lac, being very dark coloured, furnishes a stick-lac of a corresponding deep hue, and therefore of inferior value. The pure red from shell-lac is brought from the Malabar Coast. It imparts very little colouring matter. A stick-lac of an intermediate kind comes from the Mysore country, which yields a brilliant scarlet and a good shell-lac.

Shell-lac, by Mr. Hattett's analysis, consists of resin, 50; wax, 25; coloring matter, 25; wax, 4; gum, 2; loss, 1; in 100 parts.

The resin may be obtained pure by treating shell-lac with cold alcohol, and filtering the solution in order to separate a yellow very impure resinous matter. When the alcohol is again distilled off, a brown, translucent, hard, and brittle mass of resinous matter remains. It melts into a viscous mass when heated, and assumes no permanent colour. A hydrous alcohol dissolves it in all proportions. According to John, it consists of two resins, one of which dissolves readily in alcohol, ether, the volatile and fat oils; while the other is little soluble in alcohol, and is insoluble in ether and the volatile oils. Unwin, however, has demonstrated that shell-lac consists of two resins, and some other substances in solution. Macleod dissolves with care in ether, marginic and acetic acids, but not in mineral sulphuric acids. The resin of shell-lac has a great tendency to combine with alkaline bases, as well as mineral bases, where it is derived of an alkaline base.

This substance, which is of a dark red colour, dries into a brilliant, transparent red-lac upon mass, which may be re-dissolved in both water and alcohol. By passing chlorine in contact through the shell-lac, and allowing it to remain, the lac-resin is precipitated in a colorless state. When this precipitate is washed and dried, it forms with alcohol an extremely pale-yellow varnish, especially with the addition of a little turpentine and rosin.

With the aid of heat, the shell-lac dissolves readily in a mixture of benzene.

The substances which have been found in shell-lac are the following:

1. A resin, soluble in alcohol and ether;
2. A resin, soluble in alcohol, insoluble in ether;
3. A resinous body, little soluble in cold alcohol;
4. A crystallizable resin;
5. A resin, soluble in alcohol and ether, but insoluble in petroleum, and uncrystallizable;
6. The unsaponifiable fat of the coccos kernel, as well as olive and margarine seeds.
7. Wax.
8. The lac-resin of Dr. John.
9. An extractive coloring matter.

Shell-lac is largely used in the manufacture of sealing wax and varnishes, and for japanning.

LAC-DYE, LAC LAKE, or *lake-lac*, is the watery infusion of the ground stick-lac, evaporated to dryness, and formed into cakes about two inches square and half an inch thick. Dr. John found it to consist of coloring matter, 50; resin, 25, and solid matter, composed of alumina, plaster, chalk, and sand, 25.

Dr. Macleod, of Madras, states that he prepared a very superior lac-dye from stick-lac, by digesting it in the cold in a slightly alkaline decoction of the dried leaves of the *Memecylon tinctorium* (perhaps the *M. caput-meduse*, from which the natives of Malabar and Ceylon obtain a saffron yellow dye). This solution being used along with a mordant consisting of a saturated solution of tin in muriatic acid, was found to dye woollen cloth of a very brilliant scarlet hue.

The cakes of lac-dye imported from India, stamped with peculiar marks to designate their different manufacturers (the bear D^r, the second JMcR, the third CE), are now employed in England for dyeing scarlet cloth, and are found to yield an equally brilliant colour, and one less easily affected by perspiration than that produced by cochineal. When the lac-dye was first introduced, sulphuric acid was the solvent applied to the pulverised cakes, but as muriatic (hydrochloric) acid has been found to answer, it has to a great extent supplanted it. A good solvent (No. 1) for the dye-stuff may be prepared by dissolving 5 pounds of tin in 60 pounds of muriatic acid, of specific gravity 1.19. The proper mordant for the cloth is made by mixing 27 pounds of muriatic acid of sp. gr. 1.17, with 1½ pounds of nitric acid of 1.19; putting this mixture into a salt-glazed stone bottle, and adding to it in small lots at a time, grain by grain, till 4 pounds be dissolved. This solution (No. 2) may be used within twelve hours after it is made, provided it has become cold and clear. For dyeing, three quarters of a pint of the solvent No. 1 is to be poured upon each pound of the pulverised lac-dye, and allowed to digest upon it for six hours. The cloth being subjected to the dye bath, must be secured in the mill with fustic's earth. To dye 100 pounds of pelase cloth, a tin boiler of 300 gallon capacity should be filled nearly brimful with water, and a fire kindled under it. Whenever the temperature

ries to the Fabr., a handful of soap, and half a pint of the solution of tin (No. 2) are to be introduced. The froth, which rises as it approaches ebullition, must be skimmed off; and when the liquor has 1½ pounds of the dye, previously mixed with 7 parts of the solvent No. 1, and 2½ pounds of solution of tin No. 2, must be poured in. An instant afterwards, 1½ pounds of tartar, and 4 pounds of ground sumach, both tied up in a linen bag, are to be introduced in the boiling bath for five minutes. The fire being now withdrawn, 20 gallons of cold water, with 1½ pints of solution of tin being poured into the bath, the cloth is to be immersed in it, moved about rapidly during ten minutes; the fire is to be then re-kindled, and the cloth moved more slowly through the bath, which must be made to boil as quickly as possible, and maintained at that pitch for an hour. The cloth is to be next washed in the river; and lastly with water only, in the fulling mill. The above proportions of the ingredients produce a brilliant scarlet tint, with a slightly purple cast. If a more orange hue be wanted, white Florence argal may be used, instead of tartar, and some burnt sumach. Lac-dye may be substituted for cochineal in the same manner.

To determine the tinctorial power of lac-dye by experiment, with proved samples, a dye-bath is prepared as follows—5 grains of argal, 20 grains of the seller's white cloth, 2 grains of lac-dye, 8 grains of chloride of tin, 1 quart of water. Heat the water to the boiling point in a tin or brass vessel; add thereto the argal, and then the piece of cloth or flannel. Weigh off 5 grains of the lac-dye and pulverise it in a Wedgwood mortar, with the 8 grains by measure of chloride of tin, and pour the whole into the hot liquor containing the cloth, taking care to stir the mortar with a stick in the hot liquor; keep the whole boiling for about half an hour stirring the cloth or flannel about with a glass rod; then withdraw the cloth, wash and dry it for comparison.—*Norman.*

In the former edition was a table of the imports and exports of lac-dye and lac-like, which show that in 1852 only 253 lbs. were imported, which rose, however, in 1857, to 1,011,674 lbs.; the imports, &c., for the last three years being—

LACCIC ACID crystalline, has a wine-yellow colour, a sour taste, is soluble in water, alcohol, and ether. It was extracted from black-lac by Mr. John.

LACCINE is the portion of shell-lac which is soluble in alcohol. It is brown, brittle, translucent, consisting of aggregated pellucles, more like a resin than anything else. It is insoluble in ether and oils. It has not been applied to any use.

LACE BARK. The reticulated bark of the *Lagetta lanceolata*. This splits into fibres, which resemble lace.

LACE MANUFACTURE. The pillow-made, or bone-lace, which formerly gave occupation to multitudes of women in their own houses, has, in the progress of mechanical invention, been nearly superseded by the bobbin-net lace, manufactured at first by hand-machines, but recently by the power of water or steam. Bobbin-net may be said to surpass every other branch of human industry in the complex ingenuity of its machinery; one of Fisher's spinning frames being as much beyond the most curious chronometer in multiplicity of mechanical device, as that is beyond a common roasting-jack.—*Ure.*

The threads in bobbin-net lace form, by their intertwining and decussation, regular hexagonal holes or meshes, of which the two opposite sides, the upper and under, are directed along the breadth of the piece, or at right angles to the selvage or border. Fig. 1034 shows how, by the crossing and twisting of the threads, the regular six-sided mesh is produced, and that the texture results from the union of three separate sets of threads, of which one set proceeds downwards in serpentine lines, a second set proceeds from the left to the right, and a third from the right to the left, both in slanting

directions. These threads twist themselves round the vertical ones, and thus form a mesh, the warp threads, in a parallel manner. This may be easily understood by examining the preceding plate. In comparing this net with a common web, the perpendicular threads in the former which are parallel to the border, may be regarded as the warp, and the two sets of slanting threads as the weft.

1054

1055

The warp threads are extended up and down in the longitudinal direction of the piece between a top and bottom horizontal roller or beam, of which one is raised the warp beam, and the other the lace beam, because the warp and finishing line are wound upon them respectively. These slanting weft threads receive their position from the tension of the weft threads twisted obliquely round them alternately in the right and the left hand. Were the warp threads not tightly drawn, that they became flexible, like rubber-strings, then the lace would assume the appearance shown in fig. 1053, and although this condition does not really exist, it may serve to illustrate the structure of the web. The warp threads stand in the positions *a, a', a'', and a'''*; the one half of the weft proceeds in the direction *b, b', b'', and b'''*, and the second crosses the first by running in the direction *c, c', c'', and c'''* towards the opposite side of the fabric. If we pursue the path of a weft thread, we find it goes on till it reaches the outermost or last warp thread, which it twice encircles, as with the others, but twice; and then returning towards the other border, passes in a reverse direction. It is from this double twist, and by the return of the weft threads, that the selvedge is made.

The ordinary material of bobbin-net is two cotton yarns, of from No. 16 to No. 20, twisted into one thread; but sometimes strongly twisted single yarn has been used. The beauty of the fabric depends upon the quality of the material, as well as the regularity and smallness of the meshes. The number of warp threads is a yard in breadth is from 600 to 900, which is equivalent to from 20 to 30 in an inch. The size of the holes cannot be exactly inferred from that circumference, as it depends partly upon the oblique traction of the threads. The breadth of the pieces of bobbin-net varies from edges of a quarter of an inch to webs 12 or even 20 quarters, that is, 3 yards wide.

Bobbin-net lace is manufactured by means of very costly and complicated machines, called frames. The limits of this Dictionary will admit of an explanation of no more than the general principle of the manufacture. The threads for winding and twisting round the warp, being previously gassed, that is, freed from loose fibres by steeping with gas, are wound round small pulleys, called bobbins, which are, with the view, deeply grooved in their periphery. Figs. 1056, 1057, exhibit the bobbin alone, and with its carriage.

In the section of the bobbin *a*, fig. 1056, the deep groove is shown in which the thread is wound. The bobbin consists of two thin discs of brass, cut out in a lamp-press, in the middle of each of which there is a hollow space *c*. These discs are pressed together leaving an interval between their edge all round, in which the thread is coiled. The round hole in the centre, with the little notch at top, serves for putting them upon a feathered rod, in order to be filled with thread by the rotation of that rod in a species of reel, called the bobbin-filling machine. Each of these bobbins (about double the size of the figure) is inserted into the vacant space *a* of the carriage, fig. 1057. This is a small iron frame (also double the size of the figure), which, at *e e*, embraces the grooved border of the bobbin, and by the pressure of the spring at *f*, prevents it from falling out. This spring serves likewise to apply sufficient friction to the bobbin, so as to prevent it from giving off its thread at *g* by its rotation.

unless a certain small force of traction be employed upon the thread. The curvilinear groove δ δ , sunk in each face or side of the carriage, has the depth shown in the sec-

tion at δ . The groove corresponds to the interval between the teeth of the comb, or bars of the belt, in which each carriage is placed, and has its movement. A portion of that belt or comb is shown at a , *fig.* 1038 in plan, and one bar of a circular belt machine at b , in section. If we suppose two such combs or belts placed with the ends of the teeth opposite each other, but a little apart, to let the warp threads be stretched, in one vertical plane, between their ends or tips, we shall have an idea of the skeleton of a bolt-net machine. On of these two combs, in the double bolt machine, has an occasional lateral movement called *shogging*, equal to the interval of one tooth or bolt, by which, after it has received the bobbins, with their carriages, into its teeth, it can shift that interval to the one side, and thereby get into a position to return the bobbins, with their carriages, into the next series of intervals or gates in the other belt. By this means the whole series of carriages receives successive side steps to the right in one belt, and to the left in the other, so as to perform a species of counter march, in the course of which they are made to cross and twist round about the vertical warp threads, and thus to form the meshes of the net.

The number of movements required to form a row of meshes in the double tier machine, that is, in a frame with 2 combs or bars, and 2 rows of bobbins, is six, that is, the whole of the carriages (with their bobbins) pass from one bar or comb to the other six times, during which passages the different divisions of bobbin and warp threads change their relative positions 12 times.

The interchange or traversing of the carriages with their bobbins, which is the most difficult thing to explain, but at the same time the most essential principle of the lace-machine, may be tolerably well understood by a careful study of *fig.* 1039, in which the simple line $|$ represents the bolts or teeth, the sign ϕ the back line of carriages, and the sign ϕ the front line of carriages. δ is the front comb or bolt bar, and τ the back bolt

bar. The former remains always fixed or stationary, to receive the carriages as they may be presented to it by the shogging of the latter. There must be always one odd carriage at the rod; the rest being in pairs.

small trouble and expense a very large quantity of product. In fact, he has prepared with facility upwards of three parts of lactic acid from lactate of lime obtained in this manner. Dissolve 6 lbs. of lump sugar, and half an ounce of tartaric acid in two gallons and a half of boiling water. Leave for a day or two, and then add two ounces of rotten cheese, and a gallon of skimmed milk stirred up with three pounds of well washed prepared chalk. The temperature should not fall below 66° F., nor rise above 90°. The water lost by evaporation must be made up by adding a little every few days. After a time, varying from ten days to a month, according to the temperature and other circumstances, the whole becomes a magma of acetate of lime. Two gallons of boiling water must then be added, and half an ounce of quicklime and the whole, after being boiled for half an hour, is to be filtered through a linen or flannel bag. The filter should be to be evaporated until it begins to get somewhat syrupy, the fluid in the stove being put aside to allow the salt to crystallize. The crystals, after being slightly washed with cold water, are to be recrystallized two or three times. To obtain lactic acid from the lactate of lime, it is necessary, in the first place, to convert the latter salt into that of zinc. For this purpose a crude lactic acid is first obtained thus: to every two pounds three ounces of lactate of lime dissolved in twice its weight of boiling water, seven ounces of oil of vitriol previously diluted with twice its volume of water are to be added. The boiling fluid is to be strained through a linen bag to remove the precipitate of gypsum, and the filtered liquid is to be boiled for 15 minutes with 1½ ounces of carbonate of zinc. The boiling must not be continued longer, or a violent effervescence will be produced. The liquid, which is to be filtered through a wet deposit on cooling the lactate of zinc in colourless crystals, which are to be washed with a little cold water, and after being drained are to be dried by exposure to the air in frames covered with filtering paper. The mother liquid will yield a fresh quantity of lactate if it be boiled with the salt remaining on the filter and evaporated.

From the lactate of zinc the acid is to be separated by passing sulphuretted hydrogen through the solution of the salt in eight times its weight of boiling water. The gas is to be expelled by heat, and the fluid on evaporation yields pure syrupy lactic acid.

Lactic acid is a colourless syrupy liquid of a powerful pure acid taste. Its specific gravity is 1.115. It is bibasic, consequently the general formula for the lactates is $C^3H^5O^4, 2MO, M$ representing any metal.

The most important salts of lactic acid are those of zinc and lime. The former salt is that generally formed in examining animal or vegetable fluids with a view to the isolation of the acid. It is found with two different quantities of water according to the circumstances under which it is prepared, and it is worthy of remark that the amount of water of crystallisation remarkably affects the solubility of the salt in water and alcohol.

Lactic acid is produced from alanine by the action of nitrous acid according to the following equation. —

Anhydrous lactic acid, $C^3H^5O^4$, is produced by the action of heat on the syrupy acid. Lactic acid is considered by chemists to be constructed on the type of four atoms of water in which two atoms of hydrogen are replaced by the radical lactyl, thus: — $\left. \begin{matrix} C^3H^5O^4 \\ H^2 \end{matrix} \right\} O^2$.

The other two atoms of hydrogen are consequently basic. It has been said that lactic acid may, by fermentation, be converted into butyric acid; the following equation represents the metamorphosis.

All the butyric acid employed for the preparation of butyric ether, or pine-apple essence, is now prepared by the fermentation of lactate of lime, — C. G. W.

LACQUER, is a varnish, consisting chiefly of a solution of pale shell-lac in alcohol, tinged with saffron, annatto, or other colouring matters. See VANSTEN.

LACTOMETER is the name of an instrument for estimating the quality of milk, called also a Galactometer. The most convenient form of apparatus would be a series of glass tubes each about 1 inch in diameter, and 12 inches long, graduated through a space of 10 inches, to tenths of an inch, having a stopcock at the bottom, and suspended upright in a frame. The average milk of the cow being poured in to the height of 10 inches, as soon as the cream has all separated at top, the thickness of its

Only may be measured by the scale; and then the slowness may be run off by a
small horizontal glass, in order to determine its quantity by the velocity of descent in a small
manometer, and deliver with water.

FACT INFORMATION (a publication) belonging to a book

[illegible]

Red Lake - The water in Cannon Lake is usually colored by the presence of iron from the rocks. It is usually reported as being "red" or "brown" in color. The water is not only colored, but it is also very hard. The water is not only colored when lakes are the product of the dyer's

Brazil wood is a red dye. The wood is used as a preservative for iron for its tannic acid, and then also as a substitute of the tanning agent. It is also used for coloring and staining of parchment as long as it remains a preservative. This is separated by a filter, the powder is washed, and being dried in a kiln, ground in water, and used as a cake. Because the Brazil wood is made with very small amount of water. An excess of water produces a lake of a white color, and a small amount of tartar gives it a brown line.

Ma... is made in the preparation of lakes

The title of the paper is "The Role of the Teacher in the Classroom."

1866. 1 lb. of gum mastic, 4 lb. of water, and after a maceration of 10 days, strain and squeeze the grounds in a press. Repeat the same process. Ac. 1 lb. upon the same part of mastic. It will be a fine yellow color. It must then be mixed with five or six pounds of water and half a pound of hydrated alum, and heated upon a water-bath for 3 or 4 hours, with the addition of water, as it evaporates; after which the whole must be thrown on a filter. The liquor which passes through is then to be filtered through paper, and precipitated by carbonate of potash. If potash be added in three successive doses, three different colors will be obtained of diminishing beauty. The precipitates must be washed until the water comes off colourless, then with gum water made into cakes.

Yellow Lake: are made with decoctions of Persian or French berries, to which some potash or soda is added: into the mixture a solution of alum is to be poured as long as any precipitate falls. Quercitron will yield a yellow lake, provided the decoction is perfumed by either butter-milk or glue. Annott lake is formed by dissolving this substance in a weak alkaline lye, and adding a solution of alum to the solution.

Lakes of other colours can be prepared in a similar manner; but true lakes of other colours are not usually manufactured.

LAMINABLE is said of a metal which may be extended by passing between steel or hardened (chilled) cast-iron rollers.

In the manufacture of rail and bar iron, laminated iron is rolled together at a welding heat, until the required bar or rail is formed (see Rattle). This is, even under the best possible circumstances, a defective manufacture. The union of the bars is never absolutely complete, and the result of the long-continued action of traffic of carriages upon all rails is the development of the laminated plates, which frequently peel off, layer after layer, to the destruction of the rail, and to the great danger of the traveller. Railway iron should be rolled into form from perfectly homogeneous masses of metal. The lamination of iron rails has been laid hold of by those who advocate the hypothesis that the slate rocks owe their lamination to mechanical pressure, whereas it is evidently the result of an imperfect manufacture. See RATTLE, MILL.

LAMUM ALBUM or the dead nettle, is said by Leon. to afford in its leaves a greenish-yellow dye. The *L. purpureum* dyes a reddish grey with salt of tin, and a greenish blue with iron liquor.

LAMP-BLACK. Every person knows that when the combustion of oil in a lamp is imperfect it pours forth a volume of dense black soot. According to the quantity

of carbon is used in the material employed, so is the illuminating power of the flame produced by combustion. If, therefore, we have a very brilliant flame, and we subject it to any conditions which shall impede the progress of the combination of the carbon with the oxygen of the air, the result is at once the formation of solid carbon, or lamp-black. This is exhibited in a remarkable and often an annoying manner by the lamp-lamp. If oil of turpentine, resin, pitch, or fat oil, be burnt in lamps under a hood, with either a rapid draught or an insufficient supply of air, the lamp-black collects on the hood, and is constantly removed. Sometimes a metallic roller, generally of tin, is made to revolve in the flame, and rub against a brush. By the cooling action of the metal, the base of the flame is diminished, the combustion retarded, and the carbon deposited, and in the revolution of the cylinder swept off. Lamp-black burning forms a very beautiful black, which is sometimes used as a pigment.

The common varieties of lamp-black are made from all sorts of refuse and noxious matters, and from the rejected fragments of paper, &c. In Germany, a large fire is constructed in connection with the furnace in which the refuse substances are burnt, and this fire communicates with a hood, composed of a loose wooden cloth, held up by a rope passing over a pulley. Upon this the soot collects, and is from time to time shaken down. In the best candle-manufactories about 3 cwt. of lamp-black is consumed in each hour in about twelve hours. In England, lamp-black is sometimes prepared from the refuse of the glass, or it is obtained in connection with coke ovens. The lamp-black, however, obtained from the combustion of coal or woody matter is never pure. See BLACK, LAMP, IVORY PLAIN.

LAMP, DAY. See SAFETY LAMP.

LAMPS. Under ILLUMINATION, will be found some account of several kinds of lamps, with especial reference to the quantity of light produced by them.

Lamps are very varied in form, and equally varied in the principles involved. A brief description, however, of a few of the modern varieties must suffice.

The *moderator lamp*.—The spiral spring has recently been introduced into the *moderator lamp*, for the purpose of forcing the oil up the wick of the lamp. This will be understood by the following description and drawings. 1060

The distinguishing character of the *moderator lamp* is the direct transmission of the power, in the reservoir of oil, to the resistance offered by the weight of the column of oil, as it rises to the cotton;—and secondly, the introduction of a rectangular regulator, which equilibrates constantly by the resistance of the oil and the force applied to raise it. In the reservoir (fig. 1061), is a spiral spring which presses on the disc or piston, fig. 1061, which is furnished with a valve opening downwards. This spring is attached to a tooth rack, worked by a piston wheel, by the action of which it is wound up. The mechanical force of the spring is equal to from 15 to 20 pounds; and so this force is exerted upon the disc, forcing on the oil, this is forced up through the tube, and it overflows to the argand burner, thoroughly saturating the cotton, and supplying a constant stream of oil. This oil falls back into the reservoir, and is, of course, above the disc. When the spring has run down, it is again wound up, and then the valve opening downward allows the oil to flow back beneath the disc, to be again forced up through the tube. As the pressure employed is so great, the oil would, but for the "moderator," flow over with too much rapidity. The *moderator*, or regulator, is a tapering rod of iron-wire, which is placed in the ascending tube; and, as the pressure increases it is forced more into it, and checks the flow of oil; whereas as it diminishes it falls, and being tapering, allows more oil to rise. Several ingenious adjustments are introduced into these lamps, as manufactured by the Messrs. Tyler of Warwick Lane, with which we need not at present deal. The cylinders containing the oil are covered with enameled metal or sometimes of porcelain. Two drawings of these are shown (fig. 1062 and fig. 1063). These lamps admit evidently of yet more elegant forms than have been given them. The urn-shaped, from the antique, in very pure taste, is the last introduction of the house above named.

It would be tedious to enumerate the various modifications of form and action to which the oil lamp has been subject, previous to its arrival at what may be deemed its perfect construction by Argand. The discovery of the mode of applying a new principle

1061

the upper rim, and the margin, there is a small projecting pin *e*, which, when the whole apparatus is combined, fits into the cavity of the lower *l*. To prepare the lamp for use, the tube *u* is pushed between *A* and *a* as just described, the ring *r*, with its convex surface, is next turned, the pin *e* of the middle fitting fits the spiral groove, and that of the outside moving the rest of the tube *u*, which, on being turned about, causes the lower *v* to slide along the curved lower tube, until the water only just rises above the lower *e* above of the tube, in the interval between which it lies in the oil. In this stage, the funnel *l* is placed in the neck in the collar at *e*, falling upon the pin over the top of *u*, the lower tube *f*, is pushed over the tube *A*, at once presents a convenient support for the glass chimney, and a finger-ring for raising the work. The central tube is open throughout, and, unscrewing, at its lower end, with the brass rim *A*, the lower is performed at top, to admit the air which, by circulating through the above tube, and the burning flame which surrounds it, causes the lamp to burn with that peculiar softness and brilliancy which distinguishes the Argand combustion. The last-mentioned receptacle *h* is a cap for any small quantity of oil which may pass over the lower tube during the combustion of the work. *z* is the brass peg, which fits into the upper part of the point, in the table lamp.

In addition to the various variety of small portable lamps, the production of which it would be tedious to particularise, and the merit of which, as compared with those of the Argand principle, remains, in the great part, in their cheapness, the more important articles, and those generally in demand, may be distinguished as fixed or bracket lamps, suspended or chandelier lamps, and table or French lamps—all these having, however, as the principle above described. The former sort were, previous to the introduction of gas, very common in shops. The given *A* (Fig. 1444), which is sometimes made plain and

sometimes enameled, as in the cut, set us off, when the oil is poured in at an opening in the lower part, which is afterwards closed by means of a stop at the stem, *n*, and the globe, thus replenished, is inverted and screwed into the part, *c*. When the lamp is used, the stem *n* is raised a little, and the oil is suffered to flow through the intermediate tube into the cavity *n*, only at the rate at which it is consumed by the burning of the wick. The peculiar form of the glass chimney *a* is admirably calculated to assist in the more complete combustion of the matter drawn up to the wick when impure oil is used, a desideratum originally in part secured by placing over the central tube, and in the midst of the flame, a circular metal plate, by means of which the ascending column of air was turned out of its perpendicular course, and thrown immediately into that part of the flame where the smoke is formed, and which by this ingenious contrivance is effectually consumed; this application, however, is not necessary, nor the form of such moment, when purified sperm oil is used. These lamps being usually made to move on a pivot at *e*, attached to the wall or other support, are very convenient in many situations, as being easily advanced over a desk or counter, and afterwards turned aside, when not in use.

The chemical lamp has no possibility of improvement to be described.

The use of spirit lamps is inferior, and we have the alcoholic and naphthalene lamps of the same kind. The alcoholic lamp, however (the latter shows the possibility of the naphthalene lamp where the reservoir of spirit is impregnated, deprived of smell, is far below the former, to which it is added by impurity introduced through the tubes of the same work. Lamps to burn naphthalene (Naphthalene, A.) are constructed on the same principle.

One of the best oil lamps, is that known as Cam's lamp.

In this lamp the oil is raised through some by clock work, as is commonly the case, at the bottom of the burning work, thus keeping it thoroughly agitated, while the excess of the oil drops back into the common lower. I have possessed the best of years an excellent lamp of this description, which produced most satisfactory light, but it can hardly be trusted in the hands of a servant, and when a gets at all damaged it must be sent to the chemist to be repaired. The light of this lamp when furnished with an appropriate tall glass chimney, is very brilliant, though not perfectly uniform, since it fluctuates a little, but always perceptibly to a sensitive observer, with the alternating action of the pump-work, becoming almost a very successive jet of oil, and lighter just before its return. The flame, however, always thickens again or not, owing to the powerful draught, and it is a good example of the shoulder of the chimney. The mechanical lamp is, however, remarkable for its economy in burn, and may with advantage be used with increasing splendour for 2 or 3 hours; the variety of the combustion increasing even with the increased temperature and density of the oil, which by its constant circulation through the burning work, is eventually very warm. In the comparative experiments made upon different lights by the Philosophical Society, the mechanical lamp is certainly taking as the standard. I do not think it essential to this purpose, but it may be made to emit very different quantities of light, according to difference in the nature and supply of the oil, as well as variations in the form and position of the chimney. Hence, such lamps are the rare in this country to be selected as standards of illumination.

The following experiments by Dr. Ure, are well worth preserving.

The great variety in the quality of lamps in the vicinity, and consequent supply of oil, to the water, as shown nearly as perfect with lamps of the common construction during the winter months. The relative viscosity or relative fluidity of different liquids at the same temperature, and of the same liquid at different temperatures, has not, I believe, been hitherto made the subject of accurate researches. I was, therefore, induced to make the following experiments with this view.

Into a brass-hermetic cup of platinum, resting on the ring of a chemical stand, I introduced 2000 grain-measures of the liquid whose viscosity was to be measured, and ran it off through a glass siphon, of an inch in the bore, having the outer leg 4 inches, and the inner leg 3 inches long. The time of efflux became the measure of the viscosity; and of two liquids, if the specific gravity and consequent pressure upon the siphon were the same, that time would indicate exactly the relative viscosity of the two liquids. Thus, oil of turpentine and sperm oil have each very nearly the same density; the former being, as sold in the shops, = 0.876, and the latter from 0.876 to 0.880, when pure and genuine. Now I found that 2000 grain-measures of oil of turpentine ran off through the small siphon in 93 seconds, while that quantity of sperm oil took 37.5 seconds, being in the ratio of 1 to 2.5; so that the fluidity of oil of turpentine is 2.5 times greater than that of sperm oil. Pyroxene spirit, commonly called naphtha and alcohol, each of specific gravity = 0.8, were found to run off respectively in 80 and 120 seconds, showing that the former was 30 per cent. more fluent than the latter. Sperm oil, when heated to 100° Fahr., runs off in 30 seconds, or one-ninth of the time it took when at the temperature of 60°. Southern whale oil, having a greater density than the sperm oil, would flow off faster were it not more viscid.

2000 grain measures of water at 60° run off through the said siphon in 73 seconds, but when heated to 180° they run off in 61.

Concentrated sulphuric acid, though possessing the great density of 1.840, yet flows off very slowly at 60°, on account of its viscosity; whence its name of oil of vitriol. 2000 grain-measures of it took 660 seconds to discharge.

LAMPIC ACID. Syn. Aldehydic acid; Acetylous acid. (*Ac. Lampicæ*, Fr.) If a little ether be placed at the bottom of a glass, and some spongy platinum attached to a wire of the same metal be ignited and suspended about an inch from the fluid, it will glow and continue to do so for a long time. On the other hand, if a spiral of platinum wire be placed over the vessel of a spirit lamp, and the latter be first ignited and then blown out, the wire will continue at a red heat until all the spirit is consumed. Numerous sequi-ades, when placed warm on wire gauze over capsules containing

alcohol, will flow in the same manner. Under all these circumstances, a powerful colour resembling aldehyde is evolved, which severely affects the eyes. If this experiment be made in such a manner that the volatile product may be condensed, it will be found to be strongly acid. It is powerfully reducing in its tendency, and if treated with the oxides of silver or gold, converts them into the metallic state, and the liquid is found to contain acetic acid and traces of aldehyde. If, however, the acid liquid be only very greatly warmed with a little of silver, a portion of the latter is dissolved; but when baryta is added to precipitate the silver as oxide, and the fluid is warmed, the metallic baryta of the oxide comes down, and the fluid when tested for the nature of the acid is found to react in reacting but acetate of baryta. These phenomena are explained by some chemists by supposing the fluid to contain an acid which they, following the late Professor Daniell, call the lampic acid, and supposed to contain $C^{II}PO^2$. When lampic acid is treated first with oxide of silver and then with baryta water and heated, they consider that the oxygen of the oxide of silver is transferred to the lampic acid, converting it into acetic acid, which combines with the baryta, while the metallic silver is precipitated. The following equation expresses the reaction supposed to take place:—

Lampic acid.

Acetate of baryta.

The conversion of the lampic into acetic acid is therefore attributed to the oxidising tendency of the oxide of silver. Those who regard the decomposition from the above point of view, consider lampic acid to be acetylous acid, that is to say, to bear the same relation to acetylous acid (acetic acid) that acetylarous acid does to acylous acid.

The above explanation, although simple, does not really render a satisfactory account of the reaction which bears upon the subject. Aldehyde, when treated with oxide of silver does, it is true, become converted into the same, or apparently the same, substance as lampic acid, but the probability is in favour of Gerhardt's supposition, that the lampates are in fact aldehydyle, in which an equivalent of hydrogen is replaced by a metal. That the aldehydes are capable of uniting with metals with elimination of hydrogen has been, on more than one occasion, proved by experiment. There is great difficulty in preparing the sodium aldehyde of the same series, but the author of this article has found that if caustic aldehyde from oil of rose be treated with sodium, a definite compound is formed, having the formula $\left. \begin{array}{c} C^{II}H^2(O^2) \\ Na \end{array} \right\}$.

If, therefore, we admit aldehyde to be formed on the hydrogen type, that is to say, two atoms of hydrogen in which one is replaced by the oxidised radical acetyl, we shall have for aldehyde:— $\left. \begin{array}{c} C^{II}H^2(O^2) \\ H \end{array} \right\}$; and for the lampates, acetylous, or aldehydylates, — $\left. \begin{array}{c} C^{II}PO^2 \\ M \end{array} \right\}$. M. Gerhardt, who views the lampates in the above light, regards

aldehyde as the true acetylous acid. See ACETYL — C. G. W.

LANCE WOOD (*Casura lanceolata* or *Giosteria veyana*). This wood is imported from Jamaica and Cuba in long poles from 3 to 6 inches diameter. Lance wood is paler in colour than box; it is selected for elastic works, as gig-shafts, archery bows, springs, &c. These are bent into the required form by boiling or steaming. Surveyor's rods, ordinary rules and billiard cues are made of lance wood.

LANDER. In mining, the man who attends at the mouth of the shaft to receive the "hibble of ore" as it reaches the surface.

LAPIDARY, *Art of*. The art of the lapidary, or that of cutting, polishing, and engraving gems, was known to the ancients, many of whom have left mineral specimens of their skill. The Greeks were passionate lovers of rings and engraved stones; and the most personifications among the higher classes of the Cyrenians are said to have worn rings of the value of ten minae (about 30*l.* of our money). By far the greater part of the antique gems that have reached modern times may be considered as so many models for forming the taste of the student of the fine arts, and for inspiring his mind with correct ideas of what is truly beautiful. With the cutting of the diamond, however, the ancients were unacquainted, and hence they wore it in its natural state. Even in the middle ages, this art was still unknown; for the four large diamonds which enrich the clasp of the imperial mantle of Charlemagne, as now preserved in Paris, are uncut, octahedral crystals. But the art of working diamonds was probably known in Hindostan and China in very remote periods. After Louis de Berghem's discovery, in 1476, of polishing two diamonds by their mutual attrition, all the finest diamonds were sent to Holland to be cut and polished by the Dutch artists, who long retained a superiority, now no longer admitted by the lapidaries of London and Paris. See DIAMOND.

The operation of gem cutting is performed by two wheels, 1, by revolving it by turning it round with a fine wire, wound with diamond powder, and fixed to the neck of a handle. I mention to the only process which is not carried out with diamond powder, worked with other materials, as the plate of very soft lead.

Orbital rubber supplies, and lapidary are cut with diamond powder worked with a wire, or a very wheel. The stone they support are otherwise polished by another upper wheel, with cloth, composed with water.

Finally, by another smooth, the gemstone is again, and other similar stones are cut as a low wheel, with many and water, and are polished in a low wheel with fresh and water, or, still better, in a very wheel, with pieces of the said water.

The more highly polished stones, and even the pieces, are not on a wheel of hard wood, with many and water, and are polished with crystal and water on another wheel of hard wood.

When the lapidary says it always the same tools, whatever be the stone which he cuts or polishes, and even the wheel stone stone, as long as the operation is the same, we shall know the first of all, the operation, and then the circumstances for diamond cutting, which are necessary to every species of stone.

The lapidary's mill, or wheel, is shown in perspective in fig. 1067. It consists of a strong frame made of oak, composed, with some oak support frame, fixed together with strong bolts and screws. The frame is a parallelogram of four feet 2 inches long, by 6 ft 7 inches high, and about 2 feet wide. These dimensions are large enough to contain two cutting wheels, the diameter of each wheel, as represented in the figure.

Between the two wheels there is, we perceive in the figure, a third wheel, *a*, *b*, *c*, *d*. The two wheels have each, on a part of the frame work, and serve to hold it. The two wheels are 1 inch 2, carry each in the middle of their length, a piece of wood as thick as themselves, but only 4 inches long.

Between the two wheels there is, we perceive in the figure, a third wheel, *a*, *b*, *c*, *d*. The two wheels have each, on a part of the frame work, and serve to hold it. The two wheels are 1 inch 2, carry each in the middle of their length, a piece of wood as thick as themselves, but only 4 inches long.

(see fig. 1067). I mention to the only process which is not carried out with diamond powder, worked with other materials, as the plate of very soft lead.

In fig. 1068 this face is shown better, in order to explain how the wheel is placed and supported. The same letters point out the same things, both in the perspective and the following figure.

In each of these summers a square hole is cut out, exactly opposite to the other, which are adjusted by friction a square piece of oak, *a*, *b*, *c*, *d*, fig. 1068, whose extremities are perforated with a round hole, which receives the two ends of the arbor *n* of the wheel *z*, and forms its socket. The square bar is adjusted at a convenient height by a double written wedge, *b*, *b*. The cross bar in the middle *x*, supports the table *e*, a strong plank of oak. It is perforated with two large holes, whose centres coincide with the centres of the round holes hollowed out at the end of the square piece. These holes of about 6 inches diameter each, are intended to let the arbor pass freely through near to the opposite wheel. (See also of these holes at *z*, in fig. 1067 below.)

Each wheel is composed of an iron arbor *n*, *n*, *n*, of a grinding wheel *z*, which differs in shape according to circumstances, as a ready outlet, and of the pulley *s*, furnished with several grooves (see fig. 1067), which has a square fit upon the arbor. The arbor carries a nut *d*, which are 4 iron pegs of pine that enter into the wheel to fasten it.

The wheel plate, of which the ground piece is cut out at *n*, is hollowed out towards its centre to half its thickness when it is in its position on the arbor, so intended to diminish the weight of the wheel. In fig. 1069 the wheel-plate is represented in section, the construction of the wheel parts may be seen.

A board *y* (see fig. 1067 and fig. 1073), about 7 inches high, is fixed to the

1069, a washer or ferrule of wrought iron is put over it, and secured in its place by a double wedge. In fig. 1069 the wheel-plate is represented in section, the construction of the wheel parts may be seen.

A board *y* (see fig. 1067 and fig. 1073), about 7 inches high, is fixed to the

part of the frame opposite to the side at which the lapidary works, and it prevents the cutters made use of in the cutting and grinding from being thrown out of position by the centrifugal force of the wheel.

Behind this apparatus is mounted for each grinding-plate, a large wheel *z* (see fig. 1077), similar to a cutter's, but placed horizontally. This wheel is grooved round its circumference to receive an endless cord or band, which passes round one of the grooves of the pulley *j*, fixed below the wheel-plate. Hence, on turning the fly-wheel *z*, the plate revolves with a velocity relative to the velocity communicated to the wheel *z*, and to the difference of diameter of the wheel *z* and the pulley *j*. Each wheel *z*, is mounted on an iron arbor, with a crank (see *z*, fig. 1071).

The lower pivot of that arbor *A* is conical, and turns in a socket fixed in the floor. The great wheel *z* runs on the collar *i*, furnished with its 4 iron pins, for securing the connection. Above the wheel an iron washer is laid, and the whole is fixed by a double wedge, which enters into the mortise *l*, fig. 1071.

Fig. 1072 exhibits a general plan view of all this assemblage of parts, to express the structure of the machine. Everything that stands above the upper counter has been expressed in this representation. Here we see the table *c c*; the upper counter *m*; the wheel-plate *l*, the other having been removed to show that the endless cord does not cross; the two large wheels *z z*, present in each machine; the crank bar *x*, seen separately in fig. 1073, which serves for turning the wheel *z*.

1072

This bar is formed of 3 iron plates *a*, *a* 1, *p*, *q* and *q*, *r* (fig. 1073). The first is bent round at the point *a* to embrace the stud *s*; the second *p q* is of the same breadth and thickness as the first; and the third, *r*, is adjusted to the latter with a hinge joint, at the point *q*, where they are both turned into a circular form, to embrace the crank *x*. When all three pieces are assembled, they are fixed at the proper lengths by the bolts or square rods *t t*, which embrace these pieces, as is shown in fig. 1072.

The stud *s*, seen in fig. 1073, is fixed to the point *r*, by a wedge-key upon the arm *p*, represented separately, and in perspective, in fig. 1074. The latter serving

1073

1074

the two upright pegs or handles *s s* 1 by the alternate forward and backward motion of his arm, he communicates the same motion to the crank rod, which transmits it to the crank of the arbor *x*, and impresses on that arbor, and the wheel which it bears, a rotary movement.

Fig. 1075 shows piece-meal and in perspective a part of the lapidary's wheel-mill. There we see the table *c c*, the grind plate *l*, whose axis is kept in a vertical position by the two square plugs *a a*, fixed into the two counters by the wedges *b b*. On the two sides of the wheel-plate, we perceive an important instrument called a *chal*, which

device to hold the stone during the cutting and polishing. That instrument has received lately important modifications, to be hereafter seen. The lapidary holds this instrument in his hand, so that it may strike the piece *a*, fixed on the table, and he should be assisted by the velocity of the revolving wheel-plate. He works it sometimes with water, &c., to make it take better hold of the grinding plane.

The 1776 shows an improvement made by one of the most expert lapidaries of Geneva, whereby he cuts and polishes the facet with a circular velocity, converting

it into a true oval. Each of the two jaws has a large rounded cavity, from which is drawn a brass ball, which carries on its lower part a table *e*, to whose extremity is fixed a diamond *f*, improved with several fine-pointed corners, divided into equal parts, like the pointed-wheel cutting engine-plate, according to the number of facets to be placed in each circular facet. The table moves with moderate friction on the handle of the mounted tool, which is fixed at the proper point by a thumb screw, and shown in the figure, being controlled by the vertical link *d*, that is to be described.

A guide or link *g*, fixed with a square fit on the end of the cement rod, marks by its point the divisions on the dial plate *f*. On the side *b*, of the jaw *a*, there is fixed by two screws, a knob *d*, forming a quadrant whose centre is supposed to be at the centre of the tool. This quadrant is divided on each side into divisions, whose highest point is marked *h*, and the lowest would reach about 70° for the remainder of the arc down to 90° is measured by the jaw. For two gradually plane are used as follows:—

When the cement rod towards *a* or *b* of the knob *d* is then vertical, and before to cut the table of the facet, or the point supports it on, and presses it to the table. On making it slope a little, 5 degrees for example, all the faces will now be on the same plane provided that the inclination be not allowed to vary. On turning round the cement rod the index *g* marks the divisions so that by opening up the circle with 16 divisions, enough for some time at each 16 faces will have been beyond of perfect equality, and at equal distances, as seen in the reflection on a glass.

In cutting the stone, they are mounted on the cement rod *a*, fig. 1077, whose end is set upright in a socket placed at a middle of a sole piece at *x*, which receives the stem of the cement-rod. The head of the tool is fixed into the top of *a*. A solid clay of tin and lead is poured into the head of the cement-rod, at the point *l* of which the stone is immediately placed; and whenever the solder has become solid, a pressure *d* is pushed off from the top of the diamond *f*, to give the perpendicular stroke in the figure at *u*.

There is an instrument employed by the watch-makers for pieces of clock work, and by the man-factory of watch-glasses for polishing their edges. It consists of a solid taken table fig. 1078. The top is perforated with two holes, one for passing through the pulley and the arbor of the wheel plate *a* made either of lead or of hard wood, according to circumstances; and the other *c* for receiving the upper part of the arbor of the large pulley *t*. The upper pulley of the wheel plate is supported by an iron prop *r*, fixed to the table by two wooden screws. The inferior pivots of the two pieces are supported by screw-sinks, working in an iron screw nut sunk into the counter for *r*. The legs of the table are made longer or shorter, according as the workman chooses to stand or sit at his employment. Emery with oil is used for friending down, and tin putty or whetstone for polishing. The workman lays the piece on the flat of the wheel plate with one hand and presses it down with a lamp of cork, while he turns round the handle with the other hand. See the different cases under their respective heads.

LAPIS LAZULI. A silicate of soda, lime, and alumina, with the sulphide of iron and sodium in minute quantities. This beautiful mineral is found in crystalline limestone of a greyish colour, on the banks of the Indus, and is granite in Persia, China, and Siberia.

The finest varieties are highly esteemed, being employed in the manufacture of costly vases. It was also the source from which the beautiful pigment ultramarine was obtained, but this colour is now prepared artificially at a very cheap rate. See ULTRAMARINE.

LAPIS. Metal polishing wheels. Metal wheels or laps made of nearly every metal and alloy in common use, have been more or less employed in the mechanical arts as vehicles for the application of several of the polishing powders. But of all types, notwithstanding their variety, those of lead, slightly alloyed, and supported with powdered emery, render the most conspicuous service. Generally the plane, or flat surface

of the lap, is employed; at other times the cylindrical edge, as by cutlers; but the portion actually used in either case is called the *face* of the lap. There are several kinds of laps. The lap is in some cases a thin disc of metal, fixed by means of a screwed nut against a shoulder on the spindle, but it is better with lead laps to employ an iron plate cast full of holes, to support the softer metal. The casting would vary in this case be either an iron disc, with a central screw to fix the iron centre plate at the time of pouring, or the mould may be made of sand and in halves, after the usual manner of the foundry. In either case the iron plate should be made as hot as the fluid metal, which, by entering the holes, becomes firmly united to the iron, especially if the holes are largest on the reverse side, or that away from the lead.—*Illustr. &c.*

Lap is also a roll of paper or cotton for feeding the cards of a spinning machine.

LARD. The fat of the pig. Our imports from the United States have been in 1857.—

	Cwt.	Computed real value.
In British vessels	80,507	
In Foreign vessels	129,158	
	169,795	£561,944

LARD OIL. Lard being subjected to pressure, an oil, *oleine*, is expressed, *stearine* being left. The lard oil is much used for lubricating machinery, and it was employed for the adulteration of olive oil.

LAPIDS. All Indian cut stones are called *lapids*. They are in general all shaped or irregular in their form, their depth ill proportioned. The table, or face, which is in the centre of the stone, sometimes too broad or too small, and none properly polished. The chief thing regarded is making the size and weight of the stone. These stones are always new wrought when brought to Europe.

LATH WOOD. The outside cuttings of fir trees, used for being split into laths.

LATTEN is a somewhat antiquated term, which was applied to several kinds of sheet metal. "Mines of *latten*, whatever may have been meant by the word are mentioned in the time of Henry VI., who made his chaplain, John Botteright, comptroller of all his mines of gold, silver, copper, *latten*, lead, within the counties of Devon and Cornwall." Is tin meant by the term?—*Watson's Chemical Essays*.

In the reigns of Henry VIII. and Edward VI., several acts of parliament were passed, prohibiting the exportation of brass, copper, *latten*, bell metal, gun metal, schrof metal, &c. Windows framed with lead are called *lattice* windows in the West of England.

The term is now applied to sheet or plate brass. *Black latten* is rolled sheets; *alloy latten* is in thinner sheets, and *roll latten* is polished on both sides.

LAUNDER. A miner's term for a wooden tube or gutter to convey water. A long shallow trough carrying off the ore from the stamps.

LAVA. The ejected matter of volcanoes. "The stone which flows in a melted state from a volcano." (*Lyeil*.) M. Alach obtained from the lava of 1669, 48.83 silica. He made the lava to consist of 54.80 labradorite, 34.16 augite, 7.98 olivine, and 3.08 magnetic iron.

Buschhoff gives the following two analyses of lava:—

	Horta.	Kina.
Silica	54.76	49.63
Alumina	15.61	23.47
Peroxide of iron	15.60	10.50
Lime	6.14	9.05
Magnesia	1.35	2.68
Potash	3.41	3.07
Soda	1.21	0.98

LAVA WARE. A peculiar stoneware, manufactured and coloured to assume the semi-vitreous appearance of lava.

LAVER. *Nerphyra larinibus* and *Ilva latissima*. (See **ALGÆ**.)

LAVENDER, oil of. See **PURIFICATION**.

From the flowers of the *Lavandula spicata* the oil of spike is obtained, which is used by painters on porcelain, and by artists in the preparation of some varnishes.

LAWN. A fine linen fabric.

LAZULITE (Eng. and Fr.; *Lazulith*, Germ.), from an Arabic word, *azul*, meaning *azure*. It is a blue vitreous mineral, found massive and crystalline, traversing clay slate, and sometimes united with spathic iron; spec. grav. 2.76 to 2.94; scratches glass; affords a little water by calcination; fusible into a white glass; dissolves in

acids with loss of volatile, the residue leaves an all-siliceous residuum, after being treated with carbonates of ammonia, filtered, evaporated and calcined. By analysis it is found to consist of:—

	1.	2.
Phosphoric acid	43.44 . . .	46.78
Alumina	31.77 . . .	37.11
Iron oxide of iron	9.00 . . .	7.10
Magnesia	9.00 . . .	11.07
Water	1.00 . . .	7.12

LEAD. (*Plumb.* Fr.; *Blitz.* Germ.) This metal appears to have been known at a very early period. It is mentioned by Moses as a metal in common use. Job describes mining for lead, and the metal is in evidence of religious and engineering uses from lead are very fully described by both Job and Jeremiah. Lead has a bluish-grey colour, and, when freshly cut, it is of a considerable lustre, which, however, it speedily loses. It is one of the softest of the primary metals, it may cut with a knife, may be scratched with the nail, and marks paper with a grey stain. Lead is malleable, and may be beaten into thin leaves, but there are of very important property; hence, it cannot be drawn into thin wire; a wire of $\frac{1}{8}$ of an inch in diameter will not support 20 lbs.

If lead be prepared in a very finely divided state, it is pyrophoric. This is usually prepared from the tartrate of lead, by heating it in a glass tube as long as any fumes are evolved, consequently it is finely divided lead covered with some carbon. As soon as the fumes cease the tube must be closed at the blow-pipe-lance. If at any time the tube is broken, and the powder scattered in the air, it burns with a red flame.

If lead is heated in closed vessels it fuses at 600° F. (315° Cent.), and at a red heat it gives off vapours. If fused lead is allowed to cool slowly, it crystallizes in a somewhat peculiar manner, the crystals are regular in the crystalline system, but they group themselves in a very singular and interesting way. By the electro-chemical action of zinc on a solution of the acetate of lead, crystals of that metal are obtained in an arborescent form. This experiment is usually spoken of as the formation of Saturn's tree, Saturn being the astrologic name for this metal.

When fused in the air, lead oxidizes rapidly, and it becomes covered with an iridescent pellicle, often of great beauty. It then passes into a yellow powder (1. barge), composed of lead.

Pure lead is not affected by perfectly pure water for ever, but if air be present the metal is oxidized at its exposure, and the oxide thus formed, combining with carbonic acid, is deposited on the lead in minute crystals of a lead carbonate of lead. The water will then be found to contain lead in solution, and such waters drawn from impure cisterns often produce very distressing consequences. If the water contains any sulphates, the lead is thrown down as a sulphate of lead, which is insoluble.

The native formations are the following. The localities, &c., are mainly derived from Greg and Lettison's *Manual of the Mineralogy of Great Britain and Ireland*.

1. *Native lead.* Mr Greg appears to doubt the existence of native lead in this country. He says, however, "Native lead has been recently discovered in unaltered granitic specimens in the province of Guanajuato in Mexico." Some equally genuine specimens of native lead have been found in the Grassington mines; these are in the possession of the Duke of Devonshire and of Stephen Hudd, Esq.

2. *Minium.* *Native oxide of lead.* This ore is found in Angleson, at Alton Moor, the Scaillbeach Mine in Shropshire, at Grassington, the Leadhills in Scotland, and Wicklow in Ireland. Its composition is—lead, 90.6; oxygen, 9.4.

3. *Cerussite.* *Carbonate of lead.* This ore occurs in crystals, in fibrous, compact, and earthy masses. It is found at several of the lead mines of Cornwall and Devonshire, and indeed in nearly all the mines producing the ores of lead, varying much in its character with the different conditions under which it has been formed.

This ore, in its purest state, is colourless and transparent like glass, with an adamantine lustre. It may be recognized by the following characters:

Its specific gravity is from 6 to 6.7; it dissolves with more or less ease, and with effervescence, in nitric acid; becomes immediately black by the action of sulphuric acid and hydrogen, and melts on charcoal before the blow-pipe into a button of lead. According to Klaproth, the carbonate of Leadhills contains 82 parts of oxide of lead, and 16 of carbonic acid, in 98 parts. This mineral is tender, scarcely scratches calc-spar, and breaks easily with a waved conchoidal fracture. It possesses the double refraction property in a very high degree—the double image being very visible on looking through the flat faces of the prismatic crystals. Its crystalline forms are very numerous, and are referrible to the rhombohedron.

4. *Anglesite.* *Sulphate of lead, or Vitreous lead.*—This mineral closely resembles cer-

bamate of lead; so that the external characters are independent of the nature of the two, but the following are common. When pure it has the same lustre as pure silver and lead. It does not effervesce with nitric acid, it is but feebly dissolved by concentrated hydrochloric acid; it first decrepitates and then melts before the blowpipe into a transparent glass, which becomes milky as it cools. Its decomposition is that of lead and chloroform, it passes first into a red sublimate, and then into metallic lead. It melts, according to Klaproth, at 71 scale of lead, 98 of sulphuric acid, 3 of water, and 1 of iron. The specimen was from Anglesey, the Wanlockhead mineral is from France. The prevailing form of crystallization is the rectangular octahedron, whose angles and edges are variously modified. This mineral was first recognised in Anglesey, hence its name. It was found in the Cornhill Islands at Sark mine, and is occasionally met with in the Leadhills and Wanlockhead in Scotland, at Glamorgan in Wales, and at Barys in France. (C. D. B.)

Leadhillite. *Sulphate of lead.*—This ore is of a yellowish white colour, becoming grey, sometimes yellowish-green, yellow and brown. Its crystalline disposition is—

Sulphate of lead	-	-	-	-	-	-	287
Carbonate of lead	-	-	-	-	-	-	710
							997

5. Pyromorphite. *Phosphate of lead.*—This, like all the combinations of lead with arsenic, exhibits an metallic lustre, but a variety of colours. Before the blowpipe, upon charcoal, it melts into a glass, externally crystalline, which is a continuation of the heat, with the addition of iron and boracic acid, affords a white lead. Its constituents are 80 scale of lead, 18 phosphoric acid, and 16 hydrochloric acid, according to Klaproth's analysis of the mineral from Wanlockhead. The constant presence of chlorine in the various specimens examined is a very remarkable circumstance. The crystalline forms are derived from an obtuse rhomboid. Phosphate of lead is a little harder than white lead; it is easily scratched, and its powder is always grey. Its specific gravity is 6.9. It has a vitreous lustre, somewhat adamantine. Its fracture is not very distinct, its fracture is wavy, and it is easily frangible. The phosphoric and arsenic acids being, according to M. Mitscherlich, isomorphous bodies, may replace each other in chemical combinations in every proportion, so that the phosphate of lead may include any proportion, from the smallest fraction, of arsenic acid, to the smallest fraction of phosphoric acid, thus graduating insensibly into arsenate of lead. The yellowish variety indicates, for the most part, the presence of arsenic acid. It is found in Cornwall, Devonshire, Yorkshire, and Derbyshire.

6. Mimetite. *Arsenate of lead.*—The name is derived from *mimetes*, because the species so nearly resembles pyromorphite. The colour of this ore varies from straw yellow and was yellow to brown, reddish-brown, orange, yellow, and red. Before the blowpipe, on charcoal, it emits arsenical fumes and yields a bead of lead. The analysis by Dufrenoy gives the following as its composition—

Arsenate of lead	-	-	-	-	-	-	84.55
Phosphate of lead	-	-	-	-	-	-	4.50
Chloride of lead	-	-	-	-	-	-	9.95

At Drygill, in Cumberland, this ore has been met with in sufficient abundance to be worked to some extent as an ore of lead. The mimetite from this mine was used in the manufacture of flint glass, in which it gave great brilliancy. The form of the arsenate of lead, when it is crystallised, is a prism with six faces, of nearly the same dimensions as that of phosphate of lead. When pure, it is reducible upon charcoal, before the blowpipe, into metallic lead, with the copious exhalation of arsenical fumes; but only in part, and leaving a crystalline globule, when it contains any phosphoric acid. The arsenate of lead is tender, friable, sometimes even pulverulent, and of specific gravity 5.04. That of Johann-Georgenstadt consists, according to Rose, of oxide of lead, 77.5; arsenic acid, 1.5; phosphoric acid, 7.5; and chlorine, 1.5.

7. Galena. *Sulphide of lead.*—This is the most abundant ore of lead; it may be indeed regarded as the only commercial ore of any value, if we except the carbonates, which are probably formed by the decomposition of galena. Its prevailing forms are the cube and a combination of the cube and octahedron; lustre metallic, opaque, colour and streak lead grey. Fracture conchoidal, but difficult to obtain, owing to the readiness with which it cleaves. The localities of galena need not be named here, as the lead producing districts, of which a list will be presently given, will include them, and galena is included in them all. Thomson's analysis of galena gives—

Lead	-	-	-	-	-	-	65.13
Iron	-	-	-	-	-	-	0.50
Sulphur	-	-	-	-	-	-	13.02

P. J. Smith is a combination of lead and antimony. It occurs in acicular crystals, as in parallel or diverging groups, and very frequently in fibrous masses. It is found in many places in Cornwall and Devon. Hume's analysis gives the following as its composition:—

Lead	-	-	-	-	-	-	-	-	-	87.71
Iron	-	-	-	-	-	-	-	-	-	2.45
Copper	-	-	-	-	-	-	-	-	-	0.21
Zinc	-	-	-	-	-	-	-	-	-	0.74
Antimony	-	-	-	-	-	-	-	-	-	10.88
Sulphur	-	-	-	-	-	-	-	-	-	20.89

100.00

This mineral may be regarded as a double sulphide of lead and antimony, analogous to the double sulphide of copper and iron.

3. *Crocoisite. Chromate of lead. Horn lead, or chloro-chromate.*—This ore has a pale yellow colour, is reducible to metallic lead by the action of acids, and is not altered by the hydro-sulphuric. Before the blow-pipe it melts into a pale yellow translucent glass, with salt of phosphorus and oxide of copper, and assumes the prismatic character. It is fragile, and, after than (or much) of lead, and is sometimes a more beautiful white adamantine lustre. Spec. grav. 6.06. Its composition, according to Berthier, are, lead, 87.4; oxide of lead, 7.07; arsenic acid, 4.45; chlorine, 0.4; silica, 1.4; water, 0.54, in 100 parts.

10. *Plumbite. Superoxide of lead.*
11. *Limonite. Cuprous sulphate of lead.*
12. *Sulphate. Sulphate of lead.*
13. *Limonite. Sulphate of lead.*
14. *Chloride. Cuprous sulphate of lead.*
15. *Limonite. Vanadate of lead.*
16. *Wulfenite. Tungstate of lead.*
17. *Stilbite. Molybdate of lead.*
18. *Geocrinite. Sulphide of lead and antimony.*
19. *Manganite. Oxide of lead.*
20. *Manganite. Oxide.*

21. *Red lead, or Chromate of lead.*—This mineral is too rare to require consideration in the present work.

22. *Plomb Vauquelinite. Chromate of lead and copper.*

The ores of lead, which may be represented by galena, or the sulphide of lead, that being the truly commercial variety, are found in rocks of different ages from the granite and clay slates to the triassic formations. In the Devonian slate rocks, in the neighbourhood of Liskeard in Cornwall are many most productive lead mines. To the north of Truro is the lead mine Huel Rose, which has from its long celebrity given its name to the district; and again to the south of Helston there have been some valuable workings for lead. These formations of lead ore have all been in the clay slate, "killas" rocks of Cornwall. In Devonshire many most valuable lead mines have been worked in similar rocks. In these the celebrated mines of Beer Alston on the Tamar exist. With a very few exceptions but little lead has been discovered in the black slates,—the carboniferous series of Devonshire. Some lead ore has, however, been discovered in the new red sandstone and in the slate rocks immediately adjoining them near Newton St. Cyren. To the north of the carboniferous rocks of Devonshire we have a renewal of clay slate rocks, similar in all respects to those which are found near Liskeard in Cornwall; in these rocks are the most famous argenteiferous lead mines of Combe Martin, from which Edward the Black Prince derived an immense revenue.

The lead mines of the Mendip Hills which were at one time very productive, but which are now producing but small quantities of lead ore, are in the mountain limestone formations. Those of Cardiganshire are found in clay slates and gritstones, corresponding with or underlying the lowest beds described by Sir R. Murchison in his Silurian System. — *Sayk.*

In Shropshire we have lead ore occurring in the original Silurian rocks, the Llanfyllid formation. "In that lofty and rugged district of Shropshire which lies around the village of Shelve and the Cornhill mountains, and which extends west of the Sugar Stones range into Montgomeryshire" (Murchison), lead lodes are abundant. In Derbyshire, in Yorkshire, in Cumberland, Northumberland, and Durham, the lead mines prove the most productive in the mountain limestone formations, although they are some instances in which good lead mines have been worked in the sandstones and shales. In addition to these, we have the mines in the Leadhills and at Wanlock-

head, consisting chiefly of the graywacke slates, in Scotland. In glaucifer, &c. in the granite districts of Wicklow, Newlands in County Down, with a few others in Ireland, and the lead mines in the Slieve Donard of the Isle of Man. These are the principal districts from which our large supplies of lead ore are obtained.

The extensive lead mines of Mr. Menzies, which have for many years produced about one-fourth of the quantity raised in England, about one-sixth of the produce of Great Britain, and about one-tenth of that of the whole of Europe, including the British Isles, are so important, and in many respects so characteristic, that much of the description of them which appeared in the former edition is retained, as representing many of the principal and important features of lead mining. An extensive series of the great lead mining district is in the Mining Record Office of the Museum of Practical Geology. This section was executed by Mr. Sopwith, and together with a series of models explains nearly all the phenomena of mineral veins.

The datum or base line of the Allenheads section is 700 feet above the level of the sea. The drawing, 16½ feet in length, is on a true scale of 11½ feet to an inch; by a true scale being meant, that the lengths and breadths are projected to the scale or proportion, so that a true miniature profile of the country is given, as well as a correct reduction of the relative size of the various rocks. The extent of country thus shown is not quite 4 miles, being 3 miles 1,22½ yards.

The spectator is supposed to be looking to the north, and the section commences at a point about half a mile seaward from a place called Kilhope Head, which is conspicuously marked in all English maps, as much as the three counties of Northumberland, Durham, and Cumberland here meet in one spot. At about three quarters of a mile from this point of commencement, the section represents the hill called Kilhope Law; it is on the boundary line of the counties of Northumberland and Durham, and is the highest point of land in the last-named county, being 2206 feet above the level of the sea. Just out of the limits of this section, and about 10 miles south-west from Kilhope Law, the same strata which are here delineated reach an altitude of 2901 feet above the sea, and this is the highest elevation attained by the rocks which form the carboniferous or mountain limestone of the north of England.

Such being the stratification of the central portion of the narrow part of the island, of which the coal fields of the Tyne and Wear form the extremity on the east bordering the German Ocean, for some distance north and south of Newcastle, while a similar coal field is found at the western extremity near Whitehaven, it may be observed with reference to these coal fields, that they lie over or upon the mountain limestone formation. The coal beds so extensively worked in the Newcastle and Durham coal mines or collieries gradually rise to the west, and one by one crop out or burst according to the undulations of the country. At length at about 20 miles west of the German Sea, the lowest of the coal beds crops out, and from beneath it gradually appear the limestone strata, which continue to rise nearly coincident with the general rise of the country, until they reach the summit of Cross Fell (2901 feet). This general and very gradual inclination of the strata, a feature of the greatest importance in practical mining, is clearly and accurately delineated in this section.

In a thickness of about 2000 feet of the alternating beds of sandstone, clay, and limestone which form the strata of the mining districts of Allendale, Alston, and Weardale, there is one single stratum of limestone, called the "great limestone," the veins in which have produced nearly, if not quite, as much ore as all the other strata put together. This stratum, delineated in the section, lies at a depth of about 650 feet below the summit of Kilhope Law. Somewhat exceeding 2 miles eastward of this, at Allenheads, the top of the great limestone is 230 feet from the top of a shaft called Gun-Hill Shaft. Its thickness, which is tolerably uniform over several hundred square miles of country, is about 60 feet; and it is in this stratum of limestone that the largest quantity of lead has been found.

The dislocations of strata which constitute for the most part important mineral veins, are exhibited more in detail in the series of geological models already referred to.

At about a quarter of a mile to the west of, or left hand direction from Kilhope Law, the great limestone, and all other associated beds are thrown down a depth of about 100 feet for a space of nearly 700 feet; and again, at the distance of nearly a mile from Allenheads, a vast dislocation takes place, by which the great limestone is brought nearly to the surface, the amount of displacement being about 400 feet. It is in the great limestone that by far the most extensive portion of the workings of Allenheads lead mines are situated, and the galleries or levels are very extensive. In a great thickness of strata above the great limestone, only two beds of that rock are found. One of these is called "little limestone." It is from 10 to 12 feet thick, and is 75 feet above the top of the great limestone. The other is still more inconsiderable, being only 3 or 4 feet thick, and is 440 feet above the great

however. It is remarkable, with what exactness this thin bed is found near the surface of hills, the intervening spaces having apparently been removed by denudation, so as to form in this case a gap of 41 miles, and in another of 11 miles, in which the Tint Tpl. limestone is entirely cut off.

But besides the great mine, are several beds of the same description of rock, viz. at distances respectively of 30, 100, 150, 250, and 27 feet, and the thicknesses 2 ft. 1 in., 1 ft., and 15 in. These are known by descriptive local names, and some price all that are of a richness as regards lead mining operations.

The Alameda mine being situated for the most part at the base of the position varying from 100 to 200 feet are drilled, partly by ordinary water-wheels, and partly by hydraulic engines constructed by Mr. New Sir W. G. Armstrong. See WATER-PRESSURE AND LIFTING.

Such is a general view of the lead mining district of England. The following brief account of foreign lead mines is intended merely for last reference. Much additional information will be found in the article MINES.

The principal lead mines at present worked in other parts of the world are the following:—1. Poullouen and Huelgoat, near Carhaix in France, department Finistère, being veins of galena, which traverse a clay shale resting in granite. They have long been known for upwards of three centuries; the workings penetrate to a depth of upwards of 100 yards, and in 1816, furnished 500 tons of lead per annum, out of which 100 tons of silver were extracted. 2. At Valdivia and Valdivia, department of La Oroya, are galena mines said to produce 100 tons of lead per annum, 400 kilograms of silver (880 lbs. avoirdupois). 3. At Potosí and Moravia, the best of Moravia in Saxony, a galena mine extends to a depth which has produced annually 200 tons of lead, and about 600 kilograms of silver (1320 lbs. avoirdupois). 4. The mine of Vedrina near Salsburg in the Lower Saxony, is worked upon a vein of galena, traversing compact limestone of a transition district; it has furnished 700 tons of lead, from which 100 pounds avoirdupois of silver were extracted. 5. In Saxony the galena mines are of such a silver as to make the lead almost neglected. They are considered under silver veins. 6. The lead mines of the Harz have been likewise considered as silver ones. 7. Those of Huelgoat in the Harz, are of the same production. 8. The galena mines of Huelgoat and Valdivia in Carinthia, are compact limestone. 9. In Bohemia in the south-west of Prague. 10. Mines of Joachimsthal and Freiberg in the southern slope of the Erzgebirge, produce a galena of fine quality. 11. There are numerous lead mines in Spain, the most important being in the granite hills of Linares, upon the eastern slope of the Sierra Morena, and in the district of the small town of Cañete. In these countries galena mines of galena are extracted from the mines of Linares. There are also mines of galena in Castile, Granada, Murcia, and Almería, the ore of the last locality being generally poor in silver. 12. The lead mines of Sweden are very argentiferous, and worked chiefly with a view to the silver. 13. The lead mines of Prussia are numerous and rich, lying in a transition limestone, which rests on primitive rocks; their lead is neglected on account of the silver.

There have been a few lead mines in this country, which have been equally productive of silver. This was especially the case with the lead mines which were formerly worked around Combe Martin, and those at Heer-Alston in Devonshire. One of the most remarkable of recent examples, is a small mine known as Hill Florence near Tavistock, from which some lead ore has been sold at upwards of 50s. a ton, on account of the large quantity of silver it contained. At the conclusion of this article some tables will be given, showing the argentiferous character of the different lead producing districts of the United Kingdom.

Before proceeding to the consideration of the metallurgy of lead, a few brief notices of the history of lead mining may not be out of place.

As we have already stated, mining for lead must have been one of the earliest of man's subterranean labours, and at all periods of history we learn that lead mines have been worked. The Romans, especially, worked lead mines in Spain, and, after the conquest of this country, in many of our lead producing districts, especially in Cardiganshire, Shropshire, and Flintshire.

Lead mining appears to have been carried on from a very early period in Alston Moor, and some other of the northern districts. But in the west of England, lead mining must be regarded as a somewhat recent industry.

"Horlase mentions, in 1754, that lead mines had plentifully and lately been worked in Cornwall, and that those most noted formerly, were Penryn, Porthcove, Trevenno, Huelgoat, and Guarnick (Garras). He states, that Penryn mine (near Huelgoat) had been wrought for about 200 years, that is, from about the middle of the sixteenth century, and that they had yielded tolerable profit within thirty years. The only lead mine worthy of note at work in his time, was at St. Isey, near Padstow. Pryce,

describes the lead ore of Garra, near Truro, to have been so argentiferous, that when wrought about 1720, it produced 100 oz. of silver in the ton of lead. Huel Pool, near Illogan, about 1790, yielded from 40 to 80 oz. of silver per ton of lead, and works were erected for extracting the silver. The lead ore of Wheal Rose contained 60 oz. of silver per ton.

In Devonshire, the Combe Martin and Beer Alston mines, have long been celebrated for their argentiferous lead ores. It is stated, that the produce of these mines was unusually great in the reigns of Edward I. and Edward II. In 1293, William de Wyntonham accounted at the Treasury for 270 lbs. of silver raised in Devon. In 1294, it amounted to 521*l.* 10*s.* weight; and in 1294, to 704*l.* 3*s.* 1*d.* weight. In 1294, great profit is stated to have been derived from the Devon mines; and 360 miners were imported out of Derbyshire and Wales to work in them. In 1340, a writ was issued, authorising certain persons to take up as many miners and workmen as should be necessary to work in the king's mines in Devon, allowing them reasonable wages according to the custom of the country; to arrest and imprison such as should resist, till they should give security to serve the king in the said mines, and to buy and provide timber at a competent price.

Henry, bishop of Winchester and cardinal of England, as one of the executors of John, duke of Bedford, who had a grant from the King of the gold and silver mines of Devon and Cornwall, rendered 26 lbs. and 2 oz. weight of pure silver as the 15th part of the pure silver raised in those counties from 15th December, 21st, to 15th August, 23rd of the same king's reign.

The Combe Martin mines were re-opened in the reign of Elizabeth. The working of these mines was strongly recommended to the Long Parliament in 1632; but Lysons observes that they do not appear to have been again worked until the close of that century, and then without success. In 1813 they were again opened and worked for 4 years, producing only 208 tons of ore in that time. In 1837 they were again worked, and we had an opportunity of observing that the previous mining operations presented every appearance of having formerly been very unskillfully managed. The two lodes near Beer-Alston have produced large quantities of argentiferous galena, often containing from 80 to 120 oz. of silver per ton of lead. According to Mr. Hitchings, the greatest quantity which occurred in that part of them named the South Hooe mine was 140 oz. of silver per ton of lead. In 1784 and 1785 the silver produce of these mines amounted to 6500 oz. From Huel Betsy, near Tavistock, which was re-opened in 1804, from 300 to 400 tons of lead, and from 4000 to 5000 oz. of silver were annually obtained. Lead mines were worked at a very early period in the Isle of Man, but the recent workings only date from the commencement of the present century. The mines of Cheshire were evidently worked by the Romans. In the reigns of Henry VII. and of Elizabeth they attracted much attention, and German miners were invited to work them.

The English lead-miners distinguish three different kinds of deposits of lead ore; *rake-veins*, *pipe-veins*, and *flat-veins*. The English word *vein* corresponds to the French term *filon*; but miners make use of it indifferently in England and France, to indicate all the deposits of this ore, adding an epithet to distinguish the different forms; thus, *rake-veins* are true veins in the geological acceptance of the word *vein*; *pipe-veins* are masses usually very narrow, and of oblong shape, most frequently parallel to the plane of the rocky strata; and *flat-veins* are small beds of ores interposed in the middle of these strata.

In the north of England, which, on account of its great preponderance in produce, we take as the basis of our description of lead mining, the ores are for the most part found in *veins* (*lodes* in Cornish) and *flats*. Although different names have been assigned to occasional varieties, the usual occurrence of lead ore is in *rake veins*, or direct running veins, usually named as *veins*, with some distinctive appellation prefixed, as, for example, Rampgill Vein, Hudgillburn Vein. Other veins, lying parallel, receive a similar prefix, with the addition of the words north, east, or south; but for the last named the word *sun* is often used; as, for instance, Hudgillburn Sun Vein, and 2nd and 3rd Sun Vein if farther discoveries are made of other parallel veins. Considerable quantities of ore are also raised from horizontal extensions of portions of the vein called *flats*, and these are interposed between the strata adjacent to the vein.

Rake veins are the most common form in which lead ore occurs in Cumberland. They are in general narrower in the sandstone which covers the limestone, than in the calcareous beds. A thickness of less than 2 feet in the former becomes suddenly 3 or 4 feet in the latter; in the rich vein of Hudgillburn, the thickness is 17 feet in the Great limestone, while it does not exceed 3 feet in the overlying Waterfall or sandstone. This influence exercised on the veins by the nature of the enclosing rock, is instructive; it determines at the same time almost uniformly their richness in lead ore, an observation similar to what has been made in other countries, especially in the veins

Galena is, however, not always found chemically pure, as, in addition to variable quantities of earthy impurities, it almost always contains a certain amount of silver. It is usually observed that galena presenting large facettes is less argentiferous than those varieties having a closer grain, and that finely granular stony specimens generally afford the largest amount of silver.

It would appear, from recent experiments, that the silver contained in the finely-granular varieties of galena often occurs in the form of sulphide of silver, mechanically intermixed, whilst in the more stony descriptions of this ore, the sulphides of lead and silver are intimately combined.

Galena occurs in beds and veins, in granite, gneiss, clay-slate, limestone, and sandstone rocks.

In Spain it is found in the granite hills of Lanarès and elsewhere; at Freiberg in Saxony it occurs in veins in gneiss, in the Harz, Bohemia, Cornwall, and many other localities, it is found in kiesel, or clay slate. The rich deposits of Derbyshire, Cumberland, and the northern districts of England, are in the mountain limestone, whilst at Cammern, near Aix-la-Chapelle, large quantities of this ore are found disseminated in the Hunter sandstone.

This mineral is frequently associated with blende, iron and copper pyrites, the carbonate and other ores of lead, and usually occurs in a gangue of sulphate of baryta, calc-spar, spathose iron, or quartz. It is also not unfrequently associated with fluor-spar.

The next most important ore of lead is the carbonate, which is a brittle mineral, of a white or greyish-white colour, having a specific gravity varying from 6.46 to 6.60. Its composition is, —

Carbonic acid	16.05
Oxide of lead	89.56
							99.61

Large quantities of this substance occur in the mines of the Mississippi Valley in the United States of America, where they were formerly thrown away as useless, but have since been collected and smelted. Vast deposits of this substance have also been found in the Bunter sandstone, near Duren, in Prussia, and at Freyung, in Bavaria. In the two latter localities it appears to form the cement holding together the granules of quartz, of which the sandstone principally consists. These ores, which yield from 14 to 20 per cent. of metal, do not readily admit of being concentrated by washing.

The sulphate of lead does not often occur in sufficient quantities to be employed as an ore of that metal. In appearance it is not unlike the carbonate, but may readily be distinguished from it by its not dissolving with effervescence in nitric acid.

Its specific gravity is from 6.35 to 6.50, and its composition —

Sulphuric acid	25.45
Oxide of lead	74.05
							99.70

This ore of lead usually results from the oxidation of galena. At St. Martin's, near the Vega de Ribadeno, in Spain, this mineral, more or less mixed with the phosphate of lead, is found in sufficient quantities to be made, on a small scale, the subject of an especial metallurgic treatment. Large quantities of sulphate of lead ores are also annually imported into this country from the mines in Australia. These ores contain on an average 35 per cent. of lead, and 35 oz. of silver to the ton of ore, together with a little gold.

Phosphate of lead, when crystallised, usually presents the appearance of hexagonal prisms, of a bright-green, brown, or yellowish colour. Its specific gravity varies from 6.3 to 7.1. This mineral is composed of a mixture of true phosphate of lead, phosphate of lime, chloride of lead, and fluoride of calcium, and usually contains about 75 per cent. of oxide of lead. In Spain, it occurs in botryoidal forms, in connection with the sulphate of the same metal, and is treated in blast furnaces for the lead it affords.

The other minerals containing lead seldom occur in sufficient quantities to be of much importance to the smelter, and may therefore be disregarded in the present article.

The extraction and mechanical preparation of ores is the business of the miner, and not of the metallurgist who receives them from the former freed as perfectly as possible from foreign matters.

The metallurgic processes, by the aid of which lead is obtained from galena, may be divided into two classes. The first of these is founded on the following reactions: — If one equivalent of sulphide of lead and two equivalents of the oxide of the same

metals are fused together, the result is three equivalents of metallic lead and one equivalent of sulphurous acid, which is evolved.

This reaction is represented by the following equation:—

When, on the other hand, one equivalent of sulphide of lead and one equivalent of sulphate of lead are mutually treated, two equivalents of lead are obtained, and two equivalents of sulphurous acid are evolved. Thus:—

The process, founded on the foregoing reaction, and which we will distinguish as the method by double decomposition, consists in roasting the galena in a reverberatory furnace until a certain amount of oxide and sulphate has been formed, and then immediately, after having thoroughly stirred the charge, and closed the doors of the furnace, causing the whole to enter into a state of fusion.

During this second stage of the operation, the reaction between the sulphide, sulphates, and oxides takes place, and metallic lead is produced. The reaction of the ore is, in some cases, conducted in the same furnace in which the fusion is effected, whilst in others two separate furnaces are employed.

The process by double decomposition is best adapted for the richer varieties of ore, and such as are least contaminated by siliceous or earthy impurities, and is consequently that which is also at present generally employed for smelting the ore of this country.

By the second method which we will call the process by fusion, the ore is fused with a mixture of metallic iron, which by combining with the sulphur liberates the metallic lead. The reaction will be represented by symbols in the following formula:—

In practice, however, metallic iron is not always employed for this purpose; cast-iron is also frequently used, and it sometimes is the ore of iron and furnace slag are employed, as are also tap-slag and other secondary products containing a considerable percentage of this metal. None of these substances are, however, found to be so efficacious as metallic iron, since cast-iron requires to be decarburised before it can really decompose the sulphide of lead, and the ores of iron require the introduction of various fluxes, and the consequent expenditure of a substantial amount of fuel. In all cases, however, it is justifiable to subject the ore to a preliminary roasting, in order to eliminate a portion of the sulphur, and thereby reduce the expenditure of iron, as well as to agglutinate the ore and render it better adapted for the subsequent treatment in the blast furnace.

We will not attempt to describe the different forms given to roasting furnaces employed for the ores treated by this process, but would remark that they frequently resemble the kilns used for the preparation of lime, whilst in some instances the ores are roasted in heaps interstratified with wood or other fuel.

The method of treating ore by affinity is particularly adapted to those varieties that contain a considerable amount of silica, since such minerals, if treated by double decomposition, would, by the formation of oxide of lead, give rise to a slag from which it would be exceedingly difficult to extract the metal.

English process. Treatment by double decomposition.—Galena, if placed in a close vessel which protects it from the action of the air, and exposed to a gradually increasing temperature, becomes fused without the elimination of any lead taking place, but ultimately a portion of the sulphur is driven off, and a sulphide is formed, which at a very elevated temperature is volatilised without change.

If, however, the vessel be uncovered, and the air allowed to act on its contents, oxygen combines with the sulphur, sulphurous acid is evolved, and the desulphuration of the mineral is slowly effected.

When galena is spread on the hearth of a reverberatory furnace, and is so placed as to present the largest possible amount of surface to oxidising influences, it will be found that the surface slowly becomes covered with a yellowish-white crust of sulphate of lead. The oxygen of the air, by combining with the two elementary bodies of which galena is composed, will evidently produce this effect. This is not, however, the really chemical change which takes place in the charge under these circumstances; oxide of lead is produced at the same time as the sulphate, or rather the formation of the oxide is prior to that of the sulphate.

In fact, during the first stage of the operation of roasting, sulphurous acid is evolved, the sulphur quits the lead, and a portion of that metal remains in a free state. This becomes oxidised by the air passing through the furnace, and subsequently a part of it combines with sulphuric acid, formed by the oxidation of sulphur.

rous acid, and sulphate of lead is the result. In this way, after the expiration of a certain period, both oxide and sulphate of lead are present in the furnace.

During the early period of the roasting, when the temperature of the furnace is not very elevated, the proportion of sulphate is larger than that of the oxide formed, but in proportion as the heat of the apparatus increases, the production of oxide becomes more considerable, whilst that of the sulphate diminishes.

The sulphate and oxide then succeed to react in their turn on the undecomposed galena, whilst a portion of the latter, by combining with the sulphide of lead, gives rise to the formation of oxide lead.

This last compound has no action on galena, except to dissolve it in certain proportions, but is readily decomposed by the aid of carbonaceous matter.

It is therefore evident that the addition of carbon, at this stage of the operation, will have the effect of reducing the oxide and oxysulphide of lead.

Every process then that has for its object the reduction of lead ores by double decomposition, comprises two principal operations. 1st. The reduction of galena, by the aid of heat and atmospheric air, to a mixture of sulphide, oxide and sulphate, which mutually decompose each other, with the elimination of metallic lead. 2nd. The reduction of the oxysulphide by the addition of carbonaceous matter.

The reverberatory furnace.—The reverberatory furnace employed for the treatment of galena is composed, like all other furnaces of this description, of three distinct parts, the fire-place, the hearth, and the chimney.

The hearth has to a certain extent the form of a funnel, of which the lowest point is on the front side of the furnace immediately below the middle door. The molten metal descending from every side along the inclined bottom or sole, is collected in this receptacle, and is ultimately run off by means of a proper tap-hole. This tap-hole is, during the operation, closed by a jet of clay.

The inclination of the hearth is more rapid in the vicinity of the fire-bridge than towards the chimney, in order that the liquid metal may not be too long exposed to the oxidizing and volatilizing influences of a current of strongly-heated air.

The dimensions given to these furnaces, as well as the weight of the charge operated on at one time, vary considerably in different localities, but in the north of England the following measurements are usually employed:—The fire-grate is 3 ft. 9 in. x 1 ft. 10 in., and the thickness of the fire-bridge 1 ft. 6 in.; the length of the sole is 9 ft., and its average width 7 ft. The depth of the tap is about 2 ft. 6 in. below the top of the inclined sole. The height of the roof at the fire-end may be 1 ft. 4 in., and at the other extremity 11 inches.

The introduction of the charge is in some cases effected by the doors of the furnace, whilst in other instances a hopper, placed over the centre of the arch, is made use of.

On the two sides of the furnace are placed three doors about 11 in. x 9 in., which are distinguished as 1, 2 and 3, counting from the fire-bridge end. The three doors on the one side are known as the front-doors, whilst those on the other side are called the back-doors. Immediately beneath the door on the front side of the furnace is situated the iron pan into which the molten lead is tapped off.

The bottom of this arrangement is in most cases composed of fire-bricks, covered by a layer of vitrified slags, of greater or less thickness. In order to form this bottom, the slags are introduced into the furnace, the doors closed, and the damper raised. An elevated temperature is thus quickly obtained, and as soon as the scorie have become sufficiently fused, they are, by means of rakes and paddles, made to assume the required form. The charge employed, as before stated, varies in almost every locality. In the North, however, smaller charges are used than most other localities. At Newcastle, and in the neighbourhood, the charge varies from 12 to 14 cwt.; in Wales, and near Bristol, 21 cwt. charges are treated; whilst in Cornwall, charges of 30 cwt. are not unfrequently worked. The time required for smelting a charge varies with its weight and the nature of the ore, from 6 to 24 hours.

In some cases the ore is introduced raw into the furnace, whilst in others it undergoes a preliminary roasting previous to its introduction. Rich ores are generally smelted without being first calcined, but the poorer varieties, and particularly those which contain large quantities of iron pyrites, are, in most instances, subjected to roasting in a separate furnace.

In order to understand more clearly the operation of smelting in furnaces of this description, we will suppose that a charge has just been tapped off, and that, after the usual clearing the hearth, a fresh charge of raw ores has been introduced. During the first part of the operation of roasting, which usually occupies about two hours, the doors are taken off to admit free access of air, and also for the purpose of cooling the furnace, which has been strongly heated at the close of the preceding operation. No fuel is at this period charged upon the grate, since the heat of the furnace is of itself sufficient to effect the elimination of the first portions of sulphur.

ores to be smelted. This furnace has no hole for running off the slag, above the level of the tap hole for the lead, like the smelting furnace of Lea, near Matlock. A single chimney stack serves for all the castles; and receives all the fumes of the various roasting and smelting furnaces. Fig. 1081 gives an idea of the distribution of these flues. *a a a*, &c. are the furnaces; *b*, the flue, 18 in. hex. square; these lead from each furnace to the principal conduit *c*, which is five feet deep by 2½ wide; *d* is 4 feet deep by 3 wide; *e* is a round chamber 12 feet in diameter; *f* is a conduit, 7 feet high by 5 wide; *g* another, 6 feet high by 3 wide. The chimney at *A* has a diameter at bottom of 10 feet, at top of 12 feet, including the thickness of its sides, forming a truncated cone 100 feet high, which stands upon a hill a little way from the furnace, and 60 feet above their level.

a, the grate; *b*, the door of the fire-place; *c*, the fire-bridge; *d*, the arched roof; *e*, the hearth; *f f f*, &c. the working doors; *g g*, flues running into

conduit, which leads to the subterranean condensing-chamber *e*, and thence to the general chimney *y*; *A*, a hopper-shaped opening in the top of the furnace, for supplying it with ore.

This magnificent structure is not destined solely for the reduction of the ores, but also for dumping all the vapours which might prove noxious to the health of the workpeople and to vegetation.

The ores smelted at Holywell are very refractory galenae, mixed with blende, calamine, pyrites, carbonate of lime, &c., but without any dose of lime. They serve mutually as fluxes to one another. The coal is of inferior quality. The sole of each furnace is formed of slags obtained in the smelting, and they are all of one kind. In constructing it, 7 or 8 tons of these slags are first thrown upon the brick area of the hearth; are made to melt by a brisk fire, and in their stiffening state, as they cool, they permit the bottom to be sloped and hollowed into the desired shape. Four workmen, two at each side of the furnace, perform this task.

The ordinary charge of ore for one smelting operation is 20 cwt., and it is introduced through the hopper. An assistant placed at the back doors spreads it equally over the whole hearth with a rake; the furnace being meanwhile heated only with the declining fire of a preceding operation. No regular fire is made during the first two hours, but a gentle heat merely is kept up by throwing one or two shovelfuls of small coal upon the grate from time to time. All the doors are closed, and the register-plate of the chimney lowered.

The outer basin in front of the furnace is at this time filled with the lead derived from a former process, the metal being covered with slags. A rectangular slit above the tap hole is left open, and remains so during the whole time of the operation, unless the lead should rise in the interior basin above the level of that orifice; in which case a little mound must be raised before it.

The two doors in front furthest from the fire being soon opened, the head-sweeper throws in through them, upon the sole of the furnace, the slags swimming upon the

bath of lead, and a little while afterwards he opens the top-hole, and runs off the molten lead poured from these slags. At the same time he prevents the fire from going out, through the back doors. These being again closed, while the above two first doors are open, the smelter throws a shovelful of small coal or coke under upon the lead bath, and works the whole together, turning over the ore with the paddle or rake. About three quarters of an hour after the commencement of the operation, he throws lime upon the sides of the hearth, the inside slag, which then runs upon the back of the inner basin, and which are mixed with small pieces. He next turns over these slags, as well as the ore with the paddle, and works all the mass. At the time the interior bath of the lead only the pig arrives.

The constant new turns over the ore and slag, partly to break the lead apart. A little more than an hour after the operation begins, a quantity of lead proceeding from the ore bath upwards, is run off by the top; being usually a each opening as is the case half of the inner basin. Both the workmen then turn over the ore, with the paddle, at the several doors of the furnace. Its interior is at this time of a dull red heat, the roasting being carried on rather by the combustion of the coal pieces immediately back by the action of the small quantity of coal in the grate. The smelter, after turning the first door with the exception of that next to the grate, lifts off the back slag lying upon the surface of the inside bath, drains them, and throws them back into the furnace.

An hour and a half after the commencement, the lead begins to run out in small quantities from the ore; but little should be suffered to flow before two hours have expired. About this time the two workmen turn all the doors, and turn over the ore, each at his own side of the furnace. An hour and three quarters after the beginning, there are few vapours in the furnace, so temporary being very moderate. No more lead is then seen to flow upon the slating hearth. A general turning round is the grate to raise the heat slightly, the workmen turn over the ore, and turn them all the doors.

At the end of two hours, the first fire or roasting being completed, and the lower part, the regulator is to be lifted a little, and coal thrown upon the grate again, the second fire, which lasts during 25 minutes. When the doors are now opened, the interior of the furnace is of a vivid red colour, and the lead flows down from every side towards the lower basin. The smelter with his rake or paddle pushes the slag upon that back towards the upper part of the ore, and he now spreads them uniformly over the surface through the back doors. The smelter next throws on by his inside door a few shovelfuls of quicklime upon the lead bath. The constant turning over for a quarter of an hour works the ore, and the slags together through the three back doors, and then spreads them out, while the smelter pushes the slag from the surface of the inner basin back to the upper part of the ore. The doors being now left open for a time, while the interior remains in repose, the metallic lead, which had been pushed back with the slag, flows down into the basin. This occasional cooling of the furnace is thought to be necessary for the better separation of the products, especially of the slag from the lead bath.

In a short time the workmen resume their rakes, and turn over the slag along with the ore. Three hours after the commencement, a little more fuel is put into the grate, merely to keep up a moderate heat of the furnace during the pushing. After five hours and ten minutes, the grate being charged with fuel for the third fire, the regulator is completely opened, the doors are all shut, and the furnace is left in this state for three quarters of an hour. In nearly four hours from the commencement, all the doors being opened, the assistant levelling the surfaces with his rake, in order to favour the descent of any drops of lead; and then spreads the slag, which are pushed back towards him by the smelter. The latter now throws in a fresh quantity of lime, with the view not merely of covering the lead bath and preventing an oxidation, but of rendering the slag less fluid.

Ten minutes after the third fire is completed, the smelter puts a new charge of fuel on the grate, and shuts the doors of the furnace to give it the fourth fire. In four hours and forty minutes from the commencement, this fire being finished, the doors are opened, the smelter pierces the top-hole to discharge the lead into the outer basin, and throws some quicklime upon the slag in the inner basin. He then pushes the slag thus dried up towards the upper part of the hearth, and his assistant rakes him out by the back doors.

The whole operation of a smelting shift takes about four hours and a half, or at most five hours, in which four periods may be distinguished.

1. The first fire for roasting the ore requires very moderate firing, and lasts two hours.

2. The second fire, or smelting, requires a higher heat, with shut doors; at the end the slag are dried up with lime, and the furnace is also allowed to cool a little.

3. 2. The last two periods, or the third and fourth fires, are likewise the smeltings or soundings, and differ from the first only in requiring a higher temperature. The heat is greatest in the last. The form and dimensions of the furnace are calculated to cause a uniform distribution of heat over the whole surface of the hearth. Sometimes billets of green wood are plunged into the metallic lead of the outer basin, causing an ebullition which favours the separation of the slag, and consequently the production of a purer lead; but no more metallic metal is obtained.

Ten cwt. of coal are consumed at Holywell in smelting one ton of the lead-ore which is or sludge; but at Grassington, near Skipton in Yorkshire, with a similar furnace worked with a slower heat, the operation taking from seven hours to seven hours and a half, instead of five only $7\frac{1}{2}$ cwt. of coal are consumed. But here the ores are less refractory, have the benefit of flint spar as a flux, and are more exhausted of their metal, being smelted upon a less sloping hearth.

The ore-hearth.—This furnace, called by the French *fourneau decussis*, is from 22 to 24 inches in height and 1 foot by $1\frac{1}{2}$ in area inside, but its horizontal section, always rectangular, varies much in its dimensions at different levels, as shown in fig. 1082.

C, Tapers. M, Workstone. P, Lead pot.

Treatment of lead ores by the Scotch furnace or ore-hearth.—This furnace is generally employed in the counties of Northumberland, Cumberland, and Durham, for the smelting of lead ores, which were formerly carried to them without any preparation, but they are now often exposed to a preliminary calcination. The roasted ore yields in the Scotch furnace a more considerable product than the crude ore, because it forms in the furnace a more porous mass, and at the same time it works drier, to use the founder's expression; that is, it allows the stream of air impelled by the blast to diffuse itself more completely across the matters contained in the furnace.

In proceeding to melt by means of an ore-hearth, two workmen are required to be in attendance from the beginning to the end of each smelting shift, the duration of which is from 12 to 13 hours. The first step in commencing a smelting shift is to fill up the hearth-bottom, and space below the workstone with peats, placing one already kindled before the mouth of the bellows. The powerful blast very soon sets the whole in a blaze, and by the addition of small quantities of coal at intervals, a body of fire is obtained, filling the hearth. Roasted ore is now put upon the surface of the fire, between the forestone and pipestone, which immediately becomes heated red hot and reduced; the lead from it sinking down and collecting in the hearth bottom. Other portions of ore of 10 or 12 lbs. each are introduced from time to time, and the contents of the hearth are stirred and kept open, being occasionally drawn out and examined upon the workstone, until the hearth bottom becomes full of lead. The hearth may now be considered in its regular working state, having a mass of heated fuel, mixed with partly fused and semi-reduced ore, called *Brouse*, floating upon a stratum of melted lead. The smelting shift is then regularly proceeded with by the two workmen, as follows:—The fire being made up, a stratum of ore is spread upon the horizontal surface of the brouse, and the whole suffered to remain exposed to the blast for the space of about five minutes. At the end of that time, one man plunges a poker into the fluid lead, in the hearth bottom below the brouse, and raises the whole up, at different places, so as to loosen and open the brouse, and in doing so, to pull a part of it forwards upon the workstone, allowing the recently added ore to sink down into the body of the hearth. The poker is now exchanged for a shovel, with a head 6 inches square, with which the brouse is examined upon the workstone, and any lumps that may have been too much fused, broken to pieces; those which are so far agglutinated by the heat, as to be quite hard, and further known by their brightness, being picked out, and thrown aside, to be afterwards smelted in the slag hearth. They are called "gry slags." A little slaked lime, in powder, is then spread upon the brouse which has been drawn forward upon the workstone, if it exhibit a pasty appearance; and a portion of coal is added to the hearth, if necessary, which the workman knows by experience. In the mean time, his fellow workman, or shoulder fellow, clears the opening, through which the blast passes into the hearth, with a shovel, and places a peat immediately above it, which he holds in its proper situation, until it is fixed, by the return of all the brouse, from the workstone into the hearth. The fire is made up again into the shape before described, a stratum of fresh ore spread upon the part, and the operation of stirring, breaking the lumps upon the

workmen, who, putting on the hard shoes required, after the setting of a few minutes, exert in the same manner. At every stirring a fresh part is put above the mass of the bronze, which divides the heat, and causes it to be distributed all over the hearth, and no flame away into light smoke, as happens in the fire that is blown freely into the body of the furnace. The use and purpose of this part renders it very essential for this purpose; but, in some instances, where a tendency of joints has occurred, blocks of wood of the same size have been used with little disadvantage. As the smelting proceeds, the furnace gradually warms, through which it is heated to a proper amount, and smelted into pigs.

The principal particulars to be attended to in smelting of ore-hearth properly during the smelting shift, are three: First—It is very important to maintain a proper blast, which should be carefully regulated, so as to be neither too weak, nor too powerful. The weak blast would cause the furnace to be too hot, and one too powerful has the effect of losing the contents of the hearth too fast. In this particular no certain rules can be given; for the same blast is not equally fit for every variety of ore. Soft free-grained galena, of great specific gravity, being very fusible, and easily reduced, requires a moderate blast, while the harder and lighter varieties, many of which contain more or less iron, and are often much rich in silver, require a blast considerably stronger. In all cases, it is most essential, that the blast should be so managed as to reduce the ore, after every other necessary precaution is taken in working the hearth. Second—The blast should be as much divided as possible, and made to pass through every part of the furnace. Third—The hearth should be very frequently stirred, at due intervals, and part of its contents exposed upon the workstone; when the part so exposed should be well broken to pieces, as well as those which are further exposed, so as to form slag, whereby the heat is increased. This breaking to pieces, and exposure of the bottom part of the furnace upon the workstone, has a most beneficial effect in promoting the reduction of the lead for the atmosphere, as it is blown down upon it, and, in that position, the surface is readily exposed, or is covered with sulphurous acid, having the lead in its composition. Hence it is that the reduction of lead is most abundant out of the hearth immediately after the return of the bronze, which has been spread out and exposed to the atmosphere. Fourth—The quantity of lead used should be no more than is just necessary to keep the bronze sufficiently hot, as it does not in the least contribute to reduce the ore by any chemical effect. Its use is merely to render the bronze too fast, if, from the heat being too great, or from the nature of the ore, it has a disposition to become very soft. Fifth—Coal should be also supplied judiciously; too much unnecessarily increasing the bulk of the bronze, and causing the hearth to get too full.

When the ore is of a description to smelt readily, and the hearth is well managed in every particular, it works with but a small quantity of bronze, which feels dry when stirred, and is easily kept open and permeable to the blast. The reduction proceeds rapidly with a moderate degree of heat, and the slag produced are inconsiderable; but, if in this state, the stirring of the bronze and exposure upon the workstone are discontinued, or practised at longer intervals, the hearth quickly gets too hot, and immediately begins to agglutinate together; rendering evident the necessity of these operations to the successful management of the process. It is not difficult to understand why these effects take place, when it is considered, that in smelting by means of the ore-hearth, it is the oxygen of the blast and of the atmosphere which principally accomplishes the reduction; and the point to be chiefly attended to consists in exposing the ore to its action, at the proper temperature, and under the most favourable circumstances. The importance of having the ore free from impurities is also evident, for the stony or earthy matter it contains impedes the smelting process, and increases the quantity of slag. A very slight difference of composition of perfectly dressed ore may readily be understood to affect its reducibility; and hence it is, that ore from different veins, or the same vein in different strata, as before observed, is frequently found to work very differently when smelted singly in the hearth. It happens, therefore, that with the best workmen, some varieties of ore require more coal and lead, and a greater degree of heat than others, and it is for this reason that the foreman is made movable, so as either to answer for ore which, of the with a large or a small quantity of bronze.

It has been stated that the duration of a smelting shift is from 12 to 13 hours, at the end of which time, with every precaution, the hearth is apt to become too hot, and it is necessary to stop for some time, in order that it may cool. At mills where the smelting shift is 12 hours, the hearths usually go on 12 hours, and are suspended 3; four and a half or five blags* of ore (36 to 40 cwt.) are smelted during a shift, and the

two men who manage the hearth work each four shifts per week; terminating their week's work at 3 o'clock on Wednesday afternoon. They are succeeded by two other workmen, who also work four 12-hour shifts, the last of which they finish at 4 o'clock on Saturday. In these eight shifts, from 34 to 40 bings of ore are smelted, which, when of good quality, produce from 9 to 10 fadders* of lead. At other times when the shift is 14 or 15 hours, the furnace is kindled at 4 o'clock in the morning, and worked until 6 or 7 in the evening each day, six days in the week; during this shift, 3 or $3\frac{1}{2}$ bings of ore are smelted, and two men at one hearth, in the early part of each week, work three such shifts, producing about 4 fadders of lead—two other men work each 3 shifts in the latter part of the week, making the total quantity smelted per week, in one hearth, from 30 to 35 bings.

Hearth ends and Smelter's fume.—In the operation of smelting, as already described, it happens that parts of un-reduced and semi-reduced ore are continually expelled from the hearth, partly by the force of the blast, but principally by the disintegration of the ore on the application of heat. This ore is mixed with a portion of the fuel and lime made use of in smelting, all of which are deposited upon the top of the smelting hearth, and are called *hearth-ends*. It is customary to remove the *hearth-ends* from time to time, and deposit them in a convenient place until the end of the year, or some shorter period, when they are washed to get rid of the earthy matter they may contain, and the metallic portion is roasted at a strong heat, until it begins to soften and break into lumps, and afterwards smelted in the ore-hearth, exactly in the same way as the underlying that operation for the first time, as already described.

It is difficult to state what quantity of *hearth-ends* are produced by the smelting of a given quantity of ore, but in one instance the *hearth-ends* produced in smelting 2751 bings, on being roasted and reduced in the ore-hearth, yielded of common lead 315 cwt., and the grey slag separated in this process gave, by treatment in the slag-hearth, 47 cwt. of slag lead; making the total quantity of lead 362 cwt., which is at the rate of 3 cwt. 2 qrs. 23 lbs. from the smelting of 100 bings of ore.

Slag hearth.—The various slags obtained from the different operations of lead smelting are divided into two classes. Those which do not contain a sufficient amount of metal to pay for further treatment are thrown away as useless, whilst those in which the percentage of lead is sufficiently large are treated by the slag-hearth.

Figs. 1093, 1094 represent a slag-hearth, the *furnace à manche* (elbow furnace) of the French, and the *Arummafen* (crooked furnace) of the Germans, each as is used at Alston Moor, in Cumberland, for the reduction of the lead-slag. It resembles the Scotch furnace. The shaft is a parallelopiped, whose base is 26 inches by 24 inches in area inside, and whose height is 3 feet; the sole-plate *a*, of cast iron, slopes slightly

down to the base of reception or the fore-hearth *k*. Upon both of the long sides of the sole-plate there are cast iron beams, called *bauers*, *c c*, of great strength, which support the side walls built of a coarse grained sandstone, as well as the cast iron plate *d* (*fire-plate*), which forms the front of the shaft. This stands 7 inches off from the sole-plate, leaving an empty space between them. The back side is made of cast iron, from the sole-plate to the horizontal tuyère in its middle; but above this point it is made of sandstone. The tuyère is from $1\frac{1}{2}$ to 2 inches in diameter. In front of the fore-hearth *k*, a column *e* is placed, through which water continually flows, so that the slags which spontaneously overflow the fore-hearth may become inflated and divided, whereby the lead disseminated through them may be readily separated by washing. The lead then flows from the fore-hearth *k*, through an orifice, into an iron pot *f*, which is kept over a fire. The metal obtained from this slag-hearth is much less pure than that extracted directly from the ore.

The whole bottom of the furnace is filled to a height of 17 inches, that is, to within 2 or 3 inches of the tuyère, with the rubbish of coke reduced to coarse powder and beat strongly down. At each smelting shift, this bed must be made anew, and the interior of the furnace above the tuyère required, with the exception of the front, consisting of cast iron. In advance of the furnace there is a basin of reception, which is also filled with coke rubbish. Farther off is the pit, full of water, replenished by a cold

* 1 fadder = 28 cwt.

stream, which continually runs in through a pipe. The smoke, which flows out of the furnace, passes over the sides and is the source of evaporation, and does not leave the works, where the smoke-bells, which fly over the furnace, and which they are easily washed, as is to be seen, the lead that may be contained among them.

These furnaces are urged sometimes by fans or by water-blasts, as, fig. 1. But at

the smelting works of Llan-
near Glaston, the blowing-
machine consists of two wheels,
which revolve upon horizontal
axles. Each of these wheels is
divided into two equal parts
by a small plate that passes
through the axle, and is fixed
with water to a certain height.
The water of one side passes
round with that of the other
by an opening in the lower
part of the division. Each
wheel produces a movement of

oscillation, produced by a reel attached to a crank of a wheel & wheel. At each stroke, one of the compartments, being in communication with the external air, is filled, whilst the other, on the contrary, communicates with the furnace, and supplies wind to the furnace.

Instead of being blown by a cold blast, these furnaces are sometimes supplied with heated air. When supplied with cold air, it is often found difficult to penetrate the quantity of slag or other substance, so as to produce the necessary heat, and the cost of slag which forms at the end of the furnace from the cold blast, is the property of the operation. When the substance operated on is pure for silver, and very valuable, it frequently happens that the smelter is obliged to break the same, or to add some very fusible substance in order to melt it off. By the introduction of hot air this inconvenience is removed, and by increasing or lowering the temperature of the blast, the slag may be allowed to lengthen or shorten, according as the nature of the slag may require. The temperature found to answer best is from 200° to 250° Fahr.; and when it is heated to from 200° to 250°, it is found impossible to form a slag of sufficient length to convey the blast to the front of the hearth, and therefore the back, which is expensive to rebuild, is quickly destroyed.

The advantage to be derived from the use of the hot blast will be evident, from the result of two experiments which were tried some years since.

Twenty-eight tons of slag smelted with cold blast consumed 372 cubic feet of air per minute.

Labour cost - - - - -	£3 7 8
Coke, 7 tons, at 24s. 6d. - - - - -	8 11 6
Total	£11 19 2

Thirty-five tons of similar slag smelted with hot blast consumed 300 cubic feet of air per minute.

Labour cost - - - - -	£3 7 8
Coke, 5 tons, 17 cwt., at 24s. 6d. - - - - -	7 8 4
Turf for heating air, 11 loads, 1s. 8d. - - - - -	0 10 4
Total	£11 9 4

From which it will be seen that, with one-quarter part less air, a quarter part more slag was melted per week, and a saving of expense of nearly 10s. effected.

The loss of lead experienced in smelting by the slag hearth, is, however, very great, even under the most favourable circumstances; and it has, consequently, of late years been gradually superseded by the Castilian furnace, which will be shortly described. Many large and well-conducted establishments still, however, continue to employ the slag hearth, and when well constructed and skilfully managed, the loss arising from volatilisation may be considerably reduced.

Castilian furnace — Within the last few years a blast furnace has been introduced into the lead works of this country, which possesses great advantages over every other description of apparatus which has been hitherto employed for the treatment of lead ore of low produce. This apparatus, although first employed in Spain, was invented by an Englishman (Mr. W. Grundy), who was employed in the reduction of rich slags in the neighbourhood of Carthagena.

This furnace is circular, usually about 2 feet 4 inches, or 2 feet 6 inches in

diameter, and is constructed of the best fire bricks, so moulded as to fit together, and allow all the joints to follow the radii of the circle described by the brick work. Its usual height is 8 feet 6 inches, and the thickness of the masonry invariably 8 inches. In this arrangement the breast is formed by a semi-circular plan of cast-iron, furnished with a lip for running off the slag, and has a longitudinal slot, in which is placed the tapping-hole.

On the top of this cylinder of brickwork a box-shaped covering of masonry is supported by a cast-iron framing, resting on four pillars, and in this is placed the door for feeding the furnace, and two outlets by which the various products of combustion escape to the flues. The lower part of this hood is fitted closely to the body of the furnace, whilst its top is closed by an arch of 4½ inch brickwork laid in fire-clay. The bottom is composed of a mixture of coke-dust and fire-clay, slightly rammed, and well beaten to the height of the top of the breast-pan, which stands nearly 3 feet above the level of the floor. Above the breast-pan is an arch, so turned as to form a sort of niche, 18 inches in width, and rather more than 2 feet in height.

When the bottom has been solidly beaten, up to the required height, it is hollowed out so as to form an internal cavity, communicating freely with the breast-pan, which is filled with the same material and subsequently hollowed out to a depth exactly below the level of the internal cavity. The blast is supplied by three water tuyeres, 3 inches in diameter at the smaller end, 5½ inches at the larger, and 10 inches in length. Into these the nozzles are introduced, by which a current of air is supplied by means of a fan or ventilator, making about 100 revolutions per minute. The blast may be conveniently conducted to the nozzles through brick channels formed beneath the floor of the smelting house.

The ores treated in this furnace ought never to contain more than 30 per cent. of metal, and when richer, must be reduced to about this tenure by the addition of slags and other fluxes. In charging this apparatus, the coke and ore are supplied stratum super stratum, and care must be taken so to dispose the coke as not to heat too violently the brickwork of the furnaces. In order to allow the slags which are produced to escape freely into the breast-pan, a brick is lifted out of the front of the furnace at the height of the fire-hearth, which, for the purpose of preventing the cooling of the section, is kept covered by a layer of coke-dust or cinders. From the breast-pan the slag flows constantly off over a spout into cast-iron waggonets, where they consolidate into masses, having the form of truncated pyramids, of which the larger base is about 2 feet square. As soon as a sufficient amount of lead is accumulated in the bottom of the furnace, it is let off into a lateral lead-pot, by removing the clay-stopper of the tap-hole situated in the side of the breast-pan, and after being properly skimmed it is ladled into moulds. When in addition to lead the ore treated likewise contains a certain portion of copper, this metal will be found in the form of a matt floating on the surface of the leaden bath. This, when partially solidified, is removed, and after being roasted is operated on for the copper it contains.

The waggonets in which the liquid slag runs off, are frequently made to traverse small railways, by which, when one mass has been removed, its place may readily be supplied by an empty wagonnet. When nearly cold the casings of the wagonets are turned over and the blocks of slag easily made to drop out. In addition to the facility for transport obtained in this way, one of the great advantages obtained by this method of manipulation arises from the circumstance that should the furnaces at any time run lead or matt, without its being detected by the smelter, the whole of it will be collected at the bottom of the block, from which, when cold, it may be readily detached.

In working these furnaces, care must be taken to prevent flame from appearing at the tunnel-head, since, provided the slags are sufficiently liquid, the cooler the apparatus is kept the less will be the loss of metal through volatilisation. In addition to the greatest attention being paid to the working of the furnace, it is necessary, in order to obtain the best results, that all establishments in which this apparatus is employed should be provided with long and capacious flues, in which the condensation of the fumes takes place, previous to arriving at the chimney-shaft. These flues should be built at least three feet in width, and six feet in height, so as readily to admit of being cleaned, and are often made of several thousand yards in length. The value of the fumes, so condensed, amounts to many hundreds, and in some instances thousands per annum.

In order to be advantageously worked in these furnaces, the ores should be first roasted, and subsequently agglomerated into masses, which, after being broken into fragments, of about the size of the fist, and mixed with the various fluxes, are charged as before described.

In an establishment in which the average assay produce of the roasted ore for lead

is 42 lbs, the furnace yield is 44 lbs, and the weight of coke employed to effect the reduction 22 per cent. of the roasted ore operated on. The mixture charged into the furnace, in this instance, is composed of 100 parts of roasted ore, 42 parts of coke from a previous operation, 5 parts of scrap iron, and 7 parts of limestone. Each furnace works off about seven tons of roasted ore in the course of 24 hours; the weight of slag run off is about double that of the lead obtained, and the matt removed from the surface of the pan is nearly 3 per cent. of the lead produced. The ores treated in this establishment consist of galena, much mixed with spathose iron, and are therefore somewhat refractory. A furnace of this kind requires for its construction about 1000 segmental fire-bricks, and the same number of ordinary fire-bricks of second quality.

Figs. 1086, 1087, 1088, and 1089 represent respectively a vertical section, an elevation, a ground plan, and an horizontal section of a Castilian furnace. The section fig 1086 is on the line x v. fig. 1087. A is the body of the furnace; n, the bottom composed of a mixture of lime-dust and fire-clay; c c c, the tuyeres; r, the rectangular covering of masonry; k k k, cast iron pillars; v, the breast-pan; a, slot for tapping hole; n, lip of breast-pan; z, feeding door; u, fire-hole; r. q. ground line.

Figs. 1090, 1091 are the slag-waggons, A being a movable case without a bottom, and B a strong cast-iron plate running on four wheels.

The desulphuration of the ores to be treated in these furnaces may be effected either by the aid of an ordinary reverberatory roasting furnace, or in heaps, or properly constructed kilns.

The kilns best adapted for this purpose consist of rectangular chambers, having an arched roof, and provided with proper flues for the escape of the evolved gases, as well as a wide door for charging and withdrawing the ore to be operated on.

Each of these chambers is capable of containing from 25 to 30 tons of ore, and in order to charge it a layer of faggots and split wood is laid on the floor, and then, after having been covered by a layer of ore about two feet in thickness, is ignited, care being at the same time taken to close, by means of loose brick-work, the opening of the door to the same height. When this first layer has become sufficiently ignited, a fresh stratum of ore, mixed with a little coal or charcoal, is thrown upon it, and when this layer has in its turn become sufficiently heated, more ore is thrown on. In this way more ore is from time to time added, until the kiln has become full, when the orifice of the doorway is closed by an iron plate, and the operation proceeds regularly and without further trouble until the greater portion has become eliminated.

This usually happens at the expiration of about four weeks from the time of first ignition, and the brick-work front is then removed, and the ores broken out, and after being mixed with proper fluxes, passed through the blast furnace.

The proportion of wood necessary for the roasting of a ton of ore by this means must necessarily depend on the composition of the minerals operated on; but with ores of the description above-mentioned, and in a neighbourhood where wood is moderately cheap, the desulphuration may be effected at a cost of about 5s. per ton.

Calining.—The lead obtained by the various processes above described generally contains a sufficient amount of silver to render its extraction of much importance; but, in addition to this, it is not unfrequently associated with antimony, tin, copper, and various other impurities, which require to be removed before the separation of the silver can be effected.

This operation consists in fusing the hard lead in a reverberatory furnace of peculiar construction, and allowing it to remain, when in a melted state, exposed to the oxidizing influences of the gases passing through the apparatus. By this treatment the antimony, copper, and other impurities become oxidised, and on rising to the surface of the molten bath are skimmed off, and removed with an iron rake. The hearth of the furnace in which this operation is conducted consists of a large cast-iron pan, which may be 10 feet in length, 5 feet 6 inches in width, and 10 inches in depth. The fire-place, which is 1 foot 9 inches in width, has a length equal to the width of the pan, and is separated from it by a fire-bridge 2 feet in width. The height of the arch at the bridge end is 1 foot 4 inches above the edge of the pan, whilst at the outer extremity it is only about 4 inches.

The lead to be introduced into the pan is first fused in a large iron pot fixed in
r v 3

be h-work at the side of the furnace, and subsequently ladled into it through an iron gutter adapted for that purpose. The length of time necessary for the purification of hard lead obviously depends on the nature and amount of the impurities which it contains; and, consequently, some varieties will be sufficiently refined at the expiration of twelve hours, whilst in other instances it is necessary to continue the operation during three or four weeks. The charge of hard lead varies from eight to eleven tons.

When the metal is thought to be in a fit state for tapping, a small portion taken out with a ladle, and poured into a mould used for this purpose is found on cooling to assume at the surface a peculiar crystalline appearance, which, when more seen is readily again recognised. As soon as this appearance presents itself an iron plug is withdrawn from the bottom of the pan, and the lead ran off into an iron pan, from which it is subsequently ladled into malle.

The items of cost attending the calcining of one ton of hard Spanish lead in the north of England are about as follows:—

	a.	d.
Wages	1	11 7
Onals, 27 cwt	0	4 7
It-pans, &c.	0	0 5
	<hr/>	
	2	4 4

The construction of a furnace of this description requires 5000 common bricks, 3,500 fire-bricks, and 2 tons of fire clay.

Figs. 1092 and 1093 represent an elevation and vertical section of the calcining

furnace. A is the fire-place; N, ash-pit; C, fire-bridge; H, cast iron pan; Z, fire; F F F, channels for allowing the escape of moisture; H, one of the working doors. H, apart for running off calcined metal. Fig. 1094 represents the pan removed from the masonry, and shows a groove in the lip for the introduction of a sheet iron dam, tightened with malle and bone-ash for keeping in the fused metal.

In the more modern furnaces of this description, the corners are usually rounded to prevent breakage from expansion, whilst the tapping is effected by means of a hole through the bottom near one of the sides. This, when closed, is stopped by means of an iron plug kept in its place by a weighted lever.

Concentration of the silver.—This process is founded on the circumstance first noticed in the year 1729, by the late H. L. Pattinson of Newcastle-on-Tyne, that

when lead containing silver is melted in a suitable vessel, afterwards slowly allowed to cool, and at the same time kept constantly stirred, at a certain temperature near the melting point of lead, metallic crystals begin to form. These as rapidly as they are produced sink to the bottom, and on being removed are found to contain much less silver than the lead originally operated on. The still fluid portion, from which the crystals have been removed, will at the same time be proportionally enriched.

This operation is conducted in a series of 4 or 5 cast iron pots, set in a row, with fireplaces beneath. These are each capable of containing about 4 tons of calcined lead; and on commencing an operation that quantity of metal, containing we will suppose 20 oz. of silver per ton, is introduced into a pot (say *r*, fig. 1095) about the centre of the series. This when melted, is carefully skimmed with a perforated ladle, and the fire immediately withdrawn. The cooling of the metal is also frequently hastened by throwing water upon its surface, and whilst cooling it is kept constantly agitated by means of a long iron stirrer or *stirrer*. Crystals soon begin to make their appearance, and these as they accumulate and fall to the bottom are removed by means of a large perforated ladle, in which they are well shaken and afterwards carried over to the next pot to the left of the workman. This operation goes on continually until about 4 tons of crystals have been taken out of the pot *r*, and have been placed in pot *x*, at which time the pot *r*, may contain about 40 oz. of silver to the ton, whilst that in *x*, will only yield 10 oz. The rich lead in *r*, is then ladled into the next pot *u*, to the right of the workman, and the operation repeated in *r*, on a fresh quantity of calcined lead.

In this way calcined lead is constantly introduced, and the resulting poor lead passes continually to the left of the workman, whilst the rich is passing towards his right. Each pot in succession, when filled with lead of its proper produce for silver, is in its turn crystallised, the poor lead passing to the left of the workman, and the enriched lead to his right. By this method of treatment it is evident that the crystals obtained from the pots to the left of the workman must gradually be deprived of their silver, whilst the rich lead passing to his right becomes continually richer. The final result is, that at one end of the series, the poor lead contains very little silver, whilst at the other an exceedingly rich alloy of lead and silver is obtained.

The poor lead obtained by this process should never contain more than 12 dwts. of silver per ton, whilst the rich lead is frequently concentrated to 500 oz. to the ton. This rich lead is subsequently expelled in the refining furnace.

The ladle employed for the removal of the crystals, when manual labor is used, is about 16 inches in diameter, and 3 inches in depth, but when cranes are used much larger ladles are usually employed. A form of crane has been invented which effects considerable economy of labor in this operation. When, during the operation of crystallization, the ladle becomes chilled, it is dipped into a small vessel containing lead of a higher temperature than that which is being worked, and drawn by the means of a snapper-pot. The pot containing the rich lead is generally used like No. 1 pot; in some establishments, however, the last pot is where the poor lead or crystal lead obtains this application.

Figs. 1095 and 1096 represent a plan and elevation of a set of Pattinson's pots, arranged in the usual approved way. A is the "market pot," from which the de-silvered lead is ladled out. B, C, D, E, F, G, H, and I, are the working pots, while A', B', C', D', E', F', G', H', and I, are their respective fireplaces. The "snapper pots" W, X, Y, Z, are employed for heating the ladles when they have become too much reduced in temperature.

The Figs. 1097 and 1098, are sections showing the manner of setting and the arrangement of the pots and flues. A, pot; B, main flue; C, ash pit.

1097

1098

The cost of crystallizing one ton of calcined Spanish lead, in the establishments quoted when treating of calcination, is as follows:—

		s.	d.
Wages	- - - - -	9	5 4
Coals, 4 cwt.	- - - - -	0	8 6
Repairs	- - - - -	0	2 3
Total	- - - - -	10	4 2 0

The erection of nine six-ton pots requires 15,000 common bricks, 10,000 fire bricks, 160 feet of quartz, 80 fire-clay blocks, and 3 tons of fire-clay.

In some establishments ten-ton pots are employed, and where cranes are made use of they are found to be advantageous.

Refining.—The extraction of the silver contained in the rich lead is conducted in a cupel forming the bottom of a reverberatory furnace called a refinery.

In this operation the litharge produced, instead of being absorbed by the substance of the cupel, is run off in a fluid state, by means of a depression called a gate.

The size of the fire-place varies with the other dimensions of the furnace, but is usually nearly square, and is an apparatus of ordinary size may be about 2 feet x 2 feet 6 inches. This is separated from the body of the furnace by a fire-bridge 18 inches in breadth, so that the flame and heated air pass directly over the surface of the cupel, and from thence escape by means of two separate apertures into the main flues of the establishment. The cupel or test consists of an oval iron ring, about 5 inches in depth, its greatest diameter being 4 feet, and its lower nearly 3 feet. This frame, in order to better support the bottom of the cupel, is provided with cross-bars about 4½ inches wide, and one half-inch in thickness. In order to make a test, this frame is beaten full of finely-powdered bone-ash, slightly moistened with water, containing a small quantity of pearl-ash in solution, which has the property of giving consistency to the cupel when heated.

The centre of the test, after the ring has been well filled with this mixture, and solidly beaten down, is scooped out with a small trowel, until the sides are left 2 inches in thickness at top, and three inches at the bottom, whilst the thickness of the sole itself is about 1 inch.

At the fore part or wide end of the test the thickness of the border is increased to six inches, and a hole is then cut through the bottom, which communicates with the openings or gates by which the fluid litharge makes its escape.

The test, when thus prepared, is placed in the refinery furnace, of which it forms the bottom, and is wedged to its proper height against an iron ring firmly built into the masonry. When this furnace is first lighted, it is necessary to apply the heat very gradually, since if the test were too strongly heated before it became perfectly dry, it would be liable to crack. As soon as the test has become thoroughly dry, it is heated to incipient redness, and is nearly filled with the rich lead to be operated on, which has been previously fused in an iron pot at the side of the furnace, and beneath which is a small grate where a fire is lighted.

The melted lead, when first introduced into the furnace, becomes covered with a greyish dross, but on further increasing the heat, the surface of the bath uncovers, and ordinary litharge begins to make its appearance.

The blast is now turned on, and forces the litharge from the back of the test up to the breast, where it passes over the gate, and falls through the aperture between the bone-ash and the ring into a small cast-iron pot running on wheels. The air, which is supplied by a small ventilator, not only sweeps the litharge from the surface of the lead towards the breast, but also supplies the oxygen necessary for its formation.

In proportion as the surface of the lead becomes depressed by its constant oxidation, and the continual removal of the resulting litharge, new metal is added from the melting pot, so as to raise it to its former level, and in this manner the operation is continued until the lead in the bottom of the test has become so enriched as to render it necessary that it should be tapped. The contents of the test are now so far reduced in volume that the whole of the silver contained in the rich lead operated on remains in combination with a few hundred weight only of metal, and this is removed by carefully driving a hole in the bone-ash forming the bottom of the test. The reason for the removal of the rich lead, is to prevent too large an amount of silver from being carried off in the litharge, which is found to be the case when lead containing a very large amount of that metal is operated on.

When the rich lead has been thus removed, the tapping hole is again closed by a pellet of bone-ash, and another charge immediately introduced.

As soon as the whole of the rich lead has been subjected to cupellation, and has become thus further enriched, the argentiferous alloy is itself similarly treated, either in a fresh test, or in that employed for the concentration of the rich lead. The brightening of pure silver at the moment of the separation of the last traces of lead, indicates the precise period at which the operation should be terminated, and the blast is then turned off, and the fire removed from the grate. The silver is now allowed to set, and as soon as it has become hardened, the wedges are removed from beneath the test, which is placed on the floor of the establishment. When cold, the silver plate is detached from the test, and any adhering particles of bone-ash removed by the aid of a wire brush.

A test furnace of ordinary dimensions requires for its construction about 2,000 common bricks, 2,000 fire-bricks, and 1½ tons of fire-clay. A furnace of this kind will work off 4 tons of lead per hour, and consumes 4 cwt. of coal per ton of rich lead operated on.

The cost of working a ton of rich lead in the neighbourhood of Newcastle, containing on an average 400 oz. of silver per ton, is as follows:—

	a.	d.	e.
Refiner's wages	-	-	-
Coal, 4 cwt.	-	-	-
Labour wages	-	-	-
Coal, 5 cwt.	-	-	-
Pearl ash	-	-	-
Bone-ash, 17½ lbs.	-	-	-
Repairs	-	-	-
Total	19	19	19

Figs. 1099, 1100, and 1101, represent an elevation, plan, and section of a refining furnace; A, fireplace; B, ash-pit; C, fire-bridge; D, test-ring, shown in its proper position; E, flues; F, point where blast enters; G, pig-holes.

* Pig-holes are used for introducing the lead in cases in which it is too loaded for the test to be fixed at the base.

Reducing.—The reduction to the metallic state of the litharge from the refinery, the pot dross, and the melted metallic residues from the smelting furnace, is effected in a reverberatory apparatus, somewhat resembling a smelting furnace, except that its dimensions are smaller, and the bed, instead of being lower, is usually below the middle of the furnace, gradually sloping from the fire-place to the end, where there is a depression in which is located an iron gutter, which is constantly running open, and from which the reduced metal flows continuously into an iron pot placed by the side of the furnace for its reception, whence it is subsequently ladled into moulds.

The litharge, or pot dross, is intimately mixed with a quantity of small coal, and is charged on the part of the hearth immediately before the fire-bridge. To prevent the fuel from striking the bottom of the furnace, and also to provide a sort of hollow filter for the liquid metal, the sole is covered by a layer of broken coal.

The heat of the furnace quickly causes the ignition of this stratum, which is rapidly reduced to the state of a spongy cinder. The reducing gases present in the furnace, aided by the coal mixed with the charge itself, cause the reduction of the metal, which, passing the metallic form, flows through the interstices of the cinder, and ultimately finding its way into the depression at the extremity of the hearth, flows through the iron gutter into the external cast-iron pot. The surface of the charge is frequently, during the process of elaboration, turned over with an iron rake, for the double purpose of exposing new surfaces to the action of the furnace, and also to allow the reduced lead to flow off more readily.

Fresh quantities of litharge or pot-dross, with small coal, are from time to time thrown in, in proportion as that already charged disappears, and at the end of the shift, which usually extends over 12 hours, the layer of cinder is broken up, and after being mixed with the residual material in the furnace is withdrawn. A new floor of cinders is then introduced, and the operation commenced as before. A furnace of this kind, having a sole 6 feet in length and 7 feet in width, will afford, from litharge, about $3\frac{1}{2}$ tons of lead in 24 hours.

The dross from the calcining pan, when treated in a furnace of this description, should be previously reduced to a state of fine division, and intimately mixed up with small coal and a soda ash. In many cases, however, the calcined dross is treated in the smelting furnace. The hard lead obtained from this substance is again taken to the reducing furnace, for the purpose of being softened.

The expense of reducing one ton of litharge may be estimated as follows —

	s.	d.
Wages	2	6.0
Coals (3 cwt.)	0	5.2
Repairs	0	1.6
Total	3	0.8

In the establishment from which the foregoing data were obtained, the cost of slack, delivered at the works, was only 2s. 11d. per ton, which is cheaper than fuel can be obtained in the majority of the lead-mills of this country. In North Wales the cost of small coal is generally about 4s., and at Bristol 5s. 6d. per ton.

1102

Figs. 1102 and 1103 represent a vertical section and plan of a reducing furnace. A, fire-place; u, ash-pit; c, fire-bridge; b, hearth; r, working door; z, iron spout for

conducting the reduced metal into the lead-pot *a*, which is kept heated by means of a fire beneath.

The total cost of elaborating one ton of hard lead, containing 30 oz. of silver per ton, in a locality in which fuel is obtained at the low price above quoted, is nearly as follows:—

	£	s.	d.
Calcining	0	2	4½
Crystallising	0	9	6½
Refining	0	0	9½
Refining—put dross and litharge	0	1	0½
Calcined dross	0	0	8½
Slags	0	6	3½
Booze-nash, &c.	0	0	7½
Transport, &c.	0	1	1½
Management, taxes, and interest of plant	0	5	10½
Total	1	2	5½

One hundred tons of hard lead treated gave:—

	Tons
Soft lead	94.90
Black dross	3.72
Loss	1.38
Total	100.00

On comparing the expense of each operation, as given in the foregoing abstract, with the amounts stated as the cost of each separate process, they will be found to be widely different; but it must be remembered that the whole of the substances elaborated are far from being subjected to the various treatments described.

In order therefore to give an idea of the relative proportions which are passed through the several departments, I may state that in an establishment in which the ores are treated in the Castilian furnace the following were the results obtained:—

One-hundred parts of raw ore yield:—

Roasted ore	85
Hard lead	42
Soft	36
Rich	9
Dross and litharge re-treated	18½

The importance of this branch of our metallurgic industry will be gathered from the following tabular statements, chiefly derived from Mr. Hunt's valuable statistics:—

TABLE I.

It may be remarked that for the treatment of ores of good produce the reverberatory furnace and Scotch hearth are to be preferred, but for working minerals of a low percentage the blast furnace may generally be substituted with advantage. The slag hearth, from the amount of fuel consumed and loss experienced, is a somewhat expensive apparatus, and might in many cases be advantageously exchanged for the Castilian furnace.

It is well known that the losses which take place in this branch of metallurgy are,

from the volatility of the metal operated on, usually, large. In those cases, however, in which the attention is paid to safety and a proper adjustment of ore, as well as the management of the furnace, a great economy is effected.

In some instances fluxes of three, five, or even in some cases ten, have been employed, and the most satisfactory results obtained. The attention of lead smelters is being daily more directed to the prevention of the loss of metal by volatilization, and those who have adopted the use of long flues have been, in all cases, quickly repaid for their outlay.

As an example of the great extent to which such economy may take place, on the small employed in large smelting works, we may mention the lead works belonging to Mr. Henson at Nantwich, Cheshire. Formerly the fumes of lead arising from various burning operations escaped from ordinary chimneys or short flues, and large quantities of lead were thus carried off to the use of vapour, and deposited in the surrounding land, where vegetation would be destroyed, and the health of both man and other animals seriously affected. This led to various estimations of the loss of metal or slightly inclined galleries were in use, and the quantity of lead extracted rapidly repaid the cost of construction. The last alteration of the kind was made at Allen Mill, by Mr. Spewth, the manager, and comprised a length of 275 yards (nearly five miles) of long gallery from the mill itself. This gallery is 4 feet high and 16 wide, and is two distances widely separated. There are two rows of a series of galleries for the same purpose, running with other mines belonging to Mr. Henson in the same district, and in Durham, and we learn from Mr. Spewth, that former estimations are completely exceeded. The value of the lead thus saved from being totally dissipated and destroyed, and obtained from what in common parlance might be called chimney sweeps, is considerably exalted to 1000*l.* sterling annually, and forms a striking illustration of the importance of economy in our waste products.

In the use of long and extensive flues, economies of various descriptions have from time to time been introduced, but in most instances the former have been found to be more efficient.

When, however, water can be procured for the purpose of heating the crucibles, excellent results are generally obtained.—J. A. P.

See LITHUANIAN, MINERAL, or *Red Lead*, BOLLIN, STUAM or *Arslate of Lead*, TERN, METAL, and WHITE LEAD.

LEAD ORES, ASSAY OF. The uses of lead may be divided into two classes.

The *first class* comprehends all the ores of lead which contain neither sulphur nor arsenic, or in which they are present in small proportion only.

The *second class* comprises galena, together with all lead ores containing sulphur, arsenic, or their acids.

From the facility with which this metal is volatilized when strongly heated, it is necessary to conduct the assay of its ores at a moderate temperature.

A common wind furnace is best adapted for making lead assays. For this purpose the cavity for the reception of fuel should be 2 inches square, and the height of the flue-way from the fire-bars about 14 inches. For ordinary ores a furnace 8 inches square and 12 inches deep will be found sufficient; but as it is easy to regulate, by a damper, the heat of the larger apparatus, it is often found advantageous to be able to produce a high temperature.

A furnace of this kind should be connected with a chimney of at least twenty feet in height, and be supplied with good coke, broken into pieces of the size of eggs.

ORES OF THE FIRST CLASS.—The assay of ores of this class is a simple operation, care being only required that a sufficient amount of carbonaceous matter be added to effect the reduction of the metal, whilst such fluxes are supplied as will afford a readily-fusible slag.

When the sample has been properly reduced in size, 400 grains are weighed out and well mixed with 600 grains of carbonate of soda, and from 40 to 50 grains of finely-powdered charcoal, according to the richness of the mineral operated on.

This is introduced into an earthen crucible, of such a size as not to be more than one-half filled by the mixture, and on the top is placed a thin layer of common salt. The crucible is then placed in the furnace and gently heated, care being taken to so moderate the temperature, that the mixture of ore and flux, which at first begins to soften and enter into ebullition, may not swell up and flow over. If the action in the crucible becomes too strong, it must be checked by removal from the fire, or by a due regulation of the heat by means of a damper. When the action has subsided, the temperature is again raised for a few minutes, and the assay completed. During the process of reduction, the heat should not exceed dull redness; but in order to complete the operation, and render the slag sufficiently liquid, the temperature should be raised to bright redness.

When the contents have been reduced to a state of tranquil fusion, the crucible must be removed from the fire and the assay either rapidly poured, or, after being tapped against some hard body to collect the lead in a single globule, be set to cool.

When the operation has been successfully conducted, the cooled slag will present a smooth, convex surface, with a various lustre. When still the crucible may be broken, and the button extracted. To remove from it the particles of adhering slag, it is hammered on an anvil, and afterwards rubbed with a lead brush.

Instead of employing carbonate of soda and powdered charcoal, the ore may be fused with $1\frac{1}{2}$ times its weight of black flux, and the mixture covered by a thin layer of borax.

Good results are also obtained by mixing together 400 grains of ore with an equal weight of carbonate of soda and half that quantity of crude tartar. These ingredients, after being well incorporated, are placed in a crucible, and slightly covered by a layer of borax.

Each of the foregoing methods yields good results, and affords slags retaining but a small proportion of lead.

Ores of the Spanish Class.—This class comprehends galena, which is the most common and valuable ore of lead, and also comprises several smaller products, as well as the sulphate, phosphate, and arsenate of lead.

Galena.—The assay of this ore is variously conducted; but one of the following methods is usually employed for commercial purposes.

Fusion with an alkali flux.—This operation is conducted in an earthen crucible which is to be kept covered until the contents are reduced to a state of perfect fusion.

The powdered ore, after being mixed with three times its weight of carbonate of soda and 10 per cent. of finely pulverized charcoal, is slowly heated in an ordinary assay furnace, and the mixture has become perfectly liquid, when the pot is removed from the fire, and, after having been gently tapped, to collect any loose particles of metal held in suspension in the slag is put back to cool. When sufficiently cold, the crucible is broken, and a button of metal—lead will be found at the bottom; this must be cleaned and weighed.

In place of carbonate of soda, pearl ash may be employed, or the fusion may be effected with black flux alone. When the last-named substance is used a somewhat longer time is necessary for the complete fusion of the assay. Each 100 parts of pure galena will by this method afford from 74 to 76 parts of lead.

Some of the old assays were in the habit of first driving off the sulphur by roasting, and afterwards fusing the resulting oxide with about its own weight of black flux.

This method, from the great instability of the compounds of lead, requires very careful management, and at best the results obtained are unsatisfactory. Pure galena by this method can rarely be made to yield more than 70 per cent. of lead.

Fusion with metallic iron.—Mix the ore to be assayed with twice its weight of carbonate of soda, and, after having placed it in an earthen crucible, of which it should occupy about one half the capacity, insert with their heads downward three or four tempering nails, and press the mixture firmly around them. On the top place a thin layer of borax, which should be again covered with a little common salt. The whole is now introduced into the furnace, and gradually heated to redness; at the expiration of ten minutes the temperature is increased to bright redness, when the fluxes will be fused and present a perfectly smooth surface. When this has taken place, the pot is removed from the fire, and the nails are separately withdrawn by the use of a small pair of tongs, care being taken to well cleanse each in the fluid slag until free from adhering lead. When the nails have been thus removed, the pot is gently shaken, to collect the metal into one button, and laid aside to cool; after which it may be broken, and the button removed.

Instead of first allowing the slags to cool and then breaking the crucible, the assay may, if preferred, after the withdrawal of the nails, be poured into a mould.

Assay in an iron pot.—Instead of adding metallic iron to the mixture of ore and flux, it is generally better that the pot itself should be made of that metal.

For this purpose, a piece of half-inch plate-iron is turned up in the form of a crucible and carefully welded at the edges. The bottom is closed by a thick iron rivet, which is securely welded to the sides, and the whole then finished on a properly formed mandril. To make an assay in a crucible of this kind, it is first heated to dull redness, and, when sufficiently hot, the powdered ore, intimately mixed with its own weight of carbonate of soda, half its weight of pearl ash, and a quarter of its weight of crude tartar, is introduced by means of a copper scoop. On the top of the whole is placed a thin layer of borax, whilst the crucible, which, for the ready introduction of the mixture, has been removed from the fire, is at once replaced. The heat is now raised to redness, the contents gradually becoming liquid and giving off large quantities of gas. At the expiration of from eight to ten minutes the mixture will be in a state of complete fusion; the pot is now partially removed from the fire, and its contents briskly stirred with a small iron rod. Any matter adhering to its sides is also scraped to the bottom of the pot, which, after being again placed in a hot part of the furnace, is heated during three or four minutes to bright redness.

LEAD-SHOT. (*Pom de Chasse, Fr.; Schrot, Pöschel, Ger.*) The origin of some of the imperfections in the manufacture of lead shot is the too rapid melting of the spherules by their being dropped too soon into the water, whereby their surfaces form a hard crust, while the interior remains fluid, and in its subsequent coagulation, shrinks, so as to produce the irregularities of the shot.

The poorest shot towers originally constructed in England abate this evil by exposing the fused spherules after they pass through the cullender, to a large body of water during their descent to the water tub placed on the ground. The highest erection of this kind is probably at Völsch in Carinthia, being 240 Vienna, or 245 English feet high.

The quantity of arsenic added to the mass of melted lead varies according to the quality of the metal; the harder and less ductile the lead is, the more arsenic must be added. About 3 pounds of either white arsenic or arsenic is enough for one thousand parts of soft lead, and about 4 for the harder kinds. The latter are employed generally for shot, as they are cheaper and answer sufficiently well. The arsenical alloy is made either by introducing some of this substance at each melting, or by making a quantity of the compound considerably stronger at once, and adding a certain portion of this to each charge of lead. If the particles of the shot appear less shaped, it is a proof that the proportion of arsenic has been too great; but if they are flattened upon one side, if they are hollowed in their middle, called *cupping* by the workmen, or drag with a tail behind them, the proportion of arsenic is too small.

The following is the process prescribed by the patentees, A. Kerman and Martin. Melt a ton of soft lead, and sprinkle round its sides in the iron pot about two shovelfuls of wood ashes, taking care to leave the centre clear; then put into the middle about 40 pounds of arsenic to form a rich alloy with the lead. Cover the pot with an iron lid, and lute the joints quickly with loam or mortar to confine the arsenical vapours, keeping up a moderate fire to maintain the mixture fluid for three or four hours, after which skim carefully, and run the alloy into moulds to form ingots or pigs. The composition thus made is to be put in the proportion of one pig or ingot into 1000 pounds of melted ordinary lead. When the whole is well combined, take a perforated skimmer, and let a few drops of it fall from some height into a tub of water. If they do not appear globular, some more arsenical alloy must be added.

Lead which contains a good deal of pewter or tin must be rejected, because it tends to produce elongated drops or tails.

From two to three tons are usually melted at once in the large establishments. The surface of the lead gets covered with a crust of oxide of a white spongy nature, sometimes called *crum* by the workmen, which is of use to coat over the bottom of the cullender, because without such a bed the heavy melted lead would run too rapidly through the holes for the granulating process, and would form oblong spheroids. The mounting of this filter, or lining of the cullender, is reckoned to be a nice operation by the workmen, and is regarded usually as a valuable secret.

The cullenders are hollow hemispheres of sheet iron, about 10 inches in diameter, perforated with holes, which should be perfectly round and free from burr. There must be of an uniform size in each cullender; but of course a series of different cullenders with sorted holes for every different size of lead shot must be prepared. The holes have nearly the following diameters for the annexed numbers of shot.

No.	0.	1.	2.	3.	4.	$\frac{1}{20}$ of an inch.
	-	-	-	-	-	$\frac{1}{16}$ "
	-	-	-	-	-	$\frac{1}{8}$ "
	-	-	-	-	-	$\frac{3}{16}$ "
	-	-	-	-	-	$\frac{1}{4}$ "
	-	-	-	-	-	$\frac{5}{16}$ "

From No. 5. to No. 9. the diameter decreases by regular gradations, the latter being only $\frac{1}{16}$ of an inch.

The operation is always carried on with three cullenders at a time; which are supported upon projecting grates of a kind of chafing dish made of sheet iron somewhat like a triangle. This chafing dish should be placed immediately above the fall; while at its bottom there must be a tub half filled with water for receiving the granulated lead. The cullenders are not in contact, but must be parted by burning charcoal in order to keep the lead constantly at the proper temperature, and to prevent its solidifying in the filter. The temperature of the lead bath should vary with the size of the shot; for the largest, it should be such that a bit of straw plunged into it will be scarcely browned, but for all it should be nicely regulated. The height from which the particles should be let fall varies likewise with the size of the shot; as the congelation is the more rapid, the smaller they are. With a fall of 33 yards or 100 feet, from No. 4 to No. 9 may be made; but for larger sizes, 150 feet of height will be required.

Everything being arranged as above described, the workman puts the filter-stuff into the cullender, pressing it well against the sides. He next pours lead into it with an iron ladle, but not in too great quantity at a time, lest it should run through too fast. The shot thereby formed and found in the tub are not all equal.

The centre of the cullender being less hot affords larger shot than the sides, which are constantly surrounded with burning charcoal. Occasionally, also, the three cullenders employed together may have holes of different sizes, in which case the tub may contain shot of very various magnitudes. These are separated from each other by square sieves of different fineness, 10 inches broad and 16 inches long, their bottoms being of sheet iron pierced with holes of the same diameter as those of the cullenders. These sieves are suspended by means of two bands above boxes for receiving the shot; one sieve being usually set above another in consecutive numbers, for instance, 1 and 2. The shot being put into the upper sieve, No. 0 will remain in it; No. 1 will remain in the lower sieve, and No. 2 will, with all the others, pass through it into the chest below. It is obvious that by substituting sieves of successive fineness, shot of any dimensions may be sorted.

In the preceding process the shot has been sorted to size; it must next be sorted to form, so as to separate all the spheroids which are not truly round, or are defective in any respect. For this purpose a board is made use of about 27 inches long and 16 broad, furnished partially with upright ledges; upon this tray a handful or two of the shot to be sorted being laid, it is inclined very slightly, and gently shaken in the horizontal direction, when the globular particles run down by one edge, into a chest set to receive them, while those of irregular forms remain on the sides of the tray, and are reserved to be re-melted.

After being sorted in this way, the shot requires still to be smoothed and polished bright. This object is effected by putting it into a small octagonal cask, through a door in its side, turning upon a horizontal iron axis, with rests in plummer boxes at its ends, and is made to revolve by any mechanical power. A certain quantity of plumbago or black lead is put in along with the shot.

LEAD, CARBONATE OF. See WHITE LEAD.

LEAD, NITRATE OF (*Nitrate de plomb*, Fr.; *Salpeterminerale bleinayd*, Germ.), is made by saturating somewhat diluted nitric acid with oxide of lead (litharge), evaporating the neutral solution till a pellicle appears, and then exposing it in a hot chamber till it be converted into crystals, which are sometimes transparent, but generally opaque white octahedrons. Their spec. grav. is 4.068; they have a cooling, sweetish, pungent taste. They dissolve in 7 parts of cold, and in much less boiling water; they fuse at a moderate elevation of temperature, emit oxygen gas, and pass into oxide of lead. Their constituents are 67.4 oxide and 32.6 a. l. Nitrate of lead is much employed in the chrome yellow style of CALICO-PRINTING; which see.

There are three other compounds of nitric acid and lead oxide; *v. z.* the li-basic, the tri-basic, and the se-basic; which contain respectively 2, 3, and 6 atoms of base to 1 of acid.

LEAD, OXICHLORIDE OF. A white pigment patented by Mr. Hugh Lee Patinson of Newcastle, which he prepares by precipitating a solution of chloride of lead in hot water with pure lime water, in equal measures; the mixture being made with agitation. As the operation of mixing the lime water, and the solution of chloride of lead, requires to be performed in an instantaneous manner, the patentee prefers to employ for this purpose two tumbling boxes of about 16 feet cubic capacity, which are charged with the two liquids, and simultaneously upset into a cistern in which oxichloride of lead is instantaneously formed, and from which the mixture flows into other cisterns, where the oxichloride subsides. This white pigment consists of one atom of chloride of lead and one atom oxide of lead, with or without an atom of water.

LEAD, SALTS OF. The salts of lead, beyond those already named, which enter into any of our manufactures, are few and unimportant. *Ure's Dictionary of Chemistry* should be consulted for them.

LEATHER (*Cuir*, Fr.; *Leder*, Germ.; *Leer*, Dutch; *Læder*, Danish; *Läder*, Swedish; *Cuojo*, Italian; *Cuero*, Spanish; *Kusha*, Russian.). This substance consists of the skins of animals chemically changed by the process called *tanning*. Throughout the civilized world, and from the most ancient times this substance has been employed by man for a variety of purposes. Barbarous and savage tribes use the skins of beasts as *skins*; civilised man renders the same substance unalterable by the external agents which tend to decompose it in its natural state, and by a variety of peculiar manipulations prepares it for almost innumerable applications.

Although the preparation of this valuable substance in a rude manner has been known from the most ancient times, it was not until the end of the last, and the beginning of the present century (1800) that it began to be manufactured upon right principles, in consequence of the researches of Macbride, Deyceux, Seguin, and Davy.

Skins may be converted into leather either with or without their hair; generally, however, the hair is removed.

The most important and costly kinds are comprised under sole leather and upper leather, to which may be added harness leather, belts used in machinery, leather hose, &c., but as far as the tanner is concerned, these are comprehended almost entirely in the kinds known as upper leather.

The active principle by which the skins of animals are prevented from putrefying, and at the same time, under some modes of preparation, rendered comparatively impervious to water, is called tannin, or tannic acid, a property found in the bark of the various species of *Quercus*, but especially plentiful in the gall-nut. When obtained pure, as it may easily be from the gall-nut, by chemical means, tannic acid appears as a slightly yellowish, almost a colourless mass, readily soluble in water; it precipitates gelatin from solution, forming what has been called *tannogelatin*. Tannic acid also precipitates albumen and starch. There can be little difficulty, after knowing the chemical combination just alluded to, in understanding the peculiar and striking change produced on animal substance in the formation of leather. The hide or skin consists principally of gelatin, for which the vegetable astringent tannin has an affinity, and the chemical union of these substances in the process of tanning produces the useful article of which we are treating.

Before entering upon the various processes by which the changes are effected on the animal fibre, it may not be uninteresting to speak of some of the principal astringents used for the purpose of producing these effects.

Bark obtained from the oak-tree is the most valuable and the most extensively used ingredient in tanning, and for a long time no other substance was used in England for the purpose. In consequence of the demand having become very much greater than the supply, and the consequent increase in the price of the article, it became necessary to investigate its properties, in order, if possible, to furnish the required quantity of tanning matter from other sources. Among other substitutes which were tried with some success in other countries may be mentioned *hæth*, *myrtle leaves*, *wild laurel leaves*, *birch-tree bark*, and (according to the *Penny Cyclopædia*) in 1765 oak sawdust was applied in England, and has since been used in Germany for this purpose.

Investigation proved that the tanning power of oak bark consisted in a peculiar astringent property, to which the name of *tannin* has been given, and this discovery suggested that other bodies possessing this property would be suitable substitutes.

According to Sir H. Davy the following proportions of tannin in the different substances mentioned will be found:—"8½ lbs. of oak bark are equal to 2½ lbs. of galls, to 3 lbs. of sumach, to 7½ lbs. of bark of Leicester willow, to 11 lbs. of the bark of the Spanish chestnut, to 18 lbs. of elm bark, and to 21 lbs. of common willow bark."—*Penny Cyclopædia*.

OAK BARK contains more tannin when cut in spring by four and a half times, than when cut in winter; it is also more plentiful in young trees than in old ones. About 40,000 tons of oak bark are said to be imported into this country annually, from the Netherlands, Germany, and ports in the Mediterranean. The quantity of English oak bark used we have no means of ascertaining. It is prepared for use by grinding it to a coarse powder between cast iron cylinders, and haul into the tanpits alternately with the skins to be tanned. Sometimes, however, as will be hereafter noticed, an infusion of the bark in water is employed with better effect.

MEMORA.—The bark and pods of several kinds of *Prosofia*, the astringent properties of which have rendered them valuable in tanning, are known in commerce by this

1104

1103

name. The *Mimosa* are a division of the leguminous order of plants, which consists of a large number of species, the *Acacia* being the principal. The sensitive plants

belong to this division. The propolis is found in India and South America; the genus consists both of shrubs and trees.

VALONIA.—The oak which produces this acorn is the *Quercus Fagifolia*, or great prickly cupped oak (figs. 1101, 1103). These are exported from the Morro and Levant; the husk contains abundance of tannin.

CATECHU, or Terra Japonica, is the inspissated extract of the *Azadirachta indica*. At the time the sap is most perfectly formed the bark of the plant is taken off, the tree is then felled, and the outer part removed; the heart of the tree, which is brown, is cut into pieces and boiled in water; when sufficiently boiled it is placed in the sun, and subject to various manipulations, gradually dried. It is cut into square pieces, and much resembles a mass of earth in appearance; indeed it was once considered to be such, hence the name *Terra Japonica*.

We give Sir H. Davy's analysis; the first numbers represent Bombay, the second Bengal catechu:—

Tannin	-	-	-	-	-	169	-	97
Extractive	-	-	-	-	-	68	-	73
Mucilago	-	-	-	-	-	13	-	16
Impurities	-	-	-	-	-	10	-	14

This astringent is also obtained from the *Uncaria Gambir*.

DALBERGIA is a leguminous plant of the genus *Casalpinia*, *C. coriaria*. The legumes of this species are extremely astringent, and contain a very large quantity of tannic acid and gallic acid; they grow in a very peculiar manner, and become curiously curled as they arrive to perfection. The plant is a native of America, between the tropics.

1106

Fig. 1106.

SEMAEN is a plant belonging to the genus *Illus*; several of the species have astringent properties; *Illus cotinus* and *Illus coriaria* are much used in tanning; the bark of the latter is said to be the only ingredient used in Turkey for the purpose of converting gelatin into leather. That used

in this country is ground to a fine powder, and is extensively applied to the production of bright leather, both by tanners and curriers.

Many other vegetable products have been from time to time proposed, and to some extent adopted for the same end, but they need not be enumerated.

The process first attended to by the tanner is simply to soak the skin or hide in water; those from the home market may be said to be washed merely, as they remain in water only a few hours; while hides imported from foreign countries, and which have been preserved by salting or drying, and especially the latter, require soaking for a longer period, in order to render them supple, and beating or rubbing materially assists in bringing them to the required condition.

After removing the horns, the softened or recent hides are laid in a heap for a short time, after which they are suspended on poles in a close room called a smoke-house, heated somewhat above the common temperature by a smouldering fire. In these circumstances, a slight putrefaction supervenes, which loosens the epidermis, and renders the hair easily detachable. This method for removing the hair is by no means general in this country. The plan adopted is to place the hides in a large vat or pit containing milk of lime, in which they must be moved frequently, to allow the lime to act equally on every part. When the menstruum has taken proper effect, the hair is easily removed, and for this purpose the hide is spread out, and a blunt tool is worked over the surface. The hair being removed, the hide is washed in water to cleanse it from the lime, which must be most thoroughly effected.

The heaviest hides are for the most part tanned for sole leather, and as the thinner parts are cut off previous to their being prepared for sale, they have received the name of *butts* or *backs*; the various processes through which these pass will be first described.

After removing the hair and washing, the hides are placed on a convex beam (fig. 1107), and worked with a concave tool with two handles (fig. 1108), in order to remove any flesh or fatty matter which may adhere to them; this being done they are worked on the same beam, on the grain side, to drive out the grease and remove any remaining hair. The *flaskings* are pressed into cakes and sold for making glue, as are all such portions of the hide or skin as cannot be conveniently worked. The hair is sold to plasterers, to be used in their mortar, and the tails, also for the hair, to sofa-makers and others requiring such materials.

Such hides as are designed for machinery purposes are next immersed in a pit containing water impregnated with sulphuric acid, the acid varying from $\frac{1}{10}$ to $\frac{1}{20}$ of the mixture. This process is called *raising*, because it distends the pores, and makes the fibres swell, so as to become more susceptible of the action of tanning infusions. Forty-eight hours in general suffice for this operation, but more time may be safely taken. From the term *raising* it will be concluded that the substance of the hide is increased, and this is the fact; but as the gelatine is not increased it is said that the shoemaker's hammer would condense the leather so much that it would lose any supposed advantage arising out of this increase in thickness. There is, however,

a method of augmenting the substance of sole leather called *puffing*, which, when once communicated, appears to exist permanently; the process is known to a small extent only, and the material is said to be considerably injured by this mode of preparation.

When the hides are sufficiently raised, they are transferred to a pit supplied with a weak infusion of bark; here they are handled, at first several times a day, that is, they are drawn out of the pits, or moved up and down in the liquor, to prevent the grain from being drawn into wrinkles. As the case, or tanning infusion, takes effect, they are put into pits containing stronger liquors, and after a month or six weeks they are placed in a pit, in which they are stratified with oak bark, ground by a proper mill into a coarse powder. The pit is then filled with an infusion of bark. In a month or five weeks the tanning and extractive matter of the bark will have intimately combined with the animal fibre; the pit, exhausted of its virtue, must be renewed by taking out the spent bark and repeating the dose as in the first instance. The hides, which were placed at the top of the pit at first, are now put into the bottom, to equalise the action. In about three months this also is spent, and the process being repeated two or three times more the operation is complete. The hides are now removed from the pit, and hung up in a shed. In the progress of drying they are compressed with a steel tool, and afterwards they are subjected to the action of a brass roller. The steel tool is called a *pin*; it is of a triangular shape (fig. 1109), with the sides scooped out (fig. 1110), presenting three blunt edges. The butt is thrown across a pole,

and the workman taking the pin by the handles *a, a* (fig. 1109), presses it forcibly over the grain side of the leather; after carefully compressing every part in this way, the butt is laid upon a flat bed of solid wood-work, prepared for the purpose, and the brass roller is worked backward and forward until every portion is sufficiently compressed (fig. 1111). The roller *a* is a cylinder varying from 9 to 12 inches in length, and from

7 or 10 inches in diameter; & is an open box over the roller, into which weights are placed to make the necessary pressure, let or two or three being frequently used for the purpose; & c. c. forms a flume for driving the roller from the bed to the leather; & in the hands of which the machine is worked. When the preparation is completed, the only thing remaining to be done is properly to dry the leather, and then to fit it for the market.

Some manufacturers place on the bottom of the tan pits five or six inches of Spanish bark, and two or three inches of fresh bark over it, then a hide, and an alternating bark and a hide, until they get tolerably full, reserving a small space at the top for a thicker layer of bark, over which weighted boards are laid, to condense the water down into the tanning infusion.

The operation of tanning cow leather by the above method occupies a year or more, the time depending on the use and condition of the hide.

A perfect leather is recognised by its colour, which should have a greenish marbled appearance, without any white streak in the middle.

Crop hides are manufactured very much like butts, that is to say, they are piled in much of time until the hair is sufficiently loosened, equality of colour being preserved by occasionally moving them to the sun or stream; they are then cleared of the hair and other impurities by the *strake*, a knife, worked on the convex beam already described; they are then freed from lime by thorough washing. The next process is to immerse them in a weak lime frame, which they are transferred to other pits with stronger ones; and the while they are frequently handled, that is, moved up and down in the infusion. After a month or six weeks they are subjected to a mixture of ground oak bark and stronger lime in other pits, in a series of which they are progressively subjected during two or three months.

The hides are next put in large vats called *layers*, in which they are thoroughly stratified, with more bark and a stronger infusion. After about six weeks they are taken out of these vats, and subjected to a new charge of this material, and allowed to lay some two months; this process is repeated until or twice more till the skins are thoroughly tanned. They are then slowly dried in the shed, and fitted for the market. Although in general the stouter and most valuable part hides are used as sole leather (without any that they have not been employed by the tanner, as to the case of *lows*), yet many are appropriated to other purposes by the currier, and the lighter cow hides are manufactured for the upper leather of boots, shoes, water boots, &c.

The process of tanning *skins* (as calves, seals, &c.) next claims attention. These are placed in the lime pits until the hair can be easily removed, a process which requires about ten or twelve days; this being accomplished, they are next washed in water so as completely to remove the lime, as far as washing can secure its removal, and then immersed in a *lixivium* of pigeon's dung, dog's dung, or matters of a like nature, in this state they remain about ten or twelve days, the state of the atmosphere rendering the process quicker at one time than another, here also they are frequently handled, and worked on both sides on the convex beam. The working, joined to the action of the peculiar *lixivium*, serves to separate the remaining lime, oil, and glutinous matter, and at the same time to render the skin pliant, soft, and ready to imbibes the tanning principle. It is important that great attention should be paid to the process just described, as too short a period would produce a hard and crisp leather, while a few hours more than is necessary makes the article coarse and spongy, both of which conditions should be very carefully guarded against.

The skins are next removed to a pit containing a weak solution of bark, in which they undergo nearly the same treatment as *crop hides*, but they are not commonly stratified in the layers. About three months is usually occupied in tanning calskins, but of course the stouter the skin the more will be the time required. When dried they are disposed of to the currier, who dresses them for the upper leathers of boots, shoes, and a variety of other purposes. It is not unusual for the lighter cow hides to be treated like calskins.

Horse hides are also treated like calskins; but as the horse hide, with the exception of the part on and near the animal's rump, produces a thin leather, it is usual, before subjecting the hide to the action of the bark, to cut out what is called the *butt*, which is tanned separately, and frequently used as an inferior sole leather. It is also to be remarked that horse hides and *lows* (the hides of small foreign cattle) are frequently subjected to a process called *bate skining*, in which the stout parts are reduced by a currier's knife previous to tanning, the object being to secure the complete infiltration of the animal fibres by the tannin in every part of the hide in the same time.

Sheepskins are usually prepared before the wool is removed, and before the tanning process is commenced, to get rid of the fatty matter contained in them, and which is not readily removed by ordinary working.

In all the above processes, as the animal skins on the surface of the skin absorb more readily the tanning liquor, and therefore the first is a certain device, their parts are the more or less equally of thick hide, it becomes an almost important matter to secure a uniformity of covering that of stable, and preventing the penetration of the air. The first man for ever who appears to have employed effective means for the purpose of facilitating the chemical action was Francis G. Spalding, who in April, 1812, obtained a patent for the following operation. — After the hides are freed from the hair, &c. in the usual way, they are usually inspected as to the condition, and if any holes be found, they are carefully sewed up, so as to be water tight. Two frames of wood are provided of equal dimensions, fitted to each other, with the edges of the frames held together by screw bolts. A skin about to be tanned is now laid upon the frame, and stretched over its edges, then the second frame is to be placed upon it, so that the edges of the two frames may pinch the skin all round and hold it securely; another such skin is then stretched over the upper surface of the second frame, in the manner, and a third frame being set upon this, confine the second skin. The three frames are then pushed tightly together by a series of screw bolts, passing through their outer edges, which fix the skin in a proper manner for being operated upon by the tanning liquor.

A space has been thus formed between the two skins, into which, where the frames are set upright, the liquor is introduced by means of a pipe from the cistern above, while the air is permitted to escape by a stopcock below. The cock must of course be closed whenever the bag is filled; but the one above is left open to maintain a communication with the liquor cistern, and to allow the hydrostatic pressure to force the liquor through the cutaneous pores by a slow infiltration, and thus to bring the tannin into contact with all the fibres indiscriminately. The action of this process is evinced by a constant perspiration on the outer surfaces of the skins.

When the tanning is completed, the upper stopcock is closed, and the under is opened to run off the liquor. The frames are now removed, the bolts are unscrewed, and the pinched edges of the skins pared off; after which they are to be dried and finished in the usual manner.

A modification of this ingenious and effectual process was made the subject of a patent by William Blake, of Westminster, tanner, in October, 1831. The hides, after the usual preparatory processes, are immersed in a weak tan liquor, and by frequent handling or turning over, receive an incipient tanning before being submitted to the impregnation plan. Two hides, as nearly of the same size and shape as possible, are placed grain to grain, when their corresponding edges are sewed firmly together all round by shoemaker's waxed thread, so as to form a bag sufficiently tight to hold tan liquor. This bag must then be suspended by means of loops sewed to its shoulder end, upon poles, in such a manner that it may hang within a wooden-barred rack, and be confined laterally into a hook form. About an inch of the bag is left unsewed at the upper end, for the purpose of introducing a funnel through which the cold tan liquor is poured into the bag till it be full. After a certain interval, which varies with the quality of the hides, the outer surface becomes moist, and drops begin to form at the bottom of the bag. These are received in a proper vessel, and when they accumulate sufficiently may be poured back into the funnel; the bag being thus, as well as by a fresh supply from above, kept constantly distended.

When the hides are observed to feel hard and firm, while every part of them feels equally damp, the air of the tanning apartment, having been always well ventilated, is now to be heated by proper means to a temperature gradually increasing from 70° to 100° of Fahrenheit's scale. This heat is to be maintained till the hides become firmer and harder in all parts. When they begin to assume a black appearance in some parts, and when the tan liquor undergoes little diminution, the hides may be considered to be tanned, and the bag may be emptied by cutting a few stitches at its bottom. The outer edges being pared off, the hides are to be finished in the usual way. During their suspension within the racks, the hides should be shifted a little at intervals, to prevent the formation of furrows by the bars, and to facilitate the equable action of the liquor.

By this process the patentee says, that a hide may be tanned as completely in ten days as it could be in ten months by the usual method.

Messrs. Knowles and Duesbury obtained a patent in August, 1826, for accelerating the impregnation of skins with tannin, by suspending them in a close vessel, from which the air is to be extracted by an air pump, and then the tanning infusion is to be admitted. In this way, it is supposed to penetrate the hide so effectually as to tan it uniformly in a short time.

Danish leather is made by tanning lamb and kid skins with willow bark, whence it derives an agreeable smell. It is chiefly worked up into gloves.

Of the tanning or dressing of skins for shoes, and other deep leather.

The operations of this art are, 1, washing the skins, 2, properly treating them with lime, 3, taking off the hair, 4, treatment in the leather camp.

A shed erected upon the side of a stream, with a pattern of water for washing the skins, wooden frames for cleaning them, with the back of the tanning house; pumps for removing the fibres of deer-skins, with a platform for drying them; pits, a lime-pit, a pile with a bar to lift the end of it into the tanning-house; a rolling-pin, from 13 to 15 inches long, thickened in the middle. Such are some of the utensils of a tanning establishment. There must be provided also a table for applying oil to the skins; a fluting mill, worked by a water-wheel or other power, a dressing-jug, a press for squeezing out the fatty matter, a stove, plants suspended upon bars, for stretching the skins, &c.

Fresh skins must be washed immediately after being washed, and then dried, unless they ferment, and contract cuts and holes, which, if got into in certain points, so as to open up and tear under the skin. When removed to the dry state they should be steeped in water for two days, and then treated as fresh skins. They are next strongly rubbed on the convex side with a round-edged knife, in order to remove the plants. The rough parts are removed by the fluting knife. One workman can in this way prepare 200 skins in a day.

The flesh side of each being rubbed with a cold cream of lime, the skins are piled together with the woolly side of each pair outward, and the flesh side in contact. They are left in this state for a few days, till it is found that the wool may be easily removed by plucking.

They are next washed in running water, to separate the greater part of the lime, stripped of the wool by the fluting knife, and then freed from it by means of the rolling-pin, or sometimes by rubbing with a waterstone. Unless they be fluted soon after this treatment with lime, they do not well admit of this operation, inasmuch as they are apt to get hard.

They are now steeped in the milk of lime-pit, in order to swell, soften, and remove them; afterwards in a weak pit of old lime-water, from which they are taken out and drained. This steeping and draining upon inclined tables, are repeated frequently during the space of 3 weeks. Truly the skins of young animals, or those of inferior value are now left in the water till the wool is left on, so for home use, &c.

The skins, after having been well altered in the steep, are rubbed on the outside with a whetstone set in a wooden case with two handles, in order to cleanse them completely by removing any remaining filaments of wool. These skins are rubbed with the pin in the direction of their breadth, to give them suppleness; but these skins are filled with water alone. They are now ready for the branning, which is done by mixing 40 lbs. of bran with 20 gallons of water, and keeping them in this fermentable mixture for three weeks—with the addition, if possible, of some old bran water. Here they must be frequently turned over, and carefully watched, as it is a delicate operation. In the course of two days in summer, and eight in winter, the skins are said to be raised, when they sink in the water. On coming out of the bran, they are ready for the white stuff; which is a bath composed of alum and sea-salt. Twelve, fourteen, and sometimes eighteen pounds of alum for 100 skins, form the base of the bath; to which two and a half pounds of salt are added in winter, and three in summer. These ingredients are introduced into a copper with twelve gallons of water. The salt aids in the whitening action. When the solution is about to boil, three gallons of it are passed through the cullender into a basin, in this 26 skins are worked one after another, and after draining, they are put together into the bath, and left in it for ten minutes to imbibe the salts. They are now ready to receive the paste. For 100 skins, from 13 to 15 pounds of wheat flour are used, along with the yolks of 20 eggs. After having warmed the alum bath through which the skins have been passed, the flour is dusted into it, with careful stirring. The paste is well kneaded by the gradual addition of the solution, and passed through the cullender, whereby it becomes as clear as honey. To this the yolks being added, the whole is incorporated with much manual labour. The skins are worked one after another in this paste; and afterwards the whole together are left immersed in it for a day. They are now stretched and dried upon frames, in a proper apartment, during from 8 to 15 days, according to the season.

The effects of the paste are to whiten the skins, to soften them, and to prevent them from the hardening influence of the atmosphere, which would naturally render them brittle. They would not bear working upon the dressing iron, but for the emulsion which has been introduced into their substance. With this view they are dipped in a tub of clear water during five or six minutes, and then spread and worked upon the board. They are increased by this means in length, in the proportion of 3 to 2. No hard points must be left in them. The whiteness is also better brought out by this

of the skin, which is performed upon the flesh side. The softening tool is an iron plate, about one foot broad, rounded over at one end, and upon an upright beam, the other high, which is fixed to the end of a strong wooden plank, 4 feet long, and 1 broad. This plank is heavily loaded, to make it immovable upon the floor. Sometimes the skins are first spread over an undressed plank upon the floor, and worked well with the two handled knife, for the purpose of removing the first and second epidermis, and the flour and arrow flour is the French name. They are then dried while stretched by hands and straps. When dry they are worked on the stretching iron, or they are occasionally polished with pumice stone. A delicate yellow tint is given by a mixture made of two parts of white sugar and one of oil, applied in a powdered state, and well worked in upon the grain side. After being polished with pumice, they are smoothed with a hot iron, as the islands now do linen, whereby they acquire a degree of gloss, and are ready to be delivered to the glazer.

For harness, the best sheepskins are selected, and such as are covered with the longest and most bran full wool. They are stretched in water, in order to be cleaned and polished; after which they are tanned inside by the stretching knife. They are now stretched in an old brass pit for 3 or 4 days, when they are taken out and washed. They are next stretched to the white or flesh bath, the wool being carefully folded so that a small quantity of oil can be used for it. The paste is made as for the dressed skins, and is evenly spread upon the flesh side, and left upon them for 12 hours, and is then washed. They are then hung up to dry. They are next mounted by sprinkling cold water upon them, folded up, piled in a heap, and covered with heavy wetted with heavy stones, in which state they remain for two days. They are next opened with a round knife upon the horse, and subjected to the stretching iron, being worked between the hands. They are dried with the floor underneath, in the sun if possible, and are finished upon the stretching iron.

Half and lambskins with their hair and wool are worked nearly in the same manner; only the thicker the skin, the stronger the oil in both ought to be. One pound of lard and one of salt are required for a single calf skin. It is left for days in this bath, after which it is worked upon the stretching, then tanned. When half dry, the skins are opened upon the horse. In eight days of ordinary weather, they may be completely dressed. Lamb skins are sometimes steeped during eight days in a bath prepared with unbolthead rye flour and cold water, in which they are daily moved about two or three times. They are then dried, stretched upon the iron, and stretched upon the fleecy side.

Shammy, or Shammy leather — The skins are first washed, limed, de-fatted, and blanched as above described. They are next *efflowered*, that is deprived of their epidermis by a blunt knife, blunt in its middle part, upon the convex horse-beam. The cutting part serves to remove all excrescences, and to equalise the thickness, while the blunt part softens and smooths. The skins of goats, does, and chamois are always treated in this way. They are next subjected to the fermenting brass steep for one or two days, in ordinary water; but in hot weather for a much shorter time, sometimes only moving them in the warm brass liquor for a few minutes. They are lastly wrung at the peg, and subjected to the falling mill.

When the skins have been sufficiently swelled and supplied by the branning, they may receive the first oil as follows: a dozen skins being stretched upon the table, the fingers are dipped in the oil, and shaken over the skins in different places, so as to impart enough of it to rub into the whole surface slightly, by friction with the palms of the hands. It is to the outside or grain that the oil is applied. The skins are folded four together, so as to form balls of the size of a hog's bladder, and thrown into the trough of the falling mill, to the number of twelve dozen at once. Here they remain exposed to the heater for two, three, or four hours, according to their nature and the state of the weather. They are taken out, stretched, oiled, and again folded. The stretching and folding are repeated several times, with more or less frequent oilings. Any cheap animal oil is employed.

After these operations, the skins require to be subjected to a fermenting process, to dilate their pores, and to facilitate their combination with the oil. This is performed in a chamber only 8 feet high, and 10 or 12 feet square. Poles are suspended horizontally a few inches from the ceiling, with hooks fixed in them to which the skins are attached. A somewhat elevated temperature is maintained, and by a stove if need be. This operation requires great skill and experience.

The remainder of the epidermis is next removed by a blunt concave knife and the horse, whereby the surface is not cut, but rather forcibly scraped.

The skins are now scoured to carry off the redundant oil; which is effected by a potash lye, or E. Hamel, heated no hotter than the hand can bear. In this they are stirred briskly, steeped for an hour, and lastly wrung at the peg. The scapy liquor thus expelled is used for inferior purposes. The clean skins after being dried are finished first on the stretching iron, and then on the horse or stretching frame.

Leather of Hungary.—This is manufactured by suspending strips of hides with claws, common salt, and yeast, by a rapid process, which is usually commenced in the spring of the year. The workshop is divided into two parts: 1. A kind of the pole of a narrow furnace with a wooden frame, having a grate, and other small parts. In one corner is a furnace with a boiler for heating the steam, a vat for dissolving the skins in the solution, and several subsidiary tubs. 2. A chamber, 6 feet high, by 12 feet square, capable of being made very tight, for preserving the heat. In one corner is a copper boiler, of cast-iron, into which an iron grate is placed, and a small square. This is covered with a floor. At each side of the room are large tables, which occupy its whole length, and on which the leather is spread to receive the grime. The upper part below the ceiling is filled with poles for hanging the leather open to be heated. The door is made to shut perfectly close.

The first operations are analogous to those of tanning and tawing; the skins being washed, cut in halves, shaved, and composed of 24 hours in the river. They are then cleaned with 3 or 4 pounds of alum, and 25 pounds of salt, for a pound of hide which weighs from 50 to 60 pounds. The common salt withdraws the effect of the alum, attracts the moisture of the air, and preserves the supple nature of the skin. When the alum and salt are dissolved, hot water is poured upon the hides placed in a vat, and they are tramped upon by a workman walking repeatedly from one end of the vat to the other. They are then transferred into a smaller vat containing some hot water, and similarly tramped upon. They are next steeped for eight days in alum water. The same round of operations is repeated a second time.

The skins are now dried either to the air, or a stove room; but before being quite dry, they are doubled together, well stretched to take out the wrinkles, and put up. When dry, they are again trampled to open the pores as well as to remove the skin plant, after which they are whitened by exposure to the sun.

Tallow of inferior quality is employed for greasing the leather. With this view the hides are hung upon the poles in the close stove room, then laid upon the table, and lubricated with the tallow melted till it begins to crackle. This pole is laid on another table, is there covered with a second, similarly greased, and so forth. Three pounds of fat are commonly employed for one piece of leather.

When the thirty strips, or fifteen hides, passed through the grease in one operation are completed, two workmen take the first piece in their hands, and stretch it over the burning charcoal on the grate for a minute with the flesh side to the fire. The rest are passed over the flame in like manner. After flowing the pieces are successively laid on an inclined table exposed to the fire, where they are covered with a cloth. They are finally hung upon poles in the air to dry; and if the weather be warm, they are suspended only during the night, so as to favour the hardening of the grain. Instead of the alum bath, M. Caraudan has employed with advantage a steep of dilute sulphuric acid.

Russian leather.—The Russians have long been possessed of a method of making a peculiar leather, called by them *jarten*, dyed red with the aromatic saunders wood. This article has been much sought after, on account of not being subject to mould in damp situations, being proof against insects, and even repelling them from the vicinity of its odour. The skins are freed from the hair or fleece, by steeping in an alkali too weak to act upon the animal fibres. They are then rinsed, soaked for a longer or shorter time according to their nature, and fermented in a proper steep, after having been washed in hot water. They are taken out at the end of a week, but they may be steeped a second time if deemed necessary, to open their pores. They are now cleaned by working them at the horse on both the flesh and grain sides.

A paste is next composed, for 200 skins, of 38 pounds of rye flour, which is set to ferment with yeast. This dough is worked up with a sufficient quantity of water to form a bath for the skins, in which they are soaked for 48 hours; they are then transferred into small tubs, where they remain during fifteen days, after which they are washed at the river. These operations serve to prepare the skins for absorbing the astringent juices with uniformity. A decoction of willow bark (*Salix cinerea* and *Salix caprea*) being made, the skins are immersed in the boiler whenever the temperature of the liquor is sufficiently lowered not to injure the animal fibres, and handled and pressed for half an hour. This manipulation is repeated twice daily during the period of a week. The tanning infusion is then renewed and applied to the same skins for another week; after which, being exposed to the air to dry, they are ready for being dyed, and then carried with the empyreumatic oil of the bark of the birch tree. To this substance the Russian leather owes its peculiarities. Many modes have been prescribed for preparing it; but the following is the one practised in Russia.

The whitish membranous epidermis of the birch, stripped of all woody parts, is introduced into an iron boiler, which, when stuffed full, is covered tight with a vat and

iron still, having a pipe rising from its centre. A second boiler into which this pipe passes without reaching its bottom, is set over the first, and is luted to it at the edges, after the two are held together. They are then inverted, so that the upper one contains the bark bark. The under half of this apparatus is sunk in the earth, the surface of the upper boiler is covered over with a clay lute, then surrounded with a fire of wood, and exposed to a red heat, till the distillation be completed. This operation, though rude in appearance, and wasteful of wood, answers its purpose perfectly well. The iron cylinder apparatus used in Britain for distilling wood vinegar would, however, be much more convenient and productive. When the above lutes are united, there is found in the upper boiler a very light powder of charcoal, and in the under one, which served as a receiver, there is an oily, brown, empyreumatic fluid, of a very strong smell, which is mixed with the tar, and which flows over a small quantity of crude vinegar. The former matter is the oil employed to impregnate the skins, by working it into the flesh side with the carrier's tumb. It is difficult to make this oil penetrate with uniformity; and the Romans do not always succeed in this process, for they turn out many skins in a spotted state. This oil is at present burned in France by distilling the bark bark in copper stills, and condensing the products by means of a glass placed in cold water. About ten per cent. of the weight of the bark is extracted.

The skins which are oil are equally before they are fully dry. Care must be taken not to apply too much of it, for fear of its passing through and staining the grain side of the leather. Chevreul has investigated the chemical nature of this odorous substance, and finding it to be a peculiar compound, has called it *betanhar*.

In the *Franklinian* for February, 1844, Mr. Gideon Lee has published some judicious observations on the process of tanning. He believes that much of the animal gelatine of the hides is never combined with the tannin, but is wasted; for he thinks that 100 lbs. of perfectly dry hide, when cleaned from extraneous matter, should, on chemical principles, afford at least 100 lbs. of leather. The usual preparation of the hide for tanning he believes to be a wasteful process. In the liming and liming, or the unhairing and the cleansing, the general plan is first to steep the hides in milk of lime for one, two, or three weeks, according to the weather and texture of the skin, until the hair and epidermis be so loosened as to be readily removed by rubbing down, by means of a knife, upon a beam or block. Another mode is to compound the hides in a close chamber, heated slightly by a smouldering fire, till the epidermis gets loosened by ineffectual putrefaction. A third process, called sweating, used in tanneries, consists in laying the hides in a pack or pile, covered with tan, to promote fermentative heat, and to loosen the epidermis and hairs. These plans, especially the two latter, are apt to injure the quality of the hides.

The *hate* consists in steeping the haired hides in a solution of pigeon's dung, containing, Mr. Lee says, muriate of ammonia, murate of soda, &c.; but most probably phosphate of ammonia and lime, with urate of ammonia, and very fermentable animal matter. The dry hides are often subjected first of all to the operation of the fulling-stocks, which opens the pores, but at the same time prepares them for the action of the liming and beating also for the introduction of the tanning matter. When the fulling is too violent, the leather is apt to be too limber and thin. Mr. Lee conceives that the liming is injurious, by carrying off more or less of the gelatine and albumen of the skin. High limed leather is loose, weighs light, and wears out quickly. The subsequent fermentation in the bating aggravates that evil. Another process has therefore been adopted in New York, Maine, New Hampshire, and some parts of Philadelphia, called, but incorrectly, cold sweating, which consists in suspending the hides in a subterranean vault, in a temperature of 50° Fahr., kept perfectly damp, by the trickling of cold spring water from points in the roof. The hides being first soaked, are suspended in this vault from 6 to 12 days, when the hair is well loosened, by the mere softening effect of moisture, without fermentation.—H. M.

LEATHER, MOROCCO. (*Marroquin*, Fr.; *Saffian*, Germ.) Morocco leather of the finer quality is made from goat-skins tanned with sumach; inferior morocco leather (roan) from sheep skins. The goat skins as imported are covered with hair; to remove which they are soaked in water for a certain time, and they are then subjected to the operation called breaking, which consists in scraping them clean and smooth on the flesh side, and they are next steeped in lime pits (milk of lime) for several days, during which period they are drawn out, with a hook, from time to time, laid on the side of the pit to drain, and replunged alternately, adding occasionally a little lime, whereby they are eventually deprived of their hair. When this has become sufficiently loose, the skins are taken out one by one, laid on convex beams, the work benches, which stand in an inclined position, resting on a stool at their upper end, at a height convenient for the workman's breast, who scrapes off the hair with a concave steel blade or knife, having a handle at each end. When unhaired, the skins are once more soaked in milk of lime for a few days, and then scraped on the flesh

side to render it very even. For removing the lime which obstructs their pores, and would impede the tanning process, as well as to open these pores, the skins are steeped in a warm semi-putrid alkaline liquor, made with pigeons' and hens' dung diffused in water. Probably some very weak acid, such as fermented bran water, would answer as well, and not be so effective to the workmen. (In Germany the skins are first washed in a barrel by a revolving axle and discs.) They are again scraped, and then sewed into bags, the grain outward, like bladders, leaving a small orifice, into which the neck of a funnel is inserted, and through which is poured a certain quantity of a strong infusion of the sumach; and they are now rendered tight round the orifices, after being filled out with air, like a blown bladder. A parcel of these inflated skins are thrown into a very large tub, containing a weaker infusion of sumach, where they are rolled about in the middle of the liquor, to cause the infusion within to act upon their whole surface, as well as to expose their outanles uniformly to the tanning action of the bath. After a while these bladder skins are taken out of the bath, and piled over each other upon a wooden rack, whereby they undergo such pressure as to force the enclosed infusion to penetrate through their pores, and to bring the tannin of the sumach into intimate contact, and to form a chemical combination with the skin fibres. The tanning is completed by a repetition of the process of introducing some infusion or decoction into them, blowing them up, and floating them with agitation in the bath. In this way goat skins may be well tanned in the course of one day.

The bags are next undone by removing the sewing, the tanned skins are scraped as before on the carriers' bench, and hung up in the drying loft or shed; they are said now to be "in the crust." They are again moistened and smoothed with a rubbing tool before being subjected to the dyeing operations, in which two skins are applied face to face to receive the dye to one of their surfaces only, for the sake of economising the dyeing materials, which may be of several different colours. The dyed skins are graded by being strongly rubbed with a ball of box wood, finely grooved on its surface.

Preparatory to being dyed, each skin is sewed together edgewise, with the grain on the outside, and it is then mordanted either with a solution of tin, or with alum water. The colour given by cochineal, of which from 10 to 12 ounces are required for a dozen of skins. The cochineal being boiled in water along with a little tartar or alum for a few minutes, forms a red liquor, which is filtered through a linen cloth, and put into a clean cask. The skins are immersed in this bath, and exposed to it for about half an hour; they are taken out and beaten, and then subjected to a second immersion in the cochineal bath. After being thus dyed, they are rinsed and tanned with Sicilian sumach, at the rate of two pounds for a skin of moderate size. The process is performed in a large tub made of white wood, in the liquor of which the skins are floated like so many bladders, and moved about by manual labour during four hours. They are then taken out, drained, and again subjected to the tanning liquor; the whole process requiring a space of twenty-four hours. The skins are now unstitched, rinsed, filled with beetles, drained, rubbed hard with a copper blade, and lastly hung up to dry.

Some manufacturers brighten the colour by applying to the surface of the skins, in a damp state, a solution of carmine in ammonia with a sponge; others apply a decoction of saffron to enliven the scarlet tint. At Paris, the morocco leather is tanned by agitation with a decoction of sumach in large casks made to revolve upon a horizontal axle, like a barrel churn. White galls are sometimes substituted for sumach; a pound being used for a skin. The skins must be finally cleaned with the utmost care.

The black dye is given by applying with the brush a solution of red acetate of iron to the grain side. Blue is communicated by the common cold indigo vat; violet, with a light blue followed by cochineal red; green, by Saxon blue followed by a yellow dye, usually made with the chopped roots of the barberry. This plant serves also for yellows. To dye olive, the skins are first passed through a weak solution of green vitriol, and then through the decoction of barberry root, containing a little Saxon blue. Peach colour is communicated by logwood with a little alum; which may be modified by the addition of a little Brazil wood. In all these cases, whenever the skins are dyed, they should be rinsed, wrung, or rather drained, stretched upon a table, then besmeared on the grain side with a film of linseed oil applied by means of a sponge, in order to promote their glossiness when carried, and to prevent them becoming horny by too rapid drying.

The last process in preparing morocco leather is the currying, which brings out the lustre, and restores the original suppleness. This operation is practiced in different manners, according to the purpose the skins are to serve. For pocket-books, portfolios, and case-making in general, they must be thinned as much as possible upon the flesh side, moistened slightly, then stretched upon the table, to smooth them; dried

again, moistened, and lastly passed two or three times through the cylinder press in different directions, to produce the crossing of the grain. The skins intended for the shoemaker, the saddler, the bookbinder, &c., require more pliancy, and must be differently curried. After being thinned, they are glazed with a polisher while still moist, and a grain is formed upon the flesh side with the roughened lead plate or grainer of the curriers, called in French *pommelle*; they are glazed anew to remove the roughness produced by the pommel, and finally grained on the flesh side with a surface of cork applied under a pommel of white wood.

TAWING OF SKINS. (*Mégisserie*, Fr.; *Wassgerberei*, Germ.) The kid, sheep, and lamb skins, are cleaned as has been already described. In some factories they receive the tanning power of the submuriate of alumina (from a solution of alum and common salt) in a large barrel-churn apparatus, in which they are subjected to violent agitation, and thereby take the *alumine* in the course of a few minutes. In other cases, where the yolks of eggs are added to the above solution, the mixture, with the skins, is put into a large tub, and the whole trampled strongly by the naked feet of the operator, till the emulsion of the egg be forced into the pores of the skin. The tawed skins, when dry, are "staked," that is stretched, scraped, and smoothed by friction against the blunt edge of a semi-circular knife, fixed to the top of a short beam of wood set upright. The workman holding the extremities of the skin with both hands, pulls it in all directions forcibly, but skilfully, against the smoothing "stake."

In an entertaining article on tanning in the 11th vol. of the *Penny Magazine*, at page 215, the following description is given of one of the great tawing establishments of London.

"In the production of 'imitation' kid leather, the skin of lambs is employed; and for this purpose lamb-skins are imported from the shores of the Mediterranean. They are imported with the wool yet on them; and as this wool is valuable, the leather manufacturer removes this before the operations on the pelt commence. The wool is of a quality that would be greatly injured by the contact of lime, and therefore a kind of natural fermentation is brought about as a means of loosening the wool from the pelt." The following is a description of one of the buildings. "On the ground floor, a flight of stone steps leads down to a range of subterranean vaults or close rooms, into which the lamb-skins are introduced in a wet state, after having been steeped in water, 'broken' on the flesh side, and drained. The temperature of these rooms is nearly the same all the year round, a result obtained by having them excluded as much as possible from the variations of the external atmosphere; and the result is, that the skins undergo a kind of putrefactive or fermenting process, by which the wool becomes loosened from the pelt. During this chemical change ammonia is evolved in great abundance; the odour is strong and disagreeable; a lighted candle, if introduced, would be instantly extinguished, and injurious effects would be perceived by a person remaining long in one of the rooms. Each room is about ten feet square, and is provided with nails and bars whereon to hang the lamb-skins. The doors from all the rooms open into one common passage or vault, and are kept close, except when the skins are inspected. It is a point of much acuity to determine when the fermentation has proceeded to such an extent as to loosen the wool from the pelt; for if it be allowed to proceed beyond that stage, the pelt itself would become injured.

When the fermentation is completed, generally in about five days, the skins are removed to a beam, and there "skimed," that is, scraped on the flesh side, to remove a slimy substance which exudes from the pores. The wool is then taken off, cleaned, and sold to the hatters, for making the bowles of common hats. The stripped pelts are steeped in lime-water for about a week, to kill the grease; and are next "steaked on the beam." After being placed in a "drench," or a solution of sour bran for some days to remove the lime and open the pores, the skins are skimed, and subjected to nearly the same processes as the true kid-skins. These Mediterranean lamb-skins do not in general measure more than about 24 inches by 12; and each one furnishes leather for two pairs of small gloves. These kinds of leather generally leave the leather-dresser in a white state, but undergo a process of dyeing, softening, "stoking," &c., before being cut up into gloves.

The tanning of one average-sized skin requires about 1½ lbs. of good Sicilian sumach; but for leather which is to receive a bright scarlet dye, from one half to three quarters of a pound of gall-nuts are employed in preference. Inferior goat skins are tanned with a willow bark infusion, in pits, in which they are turned repeatedly, and laid out to drain, as in tanning sole leather. The finest skins for the brightest scarlet are cured with salt, to prevent their receiving damage in the transport, and are dyed before being tanned. This method is practiced in Germany and France.

Leather of deer and sheep skins is prepared with oil, for the purpose of making breeches, &c., and for wash-leather, used in cleaning plate. After they are completely

washed, limed, and beamrd, as above described, they have their "grain"-surface removed, to give them greater softness and pliability. This removal of the grain is called "frizing," and it is done either with the round edge of a blunt knife, or with pumice-stone. After being freed from the lime by steeping in fermented bran-water, they are pressed as dry as may be, and are then impregnated with cod-oil, by beating with stocks in the trough of a kind of fulling mill. Previously to the application of the oil, they are usually beat for some time alone to open their substance. The oiled skins are stretched, hung up for some time in the air, then filled with oil as before—a process which is 8 or 9 times repeated. The oil is slowly and evenly poured upon the skins in the trough during the action of the beaters. One hundred skins usually take up in this way from two to three gallons of oil. The filled oil skins are thrown into large tubs, and left for some time to ferment, and thereby to combine more intimately with the oil. They are lastly subjected to a weak potash lye bath, to strip them of the loosely adhering oil. They are then hung up in the air to dry, and dressed for the market.—H. M.

LEATHER, RUSSIAN, as tanned at Kazan. The hides to be tanned may be either fresh from the animal or dry, no matter which; they are first laid to soak for 3 days and nights in a solution of potash, to which some quicklime is added. The potash used is made of the tree called in Russ *dim* (the common elm), which sort is said to be preferable to any other, if not essential; it is not purified, so that it is of a brown colour and of an earthy appearance; about 12 pounds of this (the pound is 36 lbs. English), and 2 pounds of lime, serve for 100 skins. As they have no way of ascertaining the degree of causticity of the alkali but by its effect upon the tongue, when they find it weak they let the skins lie longer in the solution.

When the skins are taken out of this solution they are carried to the river, and left under water for a day and a night.

Next a vedro of dog's dung is boiled in as much water as is enough to soak 50 skins, (the vedro is equal to 2096 English Imperial gallons) but in the winter time, when the dung is frozen, twice that quantity is found necessary. The skins are put into this solution, not while it is boiling hot, but when at the heat which the hand can bear; in this they lie one day and one night.

The skins are then sewed up so as to leave no hole; in short, so as to be water-tight; about one third of what the skin will contain is then filled up with the leaves and small twigs chopped together of the plant called in Russ *Toloknanka* (*Aribulus uva-ursi*, sometimes called bear berry), which is brought from the environs of Solikamskaya, and the skin is then filled up with water.

The skins thus filled are laid one on the other in a large trough, and heavy stones upon them, so as by their weight to press the infusion through the pores of the skin in about 4 hours; yet, as it was said at the same time, that the skins are filled up with the same water which had been pressed out 10 times successively, and that the whole operation takes but one day and one night, this leaves but 2½ hours for each time.

The skins are then taken to the river and washed, and are ready for the dyeing. The whitest skins are laid aside for the red and yellow leather.

(The operations in dyeing follow, but are here omitted.)

To soften the skins after dyeing, they are harassed by a knife, the point of which is curved upwards.—H. M.

LEATHER, CURRYING OF. The currier's shop has no resemblance to the premises of the tanner, the tools and manipulations being quite different.

Within the last twenty or thirty years, many tanners have added the currying business to their establishments, and many-curriers have likewise commenced tanning; but in each case, an extension of premises is necessary, and the two departments are still separate. The advantage derivable from this arrangement are two-fold.—first, a saving of time is effected, for as the tanned leather is sold by weight, it is required to be well dried before being disposed of to the currier, an operation which is not needed where the tanner carries on the currying also; and secondly, by the currier's art, the skins can be reduced to a comparatively uniform thickness previous to their being tanned, thus saving time and *work* (used for tanning), and insuring a more equal distribution of tannin through the substance of the skin. In the following description, the business of currying will be considered as practised at the present time.

The currier's shop or premises, to be convenient, should be spacious. A frequent, though not universal method, is to have the ground-floor appropriated to such operations as require the use of a large quantity of water. The place or apartment thus used, is called the *scouring-house*, and is commonly furnished with a number of *cuts* or *casks open at one end*, in which the leather is placed for the purpose of soaking, and undergoing such treatment as will be hereafter describable. In this apartment also is placed a large, flat, slate stone, called a *scouring-stone*, or, more consistently, the

stones on which the leather is scoured. This stone, which has its face perfectly flat and smooth, and which should measure 8 or 9 feet in length, by $4\frac{1}{2}$ broad, forms a table, supported generally by masonry, but sometimes by a strong frame of wood, so constructed, that the water, which is freely used in scouring, may drain off on the opposite side from that on which the workman is engaged; an inclination of about three or four inches on the width of the table, is sufficient for this purpose. Another piece of furniture very frequently found in, or on the same floor with the scouring-house, is a block of sandstone, in the form of a parallelopipedon, between 2 and 3 feet long, and 9 or 10 inches broad, the upper face of which is kept as near as possible a perfect plane; this stone is fixed at a convenient height on a strong trussel, and is called the *rub-stone*, because here the workman rubs or sharpens his knives and other tools. In some large establishments where the premises and water are heated by steam, the scouring-house will be found with a service of pipe leading to the various vats, and the boiler, for generating the steam, may be conveniently placed in or near this part of the building.

The floor above the scouring-house, in the arrangement here laid down, is what is specially designated the *shop*. The furniture in this department consists of a beam, (fig. 1112) on which the leather is shaved. It consists of a heavy block of wood, on which the workman stands, and into one end of which a stiff piece of wood is firmly mortised, at an angle of about 85° ; this upright (so called) is about a foot wide, the height being greater or less, according to the height of the workman, each of whom has his beam adjusted to meet his convenience. On the front of the upright, a piece of deal is firmly screwed, to which is glued a face or plate of *lignum vite*, worked to perfect smoothness to agree with the edge of the knife used in the operation of shaving. It is of the greatest importance to the workman, to keep his skin from injury, that his knife and beam should be kept in good order. A table or tables, generally of mahogany, large planks of which are used for the purpose to avoid joints, may be said to form a necessary part of the furniture of this department. These tables are firmly fixed, to resist the pressure of the workman when using various tools; and as light is of the greatest consequence in the operations performed on them, they are usually placed so as to have windows in front of them. A high trussel is frequently used, across which the leather is thrown, after undergoing any of the processes, while the carrier subjects other pieces to the same operation.

Another part of the premises is termed the *drying loft*. In good buildings the drying loft is surrounded with *weather boards*, constructed to be opened or closed as may be required. The use of this part being the drying of the leather, the ceiling is furnished with a number of rails or long pieces of wood, with hooks or nails on which to hang the leather for drying, and where steam is used for this purpose, the floor is traversed with pipes for heating the loft. Here also is a table, similar to that previously described; it should not be less than 7 or 8 feet long by $4\frac{1}{2}$ broad, if possible, without joint, and with a smooth face.

There are other subordinate departments, each furnished with a table similar to those described.

Of the tools used in currying, the knife stands first in importance (fig. 1113). Here *a* and *b* are two handles, *a* is held in the left hand, and forms a powerful lever when the edge *c* is applied to the leather. The blade of the currier's knife is peculiarly tempered; it is composed of a plate of fine steel, strongly riveted between two plates of iron. This instrument is taken to the *rub stone*, and ground to a perfectly sharp edge by successively rubbing forward and backward, care being taken to keep the edge true, that is, straight. When this has been satisfactorily accomplished, it is still further rubbed on a fine Scotch or Welsh stone called a *clearing-stone*, until the scratches of the *rub-stone* disappear.

In this operation a fine thread or wire forms on the edges, for the knife has two edges (*cc*) which must be carefully got rid of; after which it is wiped dry, and the edges greased with tallow or oil. The workman then takes a strong steel, and placing himself on his knees, he fixes the straight handle *b* against any firm body, and the cross handle *a* between his knees; then holding the steel in both hands

be carefully rubb'd forward and backward the whole length of the edge. During this operation the knife is gradually raised by means of the handle *a*, until it is nearly perpendicular; by this means the edge is turned completely over. If the knife is not well tempered, the edge thus obtained will be irregular, or broken; in either of which cases it is of no use whatever.

To keep the instrument just described in proper order requires great skill on the part of the currier. The edge is so delicate and liable to injury that it cannot be used

1114

more than a minute or two without losing its keenness. To restore this a very carefully prepared small steel is used, *fig. 1114*; the point of the steel is first run along the groove which is formed by turning the edge over, and the steel is then made to pass outside the edge (*fig. 1210*). It is remarkable that a skilful hand can thus restore the efficiency of the knife, and keep it in work for hours without going for a new edge to the *rub-stone*. The other tools will be described as their uses are mentioned.

The first thing done by the currier is the soaking of the leather received from the tanner in water; the skin requires a thorough wetting, but not to saturation. In some cases the thicker parts are partially soaked before the immersion of the whole, and when from the nature of the skin this cannot be done, water is ap-

1116

1115

1117

plied to the stout parts after the dipping; it is requisite that the whole should be as near as possible equally wet. In some instances the wetted leather is beaten, and sometimes a coarse graining-board (hereafter to be described) is used, to make it more supple previous to shaving it. The skin is then laid over the beam (*fig. 1116*) and the rough fleshy portion is shaved off. This operation is generally called *shaving*. In all the operations at the *beam* the leather is kept in its place by pressure of the knees or body of the workman from behind. In *shaving* the right hand handle of the knife somewhat precedes the left, but in *shaving*, properly so called, the left hand precedes the right, *fig. 1117*. In *shaving* the knife is driven obliquely a few inches at a time, in shaving it is driven with great force, not infrequently from the top to the bottom of the beam; great skill is requisite in the performance of these operations, to guide the knife and to keep its edge. The carpenter's plane can be most completely regulated by the projection of the plane iron from the wood, but the currier's knife admits of no such arrangement, and the unskilful currier is constantly liable to injure the leather by cutting through it, as well as by failing to produce a regular substance. The

kind of skin, and the use for which it is designed will regulate the work at the beam. In some cases, as in the calf-skin, it is skived and then shaved, or, (as it is called) *flattened* at right angles to the skiving — in other kinds, as the cow-hide prepared for the upper leather of heavy shoes, after skiving it is *skaved across* (i. e. nearly at right angles to the skiving), and *flattened* by being again shaved in the same direction as the skiving. In some manufactories there are certain kinds of leather which are subjected to the operation called by carriers *stomung*, before *flattening*; this is done by forcibly driving the *stock-stone* (fig. 1115) over the grain side of the leather, thereby stretching it, and rendering the grain smooth. The *flattening* process is considerably facilitated by this stomung, and the skin has been allowed slightly to harden by exposure to air, and the edge of the knife is fine, as it should be, the workman has but to strike the flat part of the knife over the leather after the shaving is performed, to produce a beautiful face to the flesh side of the skin. It will not be difficult to understand that

1115

1119

a good hand is easily distinguished from an inferior one in this part of the business. With such nicety and a skilful workman set the edge of his knife, that although there seems nothing to guide him, he can take shaving after shaving from the hide extending from the top to the bottom of the beam, thus rendering the leather extremely even in its substance.

After the process of shaving is completed, the leather is placed in water, where it remains until it is convenient to carry on the operation next required. It is to be observed that in the condition in which leather is shaved, it cannot long be kept without becoming heated; when, however, it is put into water, it is safe from injury, and may be kept a very long time, provided the water be occasionally changed for a fresh, sweet supply; stale water is regarded as injurious for the skin to remain in.

Scouring is next proceeded with; the skin is taken out of the water, and laid on the scouring-stone. In respectable manufactories, it is usual first to *scour on the flesh*; this is done by passing a *slicker* smartly over the flesh side, by which the *grain* of the leather is brought into close contact with the scouring-stone, and, being in a wet condition, the air is easily excluded, so that the leather *sticks* to the stone. A plentiful supply of water is now applied, and a large brush, with stiff hairs, is rubbed over the flesh, or upper side. Portions of the surface, in a pulpy condition, come off with the scrubbing, and the skin presents a soft, whitened, pulpy appearance; the pores are rendered capable of containing more moisture, and, altogether, the leather is much benefited. The *slicker* is a plate of iron or steel, or for particular purposes, of brass or copper; it is about five inches long, and like the *stock-stone*, is fixed in a stock, or handle (fig. 1119). It is sharpened at the *rub-stone*, by grinding the plate perpendicularly, and then on either side, thus producing two edges (or rather, right angles). The edges thus produced are not of an order to cut the leather, but rather to *scrape* it. The *slicker* is not intended to remove irregularities in the leather but its uses are various, and it may be considered a very important tool as will hereafter appear.

In the process of *tanning* the grain side of the hide or skin becomes covered with a whitish body, derived from the bark called *blom*; this is more or less difficult to remove according to the hardness or softness of the water used in tanning, and the peculiar treatment of the tanner. It is, however, the carrier's business to remove it, which he effects thus:—In the case of leather, whose grain is *tender*, as *cordovan*, which is manufactured from horse hides, the grain being kept uppermost, the leather is spread on the scouring-stone, and being plentifully supplied with water, is stretched by using the *slicker*, or a fine pebble, ground to the shape of the *stock-stone*, the *blom* is thus loosened, and, at the same time, by making it adhere to the scouring-stone, the next operation is readily carried on, which consists in smartly brushing the grain with a stiff-haired brush, at the same time keeping a quantity of water on the surface, the *slicker* is again used to remove the water and loosened *blom*, and the scouring is complete. In the scouring of calf-skins, and cow or ox hides, the *stock-stone* is used to fix the leather, and a piece of pumice-stone, the face of which has been ground to smoothness, and afterwards cut in grooves, is then forcibly rubbed over the grain, in order to remove the *blom*. In this, as in other operations, on the scouring-stone, water is a necessary ingredient. The *blom* being sufficiently loosened by the pumice-stone, the brush is used to scrub up the remaining dirt, which is then

removed by the stock-stone or slicker. In harness leather, which is stout, and requires to be stretched as much as possible, the pumice-stone is seldom used, the stock-stone and scouring-brush being lustily applied until the bloom is sufficiently removed. Ordinary manufacturers within the present (nineteenth) century, have considered the operations of the scouring-house complete at this point. The modern currier takes a different view, and not unfrequently detains his scoured property for days, and sometimes for weeks in the scouring-house.

If the leather is imperfectly tanned, or it is required to be made of a bright colour, there are other processes to be passed through. In these cases sumach (an evergreen shrub of the natural order *Anacardiaceæ*, genus *Rhus*, and from the bark of which all the leather made in Turkey is said to be tanned) is infused in boiling water, and when cooled to a tepid state the leather is placed in it. After staying a sufficient time it is taken to the scouring-stone; if *corduan*, it is slicked as dry as can be well accomplished on the *flesh* side; other leather is for the most part slicked in a similar way on the grain side. Saddle leather which is required to be of a bright colour is still farther placed in warm water slightly acidulated with sulphuric or oxalic acid, or both; here for a time it is kept in motion, then taken to the scouring-stone, it is washed with peculiar chemical lotions, according to the taste or knowledge of the workman; then again it is dipped in tepid sumach infusion, then slicked with a copper or brass slicker (iron is liable to stain leather thus prepared), and a thin coat of oil being applied to either side it is removed to the drying-loft. Until within a very few years, much time and trouble were taken to produce very bright leather for the saddler; but of late, brown-coloured leather has been adopted to a considerable extent, as it is less liable to become soiled. Nearly all leather is placed a short time in the loft before farther manipulations are carried on, in order to harden it slightly by drying.

In the drying loft, or its immediate vicinity, the leather receives the *dubbing* (dubbing, probably) or *stuffing*. The substance so called is composed of tallow brought to a soft plastic condition by being melted and mixed with *cod-liver* oil; occasionally *wal* (an oil made in preparing sheep skins) is in very small quantities added to the mixture. This is laid upon the leather either with a soft haired brush or a mop made generally of rags.

The leather is prepared for stuffing by wetting slightly such parts as have become too dry. It is then taken to the table previously described, which being slightly oiled the process is carried on by placing the skin on the table in the manner most convenient for stretching it and making the surface smooth. In those kinds that have a rough wrinkled grain the *flesh* side is placed next the table and the *stock-stone* is used very smartly to stretch and smooth the grain. A kind of clamp or holdfast, composed of two cheeks fastened with a screw, is sometimes used to prevent the leather from moving during this operation, but in general these are not required; the slicker is then applied to remove the marks left by the *stock-stone*, and a thin stuffing being spread over the grain it is turned over, slicked on the *flesh* lightly, a coat of *stuffing* is spread over it, and it is hung up to dry. In those kinds which have to be blacked (or stained) on the grain, a little *cod* oil only is spread on the grain, and the slicker is applied on the *flesh* side most laboriously previous to *stuffing*. Much skill is required to give the requisite quantity of *stuff* (dubbing) to the leather without excess, excess being injurious, and the quantity required is farther regulated by the freshness or otherwise of the leather, the tan-yard from which it comes, and the treatment it has received in the scouring-house.

When dry, the skins or hides are folded together, to remain until required. It is certain the leather improves by remaining some weeks in this condition. It should be observed that, in drying, the leather absorbs a large quantity of the oleaginous matter with which it is charged, and the unabsorbed portion forms a thick coating of hardened greasy matter on the *flesh* side.

Leather which has to be blackened on the *flesh* (*wax leather*), from this point, receives different treatment from grain leather. *Wax leather* is taken to the *shup-side* and softened with a *graining-board*. The skin is laid on the table and doubled,

1121

1120

grain to grain, the *graining-board* (fig. 1121), which is confined to the hand by a leather strap (u o), is driven forward and drawn back alternately until a grain is raised on the

leather, and it has attained the required suppleness. Observe, the graining-board is slightly rounded on the lower surface, and traversed by parallel grooves from side to side, which are coarser or finer, as occasion requires. The grease is next removed from the flesh by the slicker, and afterwards a sharp slicker is passed over the grain to remove grease or other accumulations from it. The next process is called *whitening*. The leather is laid over the *beam*, and a *knife* with an extremely fine edge is used to take a thin shaving from the flesh side; this is a point at which a currier's skill is tested. The knife used is one that has been very much worn, the quality of which has been tested to the utmost; and so extremely true is the edge expected, that not the slightest mark (*scratch*) is allowed to appear on the surface of the leather. Only a good workman can satisfactorily accomplish this. The slightest gravel in the flesh of the skin may break the edge of the knife in pieces, and it is not easy to rectify so serious a misfortune; besides, a poor workman may tear up the edge by *steeling*, an operation which ought to mend the mischief instead of provoking it.

A fine *graining-board* is next used to soften the leather; the stiffer parts being *boarded* both on the grain and flesh sides, and the operation being carried on in two or three directions, to insure both softness and regularity of grain. *Flouring* is performed by doubling the leather and driving the double part forward and drawing it back by the graining-board.

The leather is now prepared for the *waxer*, and passes, consequently, into his hands. Waxing, in large establishments, is a branch considered separate from the general business, and is usually in the hands of a person who confines himself to this occupation alone. The skin is laid on a table and the *colour* rubbed into the flesh side with a brush. It is necessary to give the brush a kind of circular motion to ensure the required blackness in the leather. The *colour* is made by stirring a quantity of the best lampblack into *cod-liver oil*; sometimes a little *dabbing* is added, and in order to make it work smoothly so as not to clog the brush, some stale *tan water* from the vat in the scouring house is *beaten* up with the mixture until it combines therewith. The preparation of the *colour* is an important affair, and requires a considerable amount of time and labour to render it such as the *waxer* desires.

A *slick-stone*, or *glass*, is next used; this tool is about the size and shape of the slicker, but instead of being ground like it, the edges are very carefully removed, so that while, from end to end, it preserves nearly a right line, it is circular across the edge. The *stone* (a fine pebble) is little used now, plate-glass being substituted for it. The use of the tool just described is to smooth the flesh after the operation by the colouring brush, thereby getting rid of any marks made on the surface.

The next step in waxing is what is called *sizing*. Size is prepared by boiling glue in water—the melted glue is diluted with water to the extent required—in some cases it is softened by mixing *cod-liver oil* with it in cooling. When cold, it is beaten up with various ingredients, according to the taste or experience of the *waxer*; the *waxer* then well rubs the size into the coloured side of the leather, and with a sponge, or, more generally, the fleshy part of his hand, smooths it off. When dry, the *slick-stone*, or *glass*, is again applied, thus producing a polish on the size; and a very thin coat of oil completes the work. In different manufactories different methods are pursued, but the above is convenient and satisfactory in almost all circumstances. It is now ready for the shoemaker.

Leather intended to be blacked on the grain, is left folded up when dry after stuffing. Some years ago it was the custom to stain these kinds of leather, while wet in the scouring-house, by spreading stale urine over it and then applying a solution of *copperas* (sulphate of iron). That method is now exploded. The dry skins or pieces of leather are laid on the shop-board; a brush is used to saturate the grain with urine, or so is now more common, a solution of soda in water, and a peculiar preparation of iron is afterwards laid over it, which blackens the surface. It may be observed that in wax-leather a body of black is laid on, and rubbed into the flesh; in grain leather the black is a stain. After the blackening, it is necessary to rub a small quantity of oil or *dabbing* over the blackened surface, then turning the oiled grain toward the table, a sharp slicker is used on the flesh side; the leather sticks to the table by means of the oil, and the slicker is driven so smartly over it, that it is *stretched* on the table, at the same time that the grease is removed. It is quite an important point to take *all the stretch* out of the leather in this operation, after which it is turned over; the flesh is covered with a very thin coat of hard tallow, a roll of tallow being rubbed over the table, for the purpose of keeping the leather fastened to it. A dull slicker is used on the grain to remove remaining marks and wrinkles, or to smooth any coarse appearance on the grain; a sharp slicker removes all the grease, and a thin coat of weak size, made of glue dissolved in water, is spread over it and the process, usually called *seasoning*, is completed. The next object is carefully to dry the *seasoned* leather, and in this state it may be stored without injury.

The next step is very similar to that described in the case of *raw leather*, and called *whitening*:—it is then softened by means of a fine graining-board, or a board of the same shape and size covered with cork, the grain side is placed next the table, and the flesh doubled against the flesh, and thus driven forward and backward until the required degree of suppleness is obtained. The loose particles of flesh are brushed off and a slicker carefully passed over the grain removes all marks of the last operation. If a sufficiency of stuff has not been applied in the drying-loft, the deficiency is remedied by a coat of *tallow-dubbing* now spread over the grain and allowed to remain some hours. As the leather absorbs the oily matter a hardened coat of grease has to be removed by the aid of the slicker. The leather is then sized, and a very thin coat of oil spread over the size, completes the operation.

In the preparation of various kinds of leather, or of leather for particular purposes, the currier has particular appliances. Harness leather is considerably dryer than other kinds before stuffing, and is subjected to immense labour by the stock-stone and slicker, to procure a smooth grain. It is blackened when dry like other grain leather, but instead of the oiling and other processes described, the hardest tallow procurable is rubbed into it, *stained* with a fine pebble, slicked, and tallow again rubbed into it by the hand. When dry after this operation, the grease is slicked from the flesh side, and a repetition of the tallowing, stoning, and rubbing finishes the work.

Saddle leather, which is cut into comparatively small pieces, after hardening in the drying loft, is passed through a very different process from any described previously. The skin of the hog is much used for certain parts of hackney saddles, and the bristles, when removed by the tanner, leave indentations, or even holes in the tanned skin. Probably it was deemed desirable to obtain some imitation for the parts of the saddle where the hog skin was not suitable. The skin of the dog-fish (*Squalium*, Cuv.), to some extent supplied the imitation, having hard tubercles on its surface. At first the skin was laid on the leather and lustily pressed into it by rubbing it with a pebble or plate of glass; at length a press was invented, and more recently various methods have been proposed to produce the best effect. We have here (fig. 1122) a

1122

representation of one of these presses, which may stand as a type of all others: *a a* are the feet into which the uprights are inserted; *b b* are the two upright sides tied at the top by *c*, a similar cross piece ties them a little above the feet; *d* is a leaf fastened with hinges, which closes upon *c* when the press is not in use; *e e* are screws which press off the iron plate, in which the axes of the roller *f* are inserted. These plates imbedded in the uprights *b b* have considerable play, so as to allow the rollers *f f*

more or less pressure as the case may require. The dotted line *i i'*, represents an iron bar or cylinder, supplied with a small cog wheel at *i'*, and a *crank-handle j*, this is turned round by the hand, and the small cog wheel acts on a larger one *k*, which is attached to the axis of the roller *f*. *f* is a solid roller of hard wood, such as *lynum vite*; upon this cylinder is strongly glued the *fish skin*, previously alluded to; *h* is a cylindrical solid piece of wood covered with stout flannel; *l* is a piece of leather on which the leather to be pressed is placed; when all is adjusted the piece to be pressed is placed on *h*, the handle is moved slowly round, and the whole is carried between the rollers; the leather thus receives the imprint of the *fish skin*, and at the same time becomes extremely soft. After drying, this is fit for the saddler.

Of late years the currier has undertaken an office which was previously the business of the boot maker; namely, the *blocking* of boot fronts. This is performed by the instrument represented by *fig. 1123*. The leather is first dressed, as previously

1123

described, up to the point of being ready for *whitening*. The fronts are then cut (*fig. 1123 a*), and when folded or doctiled appear as *fig. 1123 b*. 1' 1', 1 1, is a strong frame-work; 2, represents a pair of cheeks, strongly fastened in the frame, and regulated as to distance by a screw, these cheeks are lined with zinc; 3 is a strong plate of metal, the angle at 3 corresponding exactly with the angle of the cheeks; the ends of this plate are fixed in movable plates passing down the columns 1' 1'; 4 is a handle by which the instrument is worked, and which by cog-wheels acting on the movable plates brings 3 downwards. The front, *a*, is laid, after a thorough soaking in water,

over the check 2, the handle being turned, it comes down upon the front, and forces it through the small opening between the checks, and when brought out below the checks, it has the appearance here given (fig. 1124). The piece 3 having passed the front between the checks, is removed (lower), and the weight 3 comes in bringing the perpendicular movable plate in their place, when 3 is again put in position, and thus the operation is rapidly carried on. After this the fronts are regularly placed on a block, being bound into position by an instrument called the *flange* (fig. 1124) and held in their place, after this they are slightly dried and

1124

dried. Some ingenious methods have been adopted for softening the fronts, so as not to disturb the blocking. They are whitened on a very sloping beam (fig. 1125), which enables the workman to hold them better than he could on the common beam. They

1125

are again blocked by the water, and when these processes are carefully performed, much trouble is saved to the boot-maker. Of course, in a manufactory many appliances are found which are not here mentioned; the general idea, however, may be easily gathered from this description. The work is dirty and very laborious, requiring great skill and experience, and consequently good workmen have generally commanded better wages than other mechanics.

It has intended for covering coaches are shaved as thin as shoe blades, and blocked on the grain.—H. M.

LEATHER SPLITTING. This operation is employed sometimes upon certain sorts of leather for gloves, for bookbinders, shoemakers, and always to give a uniform thickness to the leather destined for the soles and wing card-shoes.

Figs 1126, 1127, 1128, 1129 represent a well constructed machine for that purpose, of which *fig. 1126* shows the front view, *fig. 1127* a view from the left side, *fig. 1128* a ground plan, and *fig. 1129* a vertical section across the machine. *a* is a strong table, furnished with four legs *b*, which to the right and left hand bears two horizontal pieces *c*.

1126

Each of these pieces is cut out in front, so as to form in its substance a half-round fork, that receives a cylinder *d*, carrying on its end a toothed spur-wheel *e*. Motion is communicated to the wheel by means of the handle *f*, upon whose axis the pinion *i* is fixed,

1128

1127

working into the wheel *d*, made fast to the end of the cylinder round which the leather is rolled. The leather is fixed at one of its ends or edges to the cylinder, either with a wedge pressed into a groove, or by a movable *g*, one of the cylinder itself.

The table, *a*, is cut out lengthwise with a slot, that is widened below, as shown in *fig. 1128*.

The knife *k* (*figs. 1128* and *1129*) is fixed flat upon the table with screw bolts, whose heads are countersunk into the table, and secured with taps beneath (*fig. 1129*), the edge of the knife being placed horizontally over the opening, and parallel with it.

In *fig. 1128* the leather, *l*, is shown advancing against the knife, getting split, and has a portion curled round the cylinder, which is made to revolve in proportion as the leather is cleft. The upper portion of the leather is rolled upon the cylinder *d*, while the under half, *l*, falls through the oblong opening upon the ground.

In regulating the thickness of the split leather, the two supports, *m*, act; they are made fast to the table (one on each side of the knife), and are mortised into the table by two *n*, secured beneath. These supports are furnished near their tops with keyed slots, by means of which the horizontal iron rod *o* (*figs. 1127*, *1128*) is secured,

and each of the uprights they press upon the springs *p p*, which tend to raise the *rod o* in its two end slots; but the adjusting screws *q*, which pass down through the tops of the

supports into the mortise *a* (fig. 1128), and press upon the upper half of the divided *rod o*, counteract the springs, and accordingly keep the *rod o* exactly at any desired height or level. The *rod o* carries another iron bar, *r*, beneath it, parallel and also rectangular, fig. 1128. This lower bar, which is rounded at its under face, lies upon and presses the leather by the action of two screws, which pass through two upright pieces *s* (figs. 1126 and 1128) made fast to the table; thus the iron bar *r* may be made to press forwards the edge of the knife, and it may be adjusted in its degree of pressure, according to the desired thickness of the leaf of split leather that passes through under it.

Fig. 1129 shows that the slant or obliquity of the knife is directed downwards, over one of the edges of the oblong opening *g*; the other edge of this opening is provided with an iron plate *t* (figs. 1128, 1129), which serves to guide the blade in cutting the leather to the proper depth. For this purpose the plate is made adjustable by means of the four springs *u* (fig. 1129) let into the table, which press it downwards. Four screws, *v*, pass down through the table, each belonging to its respective spring *u*, and by means of these screws the plate *t* may be raised in any desired degree. Each of the screws *v* has besides a small rectangular notch through which a screw bolt *x* passes, by which the spring is made fast to the table. Thus also the plate *t* may be made to approach to or recede from the knife.

y, in figs. 1126 and 1128, is a flat board, laid upon the leather a little behind the edge of the plate *t*; this board is pressed by the cylinder *z*, that lies upon it, and whose tenons rest in mortises cut out in the two supports *a'*. The cylinder *z* is held in its position by a wedge or plate, *b* (figs. 1126 and 1127), which passes through the supports. When the leather has been split, these pins are removed, and the cylinder rises then by means of two counter-weights, not shown in the figures.

The operation of the machine is as follows:—The edge or end of the leather being secured to the cylinder *d*, the leather itself having the direction upon the table shown in fig. 1128, and the bar *r* in its proper position over the knife, the edge begins to enter in this position into the leather, while the cylinder *d* is moved by the handle or winch, and the piece gets split betwixt the blade and the roller *d*. When the other end of the leather, *A*, advances to the knife, there is, consequently, one half of the leather split; the skin is to be then rolled off the cylinder *d*; it is turned; the already split half, or the end of the leather, *A*, is made fast into the wood of the cylinder, and the other half is next split; while the knife now acts from below, in an opposite direction to what it did at first.

That the unrolling of the leather from the cylinder, *d*, may not be obstructed by the pinion *i*, the stop-wedge *e* (figs. 1126, 1127) is removed from the teeth. In the process of splitting, the grain side of the leather is uppermost, and is therefore cut of an uniform thickness, but the under side varies in thickness with the inequality of the skin.

Several other ingenious contrivances have been introduced for this purpose, illustrated descriptions of which have been given by *Hibbert*, who states that a splitting-machine, long used by the *Mesars*, *Beverington*, of *Bermondsey*, had been made to split sheepskins into three equal parts, one of which, that on the grain side, might be used as leather; the middle portion converted into parchment; and the slice on the flesh side, being unequal in thickness, and therefore unfit for any better use, being used for glue making. In this machine the skin is drawn between two revolving rollers, and presented, as it emerges from their grasp, to the edge of a long and very sharp knife, which is kept continually moving a little backwards and forwards with great velocity. As a skin of unequal thickness could not be grasped in the proper manner between two

perfectly true and rigid rollers, the upper roller, instead of being solid, is composed of a number of circular discs or rings of metal, about half an inch thick, slipped on to an axis rather smaller than the holes in their centres, but compelled to revolve with it by means of what may be termed a planetary axis, which is a rod passing loosely through holes in the whole series of discs, between their centre and their circumference, and so connected with the axis by its ends as to be carried round with it. By this contrivance the upper roller is enabled to adapt its surface to that of the skin, which is everywhere pressed with an equal force, due to the weight of the discs of which the upper roller is composed. It is stated in the *Frans Magazine* "that this machine will split a sheepskin of the ordinary size in about two minutes, during which time the knife makes from two to three thousand vibratory motions to and fro." This machine is said to be the invention of Lieutenant Parr. Another contrivance is known as Duxbury's Patent Skin Splitting Machine, in which the knife consists of a series of plates of steel, so attached to the periphery of a wheel or disc, seventeen feet in diameter, as to form a gigantic cutting instrument, resembling a crown or trepan saw, the compound blade projecting horizontally from the rim of the wheel parallel to its axis. The skin to be split passes round the circumference of a horizontal drum, the axis of which is at right angles with that of the great disc, and lies very nearly in the same plane with its face, and which instead of being perfectly cylindrical has its sides so hollowed as to present a concavity perfectly tallying with the curvature of the periphery of the disc. As therefore the drum revolves it brings the skin, which is confined closely to its concave surface by a contrivance somewhat resembling the upper roller in the machine above described, in contact with the edge of the revolving knife, which cuts by a continuous onward movement, instead of a sawing action backwards and forwards. The extreme nicety required to fix the concavity of the feeding roller to the edge of the circular knife, and to keep the knife or cutter itself perfectly true in shape, appear to be the chief objections to this ingenious contrivance.—*Frans. Cy., Suppl., Leather.*

Exports of Leather of British Produce and Manufacture in 1850 and 1851:—

Exports of Leather of British Produce and Manufacture in 1850 and 1851.

II 31.

LEATHER, VEGETABLE. Under this name a new material, composed of India rubber spread upon linen, has been introduced. Of this the *Mechanics' Magazine*

writes :—" Having seen some specimens of these leathers, as well as various articles of utility manufactured therewith, we have been induced to pay the extensive works of Messrs. Spill and Co., the eminent & ever-greent contractors, on Stepney-green, a visit, in order to cull sufficient to place upon record the present position of artificial as a substitute for real leather. The face and general character of the vegetable leather resembles the natural product so closely, that it is only by actual examination that the difference can be determined. This is more particularly the case in that description which is made for bookbinding, the covering of library tables, and like purposes. Amongst other advantages it possesses over leather proper, may be mentioned, that however thin the imitation is, it will not tear without considerable force is exercised; that it resists all damp, and that moisture may be left upon it for any period without injury, consequently, it does not sicken or cockle, is always dry, and its polish is rather increased than diminished by friction. Add to these facts, that any attempt to scratch or raise its surface with the nail, or by contact with any ordinary substance, will not abrade it, and enough will have been said to justify its entering the list against an article of daily use, which has of late years been deemed far from sufficient for the demand, and has consequently risen in price to the manifest loss and injury of every class of the community. We believe that the largest entire piece of real leather that can be cut from a bullock's hide, is not more than 7 feet by 5 feet, and this includes the stomach and other inferior parts. Vegetable leather on the contrary, is now produced 50 yards in length, and $1\frac{1}{2}$ yard wide, every portion being of equal and of any required thickness, and the smallest portion is convertible. We were agreeably disappointed, however, to find that instead of vegetable leather being a discovery requiring the aid of ourselves and contemporaries, it was, although so young, an active agent in the fabrication of numerous articles of daily requirement, and that it had already become the subject of large, indeed we may say enormous, contracts. Caoutchouc and naphtha are used in its manufacture; but by a process known to the senior of the firm, who is himself an accomplished chemist, all odour is removed from the naphtha, and the smell of vegetable leather is rendered thereby less in strength, if anything, than that of leather. The principal objects to which it is at present applied, although it is obvious it will take a wider range of usefulness than leather itself, are carriage and horse aprons, antipolopols, soldier's belts, buckets which pack flat, harness of every description, bookbinding, &c. For, the latter, its toughness, washable quality and resistance to stains, render it remarkably fitted. Its thickness, which may be carried to any extent, is obtained by additional backing of linen, &c., combined with the caoutchouc, and its strength is something marvellous, while in the all-important commercial view, it is but one third the price of leather. Many of the articles we were shown possessed the appearance of much elegance and finish; but it was curious to observe, that although most of them could be made without a stitch, and within the factory itself, a deference to the feelings of the workmen in the several trades has been shown by the firm, and the material is given out as ordinary leather, to undergo the process of the needle, which it submits to with a greater facility than its original prototype."

LEDUM PALUSTRE. This plant is employed in Russia to tan the skins of goats, calves, and sheep, into a reddish leather of an agreeable smell; as also in the preparation of the oil of birch, for making what is commonly called Russia leather.

LEIR. An arched building, forming an annealing furnace, in which glass is tempered or annealed.

LEGUMINE is the name of a vegeto-alkali supposed to exist in leguminous plants.

LEMNIAN EARTH. A yellowish-grey earth, obtained from Lemnos by the Greeks. It is very similar to fuller's earth.

LEMONS. The fruit of the *Citrus limonum*. Both the juice and the peel of the fruit are employed medicinally, and in the preparation of lemonade. The quantity of lemons employed cannot be ascertained from the Custom House returns, as they are reckoned together with oranges. See CITRIC ACID, and OIL, ESSENTIAL.

LENSES. (*Lentille*, Fr.; *Linsenglas*, Germ.) Lenses are transparent bodies, usually made of glass, which by their curvature either concentrate or disperse the rays of light. Lenses are of the following kinds. *Double convex*, having the same or a different degree of convexity on either side. *Plano convex*, having one plane and one convex surface. *Concavo convex*, having one concave and one convex side, commonly called *meniscus lenses*. *Plano concave*, having one plane surface and one concave one; and the *double concave lens*.

The first three, which are thicker in the middle than at the edge, are *converging lenses*, because they occasion the rays of light to converge in passing through them. The others which are thicker at the edge than in the middle, and therefore cause the pencils of light refracted through them to diverge, are called *diverging lenses*.

For the most complete examination of the laws regulating the construction of lenses, and the action of these on the rays of light we must refer the reader to Sir John

Herschel's admirable treatise on *Light* in the *Encyclopedia Metropolitana*. In this work we have only to deal with the mode of manufacturing the ordinary *lenses*. The spherical surfaces are produced by grinding them in counterpart tools, or discs of metal, prepared to the same curvature as the lenses. For the formation of the grinding tools, a concave and a convex template are first made to the radius of the curvature of the required lens. The templates of large radius, are sometimes cut out of crown glass. More usually the templates are made out of sheet brass, the templates of long radii are cut with a strong radius bar and cutter, and those of only a few inches radius are cut in the turning lathe. The brass concave and convex gauges are cut at separate operations, as it is necessary to adjust the radius to compensate for the thickness of the cutter, and the brass templates are not usually corrected by grinding, as practically it is found more convenient to fit the tools themselves together. The templates having been made of the required radius, are used for the preparation of the grinding and polishing tools, which for concave lenses consist of a concave rough grinding tool of cast iron called a *shell*.

A pair of brass tools is however the most important part of the apparatus. (One of these is concave and the other convex, made exactly to the curvature of the templates and to fit each other as accurately as possible. The concave tool is used as the grinder for correcting the curvature of the lenses after they have been roughly figured in the concave shell, and the convex tool is employed for producing and maintaining the true form of the concave grinding tool itself, and also that of the polisher. These polishers are adjusted with great accuracy. The concave tool is placed upon the convex, and they are first rubbed together dry, so that by the brightened parts the inequalities may be distinguished, they are then ground true, first by means of emery and water, and then with dry emery.

The following figure (1130) represents these tools, which are fitted with screws at the back so that they can be fixed upon pillars, in connection with the machinery for giving motion to them.

By grinding with sundry varieties of motion which are required to produce the best effect, such as the production of motion which shall resemble as nearly as possible the kind of stroke which would be given by the hand, three tools are eventually brought to true spherical figures which fit each other exactly.

The glasses for lenses, being selected of suitable quality, they are brought to a circular form by means of flat pliers called *shanks*. The pressure of the pliers applied near the edges of the glass causes it to crumble away in small fragments, and this process, which is called *shanking* or *nibbling*, is continued until the glasses are made circular, and of a little larger diameter than the finished size of the lenses.

1130

A cement is made by mixing wood ashes with melted pitch. Some nicety is required in the adjustment of the proportion, since the cement must not be too adhesive nor must it be too hard or too brittle; generally about 4 lbs. of wood ashes to 14 lbs. of pitch are employed. This when melted is poured on one side of the glasses to be ground, in small quantities at a time, until a sufficient quantity adheres to the back of the lens to form a handle. The glass is rough ground by rubbing it within the spherical shell. The glass is rubbed with large circular strokes, and the shell is usually placed within a shallow tray to catch the loose emery or polishing powder which may be employed. When one side is rough ground in this way, the glass is warmed to detach it from the handle, which is transferred to the other side and the operation repeated. When both sides are thus rudely formed, the lenses are cemented upon a runner. The best object glasses for telescopes are ground and polished singly, while as many as four dozen of common spectacle glasses are ground and polished together. When many are thus fixed on one runner, the number must be such as will admit of their being arranged symmetrically around a central lens, as 7, 13, or 21, or sometimes 4 form the nucleus, and then the numbers run 14, 20. Lenses of ordinary quality are usually ground true and polished seven at a time. This runner with its lenses attached is shown in fig. 1131.

1131

The cement at the back of the lenses is first flattened with a heated iron. The cast iron runner is heated just sufficiently to melt the cement, and carefully placed upon the cemented backs of the lenses. As soon as the cement is sufficiently softened to adhere firmly to the runner, it is cooled with a wet sponge, as the cement must only be so far fused as to fill up the spaces nearly, but not quite, level with the surface of the lenses. The block of lenses is now mounted upon a post, and ground with the concave brass tool, fig. 1180, motion being given to it either by the hand or by

machinery applied to the grinding motion is already named. As the grinding process, the business of the emery powder employed is somewhat similar to the last operation, it is essentially the same as producing a semi-polished surface. The grinding being now pushed forward by the labourer, the wheels have to be polished. The polisher is made by warping a flat iron wheel and setting it rotating about one quarter of an inch thick with a metal rim. A piece of thick wood in which is cut to the size of the polisher and secured to it, and provided with a handle by which the bench tool works it. When this is properly adjusted it is covered with very finely divided emery powder, operated with a small wheel, and the polisher worked both the piece of the work with the bench and the tool. Repeated supplies of emery powder is put in the polisher until it reaches quite level, and it is packed round with the tool. Many hours are expended in the proper preparation of a polisher. When completed it is placed upon the back of a horse and led to the post, and worked with wide and narrow strips and circles. When a very large number of planes are ground or polished at the same time, the power motion is assisted by the eccentric movement of a lever attached to the revolving shaft. In the processes of grinding and polishing, other materials besides emery and pumice powder are sometimes employed, such as sand, or cast-iron scales of iron, the finer kinds of which are much employed in the large iron manufacturing establishments.

Much more might be said on the subject of grinding and polishing lenses, but it is one of those processes of manufacture which scarcely come within the limits of the present work. Still it was thought to be of sufficient importance to receive some general notice. The grinding and polishing of the most varieties of lenses for telescopes, microscopes, and the like, require extremely nice manipulation. The best account of the processes and of the instruments used is one by the late Andrew Ross in the fifty-third volume of the *Transactions of the Society of Arts*. In *Handbook of Mechanical Manipulation* there is also some very excellent practical information. See LIGHTHOUSE; PHOTOMANRY.

LEPIDINE CHLORIDE. A volatile base, liquid green with chlorine, found in solution in the fluid produced by dissolving chloroform with perch. C. C. W.

LEUCITE. A mineral found in volcanic rocks, containing usually 16 to 18 of silica, 23 to 40 of alumina, and 21 to 25 of potash.

LEUCOLINE. A compound of CHLORINE, produced during the destructive distillation of coal. See COAL GAS.

LEUKOL. See CHINOL.

LEVEL (a mining term). An adit gallery or horizontal working in a mine.

LEVIGATION is the mechanical process whereby hard substances are reduced to a very fine powder.

LEWIS is the name of one kind of shears used in cropping work in a mine.

LIAS. Under this term are comprehended the strata which intervene between the Trias, or New Red Series, and the Inferior Oolite. In the aggregate they form considerable thickness, and occupy a large area in this country, stretching in a northerly direction from the sea west of Lyme Regis, in Dorsetshire, to Redcar, on the coast of Yorkshire. The strata which compose the Liasic series consist, in the lower part, of compact argillaceous limestone, alternating with or forming layers in clay, to a provincial pronunciation of which word the name has probably owes its origin. This limestone forms the base of a thick deposit of blue clays and marls, which are overlaid by a series of sands and mudstone, called Marlstone; these in their turn, are separated from another mass of sands, which form the uppermost member of the group, by a stratum of clay, known as the Upper Lias Clay.

By the term lias, however, is ordinarily only understood the calcareous and argillaceous division, which constitutes the lower section of the entire formation.

In an economical point of view, it is of considerable value from its furnishing a useful and durable stone, both for building and paving; for the latter purpose it is particularly suited, not only from the large dimensions of the flags it affords, but on account of its occurrence in thin layers, which, in many cases, when required for rough purposes only, are used in the state in which they are taken from the quarry, without undergoing subsequent dressing. The lime furnished by the blue lias limestone, is also well known, and in great request, some of the beds possessing the valuable property of forming hydraulic mortars and cements, for manufacturing which it is collected from the shore and the sea cliffs at Charmouth, and largely quarried at Lyme Regis and the neighbourhood.

The clayey members of the lias furnish a poor and cold agricultural soil, which is chiefly devoted to pasture, but the land upon the marlstone is, on the contrary, of a very rich and fertile description, and constitutes a district, where it prevails, that is marked by the luxuriance of its crops, and the excellence of the cider it produces. In the upper part, it contains beds of ferruginous, brown, calcareous sandstone, which

is now fastened in the night sheds where it occurs. The stone
is always more or less ferruginous, and is a valuable ore of iron, as in the
furnace it produces such a large amount of iron, as in the
furnace of H. which a tent has lately been directed by Mr.
Edward Hull, of the Geological Survey of Great Britain.

Edward Hull, of the Geological Survey of Great Britain, said that the sands were the calcareous sands of the uppermost portion of the Mesozoic. He said the sands were a rich agricultural soil. Until recently, these sands were considered to form the base of the Lower Cretaceous series, but the researches of Dr. Wright, of the Geological Survey, had shown that they should, with more propriety, be classed with the Tertiary, and, rather than with the Cretaceous, be placed in the neighbourhood of Bristol, and

It was found at Cortem and other places in the neighbourhood of Brussels, and has in consequence received the name of Cortem marble, and has also been used for marble, from the curious delineations displayed upon polished surfaces of it, resembling trees, landscapes, &c., in a limestone from the lower part of the Parisian H. W. R. of tin, prepared by dissolving

LIBAVIAN'S, forming lichen or, is the bichloride of tin, prepared by dissolving tin in aqua regia, or by passing chlorine gas through a solution of tin in the acid, and heating the solution to drive off the acid, and leaving the residue to crystallize. The anhydrous chloride is best prepared by mixing four parts of mercuric chloride with one part of tin, previously amalgamated with a little oil of vitriol, as to render it pulverisable; and by distilling this mixture with a gentle heat. A colorless fluid, the dry bichloride of tin, or the anhydrous chloride, comes over. When it is mixed with one third of its weight of water it becomes solid. The first bichloride of tin is used in the preparation of the various tin compounds.

110111.8 A certain set of plants, composed chiefly of cellular tissue devoid of
vascular vessels, with the stems and leaves undistinguishable, are termed Thallophytes.
They are of two kinds, the first admitting of two divisions —

1. *Azotiz* thallogens, or such as are nourished through their whole surface by seawater are *Azotiz*. *Azotiz* thallogens nourished through their whole surface by seawater are *Azotiz*. *Azotiz* thallogens nourished through their whole surface by seawater are *Azotiz*.

2. The ones nourished through their thallus (spawn or mycelium) by juices derived from the matrix are *fungi*.

Lichens are numerous, as *Ground liverwort*, *Cup moss*, *Tree lichen* &c. used in Siberia as a substitute for lichen in brewing; *Gyrophora* employed by the hunters in the arctic regions as an article of food, under the name of *tripe de roche*; *Hebe*, *moos*, *Irishland moss*, much used in this country as a remedy for colds, the Chinese gather wood lichen, and some others.

The Tinctorial lichens are also numerous. They furnish four principal colours, brown, yellow, purple, and blue.

Chrysomela pulchella and *Stem. pulcherrima* yield brown colours. The latter, with mordants of tin and cream of tartar, produces on silk a durable carmelite colour. (Goussier)

Permalin parietina and *Ectopha vulgaris* produce yellow, the yellow principle of the former being called *chromophanic acid*, that of the latter *vulgaric acid*. In this country *Chromolaena*, A.C. yield purple and hence purple.

Pharmacia purpurea and *Pharmacia* are the flowers being called chrysanthemum, that of the latter being called *Pharmacia*. In this country *Pharmacia* is called *Pharmacia*, &c. yield purple and blue colors. In Holland, a blue color, &c. are the end result, purple colors, are prepared. In Holland, a blue color, &c. are the end result, purple colors, are prepared. In Holland, a blue color, &c. are the end result, purple colors, are prepared.

LICKNER'S BLUE. The Silicate of Cobalt and Potash.

LIGHT. (*Lumière*, Fr.; *Licht*, Germ.) The operation of light as an agent in the arts or manufactures has scarcely yet received attention. Sufficient evidence has however been collected to show that it is of the utmost importance in producing many of the remarkable changes in bodies which are desired in some cases as the result, but which, in others, are to be if possible avoided.

There is a very general misconception as to the power or principle to which certain phenomena, the result of exposure to sunshine, are to be referred. In general light is regarded as the principle in action, whereas frequently it has nothing whatever to do with the change. A few words therefore in explanation are necessary. The solar ray, commonly spoken of as light, contains in addition to its luminous power, caloric power, chemical power, and in all probability electrical power. (See ACTION.) These phenomena can be separated one from the other, and individually studied. All the photographic phenomena are dependent upon the chemical (caloric) power. Many of the peculiar changes which are effected in organic bodies are evidently due to light, and the phenomena which depend entirely on heat are well known.

Herschel has directed attention to some of the most striking phenomena of light, especially its action upon vegetable colours. As these have direct reference to the permanence of dyes, they are deserving of great attention. The following quotation from Sir John Herschel's paper "On the Chemical Action of the Rays of the Solar Spectrum, &c." will explain his views and give the character of the phenomena which he has studied. He writes—

"The evidence we have obtained by the foregoing experiments of the existence of chemical actions of very different and to a certain extent opposite characters at the opposite extremities (or rather as we ought to express it in the opposite regions) of the spectrum, will naturally give rise to many interesting speculations and conclusions, of which those I am about to state, will probably not be regarded as among the least so. We all know that colours of vegetable origin are usually considered to be destroyed and whitened by the continual action of light. The process, however, is too slow to be made the subject of any satisfactory series of experiments, and, in consequence, this subject, so interesting to the painter, the dyer, and the general artist, has been allowed to remain uninvestigated. As soon, however, as these evidences of a counterbalance of mutually opposing actions, in the elements of which the solar light consists, offered themselves to view, it occurred to me, as a reasonable subject of inquiry, whether this slow destruction of vegetable tints might not be due to the feeble amount of residual action outstanding after imperfect mutual compensation, in the ordinary way in which such colours are presented to light, i.e. to mixed rays. It appeared therefore to merit inquiry, whether such colours, subjected to the uncompensated action of the elementary rays of the spectrum, might not undergo changes differing both in kind and in degree which mixed light produces on them, and might not, moreover, by such changes indicate chemical properties in the rays themselves hitherto unknown.

"One of the most intense and beautiful of the vegetable blues is that yielded by the

binerals of the dark velvet variety of the common heartsease (*Viola tricolor*). It is best extracted by alcohol. The alcoholic tincture so obtained, after several days' keeping in a stoppered phial, loses its fine blue colour, and changes to a pallid brownish red, like that of port wine discoloured by age.

"When spread on paper it hardly tinges it at first, and might be supposed to have lost all colouring virtue, but that a few drops of very dilute sulphuric acid sprinkled over it, indicate by the beautiful and intense rose colour developed where they fall, the continued existence of the colouring principle. As the paper so moistened with the tincture dries, however, the original blue colour begins to appear, and when quite dry is full and rich. The tincture by long keeping loses this quality, and does not seem capable of being restored. But the paper preserves its colour well, and is even rather remarkable among vegetable colours for its permanence in the dark or in common daylight.

"A paper so tinged of a very fine and full blue colour, was exposed to the solar spectrum concentrated, as usual (October 11, 1839), by a prism and lens; a water-prism, however, was used in the experiment, to command as large an area of spectrum as possible. The sun was poor and desultory; nevertheless in half an hour there was an evident commencement of whitening from the fiducial yellow ray to the mean red. In two hours and a half, the sunbeam continuing very much interrupted by clouds, the effect was marked by a considerable white patch extending from the extreme red to the end of the violet ray, but not traceable beyond that limit. Its commencement and termination were, however, very feeble, graduating off insensibly; but at the maximum, which occurred a little below the fiducial point (corresponding nearly with the orange rays of the luminous spectrum), the blue colour was completely discharged. Beyond the violet there was no indication of increase of colour, or of any other action. I do not find that this paper is discoloured by mere radiant heat unaccompanied with light."

Dr. George Wilson of Edinburgh made some exceedingly interesting experiments on the influence of sun light over the action of the dry gases on organic colours. The results arrived at were communicated to the British Association, and an abstract of the communication is published in their transactions. The experiments were on chlorine, sulphurous acid, sulphuretted hydrogen, carbonic acid, and a mixture of sulphurous and carbonic acid, oxygen, hydrogen and nitrogen on organic colouring matters. "I had ascertained," says Dr. George Wilson, "the action of the gases mentioned already on vegetable colouring matters, so arranged, that both colouring matter and gas should be as dry as possible, the aim of the inquiry being to elucidate the theory of bleaching, by accounting for the action of dry chlorine upon dry colours. In the course of this inquiry, I ascertained that in darkness dry chlorine may be kept for three years in contact with colours without bleaching them, although when moist it destroys their tints in a few seconds (see BLEACHING); and I thought it desirable to ascertain whether dry chlorine was equally powerless as a bleacher when assisted by sunlight. The general result of the inquiry was, that a few weeks sufficed for the bleaching of a body by chlorine in sunlight, where months, I may even say years, would not avail in darkness." The form of the experiment was as follows. Four tubes were connected together so as to form a continuous canal, through which a current of gas could be sent. Each tube contained a small glass rod on which seven pieces of differently coloured papers were spiked. It is not necessary here to state the colours employed, suffice it to say, that all the tubes thus contained seven different coloured papers, of different origins, and easily distinguishable by the eye. They were arranged in the same order in each tube, and were prepared as nearly as possible of the same shade. These papers were carefully deprived of every trace of moisture by a current of very dry air. The tubes were then filled with the gas, also dried, on which the experiment was to be made. One tube of each series was kept in darkness, two others were exposed in a western aspect behind glass, and the other was turned to the south in the open air.

The results were as follows:—In the dark chlorine tube the colours were very little altered, and would probably have been altered less had not the tube been frequently exposed to light for the sake of examination. In the western tube, the original grey and green wallflower papers became of a bright crimson, the blue litmus bright red, and the brown rhubarb yellow. The whole of the chlorine had apparently entered into combination with the colouring matters for the yellow tint of the gas had totally disappeared. In the southern tube the colour of the chlorine could still be seen, the reddening action was less decided, and the bleaching action was more powerfully evinced. The general result was that the action of sunlight is less uniform than might have been expected in increasing the bleaching power of chlorine, or while some tints rapidly disappeared under its action assisted by light, other colours remained, in apparently the very same circumstances, unaffected.

Sulphurous acid, if thoroughly dried, may be kept for months in contact with dry colours without altering them; under the influence of sunlight it however recovers to some extent its bleaching power.

Sulphuretted hydrogen acts as a weak acid, and readily as a bleacher when moist, and becomes inactive in both respects if made dry and kept in darkness. With the assistance of sunlight it recovers in no inconsiderable degree its bleaching power.

Oxygen is a well known bleaching agent, but when dry its action upon colouring matter in the dark is extremely slow. In sunlight, however, it recovers its bleaching power.

Carbonic acid, when dry in darkness, loses all power on colouring matter, but a faint bleaching action is exerted by it under exposure to sunlight.

Hydrogen is without any action when dry upon colours, but it acquires a slight decolorising power when exposed to sunshine.

"The general result," concludes Dr. George Wilson, "of this inquiry, so far as it has yet proceeded, is, that the bleaching gases, viz. chlorine, sulphurous acid, sulphuretted hydrogen, and oxygen, lose nearly all their bleaching power, if dry and in darkness, but all recover it, and chlorine in a most marked degree, by exposure to sunlight."

All these experiments appear to show that the action of the solar rays on vegetable colours is dependent upon the power possessed by one set of rays to aid in the oxidation or chemical changes of the organic compound constituting the colouring matter. The whole matter requires careful investigation.

It is a proved fact, that colouring matters, either from the mineral or the vegetable kingdoms, are much brighter when they are precipitated from their solutions in bright sunshine, than if precipitated on a cloudy day or in the dark. It must not be supposed that all the changes observed are due to chemical action; there can be no doubt but many are purely physical phenomena, that is, the result of molecular change, without any chemical disturbance.

LIGHT, ELECTRIC. See **ELECTRIC LIGHT.**

LIGHTHOUSE. The importance of lights of great power and of a distinguishable character around our coasts is admitted by all. One of the noblest efforts of humanity is certainly the construction of these guides to the mariners upon rocks which exist in the tracks of ships, or upon dangerous shores and the mouths of harbours. This is not the place to enter largely upon any special description of the lights which are adopted around our shores; a brief account only will be given of some of the more remarkable principles which have been introduced of late years by the Trinity Board.

The early lighthouses appear to have been illuminated by coal or wood fires contained in "chanfliers." The Isle of Man light was of this kind until 1816. The first decided improvement was made by Argand, in 1784, who invented a lamp with a circular wick, the flame being supplied by an external and internal current of air. To make these lamps more effective for lighthouse illumination, and to prevent the ray of light escaping on all sides, a reflector was added in 1780 by M. Lenoir; this threw the light forward in parallel rays towards such points of the horizon as would be useful to the mariner. Good reflectors increase the luminous effect of a lamp about 400 times; this is the "catoptric" system of lighting. When reflectors are used, there is a certain quantity of light lost, and the "dioptric" or *refracting* system, invented by the late M. Augustin Fresnel in 1822 is designed to obviate this effect to some extent: the "catadioptric" system is a still further improvement, and acts both by refraction and reflexion. Lights of the first order have an interior radius or focal distance of 36.25 inches, and are lighted by a lamp of four concentric wicks, consuming 370 gallons of oil per annum.

The appearance of light called short eclipses has hitherto been obtained by the following arrangement. —

An apparatus for a fixed light being provided, composed of a central cylinder and two zones of catadioptric rings forming a cupola and lower part, a certain number of lenses are arranged at equal distances from each other, placed upon an exterior movable frame making its revolution around the apparatus in a given period. These lenses, composed of vertical prisms, are of the same altitude as the cylinder, and the radius of their curves is in opposite directions to those of the cylinder, in such a manner that at their passage they converge into a parallel pencil of light, and the divergent rays emitted horizontally from the cylinder producing a brilliant effect, like that obtained by the use of annular lenses at the revolving lighthouses.

Before proceeding with the description of the lenses, the following notices may be of interest: —

The Eddystone Lighthouse $9\frac{1}{2}$ miles from the Rame Head, on the coast of Cornwall, was erected of timber by Winstanley in 1696-98, and was washed away in

1703. It was rebuilt by Rudyard in 1706, and destroyed by fire in 1735. The present edifice was erected by Smeaton 1757-59. Tallow candles were used in the first instance for the lights; but in 1807 argand lamps, with paraboloidal reflectors of silvered copper were substituted.

The Skerryvore Rocks, about 12 miles south-west of Tyree on the coast of Argyshire, lying in the track of the shipping of Liverpool and of the Clyde had long been regarded with dread by the mariners frequenting these seas. The extreme difficulty of the position, exposed to the unbroken force of the Atlantic Ocean, had alone deterred the commissioners of northern lights from the attempt to place a light upon this dangerous spot; but in 1834 they caused the reef to be surveyed, and in 1838 Mr. Alan Stevenson, their engineer, inheriting his father's energy and scientific skill, commenced his operations upon a site from which "nothing could be seen for miles around but white foaming breakers, and nothing could be heard but the howling of the winds and the lashing of the waves." His design was an adaptation of Smeaton's tower of the Eddystone to the peculiar situation, a circumstance with which he had to contend. He established a circular base 42 feet in diameter, rising in a solid mass of gneiss or granite, but diminishing in diameter to the height of 26 feet, and presenting an even concave surface all around to the action of the waves. Immediately above this level the walls are 9.58 feet thick, diminishing in thickness as the tower rises to its highest elevation, where the walls are reduced to 2 feet in thickness, and the diameter to 16 feet. The tower is built of granite from the islands of Tyree and Mull, and its height from the base is 138 feet 8 inches. In the intervals left by the thickness of the walls are the stairs, a space for the necessary supply of stores, and a not uncomfortable habitation for three attendants. The rest of the establishment, stores, &c., are kept at the depot in the island of Tyree. The light of the Skerryvore is revolving, and is produced by the revolution of eight annular lenses around a central lamp, and belongs to the first order of dioptric lights in the system of Fresnel, and may be seen from a vessel's deck at a distance of 18 miles. — *Lord De Mûlley, Juror's Report, Great Exhibition, 1851.*

Some of the lenticular arrangements must now claim attention. Large lenses, or any large masses of glass, are liable to strain, which by dispersing, occasion a loss of much light.

"In order to improve a solid lens formed of one piece of glass whose section is $A, m, p, n, F, z, D, C, A$, Hutton proposed to cut out all the glass left white in the figure (1132), namely, the portions between $m p$ and $n o$, and between $n o$ and the left hand surface of $D E$. A lens thus constructed would be incomparably superior to a solid one, but such a process we conceive to be impracticable on a large scale, from the extreme difficulty of polishing the surfaces $A m, n p, o n, r a$, and the left hand surface of $D E$; and even if it were practical, the greatest imperfections of the glass might happen to occur in the parts which are left. In order to remove these imperfections and to construct lenses of any size," says Sir David Brewster,

"I proposed in 1811 to build them up of separate zones or rings, each of which rings was again to be composed of separate segments, as shown in the front view of the lens in fig. 1133. This lens is composed of one central lens $A n c u$, corresponding with its section $D E$ in fig. 1132; of a middle ring $G E L I$, corresponding to $C D E F$, and consisting of 4 segments; and another ring $K P a T$, corresponding to $A C F n$, and consisting of 8 segments. The preceding construction obviously puts it in our power to execute those lenses to which I have given the name of *polyzonal lenses*, of pure flint glass free from veins; but it possesses another great advantage, namely, that of enabling us to correct very nearly the spherical aberration by making the foci of each zone coincide." — *Brewster.*

This description will enable the reader to understand the system which has been adopted by Fresnel and carried out by the French government, and by our own commissioners of lights.

In the fixed dioptric light of Fresnel, the flame is placed in the centre of the apparatus, and within a cylindric reflector of glass, of a vertical refracting power, the breadth and height of a strip of light emitted by it being dependent upon the size of the flame and the height of the reflector itself; above and below is placed a series of reflecting prismatic rings or zones for collecting the upper and lower divergent rays, which, falling upon the inner side of the zone are refracted, pass through the second side where they suffer total reflection, and passing out on the outer side of the zone, are again refracted. The effect of these zones is to lengthen the vertical strip of

light, the size of which is dependent upon the breadth of the flame, and the height of the apparatus.

In Fresnel's revolving lighthouse, a large flame is placed in the centre of a revolving frame which carries a number of lenses on a large scale and of various curvatures for the avoidance of spherical aberration. With the view of collecting the divergent rays above the flame, an arrangement of lenses and silvered mirrors is placed immediately over it. By this compound arrangement the simply revolving character of the apparatus is destroyed, as, in addition to the revolving flash, a vertical and fixed light is at all times seen, added to which a great loss of light must be sustained by the loss of metallic reflectors. In 1831, Messrs. Wilkins and Levernnean, exhibited a catadioptric apparatus of great utility. It was thus described by the exhibitors:—

The first improvement has special reference to the light, and produces a considerable increase in its power, whilst the simplicity of the optical arrangements is also repaired. It consists, firstly, in completely dispensing with the movable central cylindrical lenses; secondly, it replaces these by a single revolving cylinder composed of four annular lenses and four lenses of a fixed light introduced between them; but the number of each varying according to the succession of flashes to be produced in the period of revolution.

The second improvement, of which already some applications that have been made serve to show the importance, consists in a new method of arranging the revolving parts, experience having shown that the arrangements at present in use are very faulty. A short time is sufficient for the action of the friction rollers, revolving on two parallel planes, to produce by a succession of cuttings a sufficiently deep groove to destroy the regularity of the rotatory movement. To obviate this great inconvenience the friction rollers are so placed and fitted, on an iron axis with regulating screws and traversing between two bevelled surfaces, that when an indentation is made in one place they can be adjusted to another part of the plates which is not so worn.

The third improvement produces the result of an increase of the power of the flashes in revolving lighthouse apparatus to double what has been obtained hitherto. By means of lenses of vertical prisms placed in the prolongation of the central annular lenses, the divergent rays emerging from the catadioptric zone are brought into a straight line, and a coincidence of the three lenses is obtained.

The whole of the prisms, lenses, and soles are mounted with strength and simplicity, accurately ground and polished to the correct curves according to their respective positions, so as to properly develop this beautiful system of Fresnel. The glass of which they are composed should be of the clearest crystal colour, and free from that green hue which so materially reduces the power of the light, and is considered objectionable for apparatus of this kind. The lamp by which the apparatus is to be lighted consists of a concentric burner with four circular wicks attached to a lamp of simple construction, the oil being forced up to the burner by atmospheric pressure only, so that there are no delicate pumps or machinery to become deranged.

Stevenson's revolving lighthouse.—This apparatus consists of two parts. The principal part is a right octagonal hollow prism composed of eight large lenses, which throw out a powerful beam of light whenever the axis of a single lens comes in the line between the observer and the focus. This occurs once in a minute, as the frame which bears the lens revolves in eight minutes on the rollers placed beneath. The subsidiary parts consist of eight pyramidal lenses inclined at an angle of 30° to the horizon, and forming together a hollow truncated cone, which rests above the flame like a cap. Above these smaller lenses (which can only be seen by looking from below) are placed eight plane mirrors, whose surfaces being inclined to the horizon at 50° in the direction opposite to that of the pyramidal lenses, finally cause all the light made parallel by the refraction of these lenses to leave the mirror in a horizontal direction. The only object of this part is to turn to useful account, by prolonging the duration of the flash, that part of the light which would otherwise escape into the atmosphere above the main lenses. This is effected by giving to the upper lenses a slight horizontal divergence from the vertical plane of the principal lenses. Below are five tiers of totally reflecting prisms, which intercept the light that passes below the great lenses, and by means of two reflections and an intermediate refraction project them in the shape of a flat ring to the horizon.

Stevenson's fixed dioptric apparatus of the first order (same as that at the Isle of May, with various improvements). The principal part consists of a cylindric belt of glass which surrounds the flame in the centre, and by its action refracts the light in a vertical direction upward and downward, so as to be parallel with the focal plane of the system. In this way it throws out a flat ring of light equally intense in every direction. To near observers, this action presents a narrow vertical band of light,

depending for its breadth on the extent of the horizontal angle embraced by the eye. This arrangement therefore fulfils all the conditions of a fixed light, and surpasses in effect any arrangement of parabolic reflectors. In order to save the light which would be lost in passing above and below the cylindrical belt, curved mirrors with their common focus in the lamp were formerly used; but by the present engineer, the adaptation of *catadioptric zones* to this part of the apparatus was, after much labour, successfully carried out. These zones are triangular, and act by *total reflexion*, the inner face *refracting*, the second *totally reflecting*, and the third or outer face, a second time *refracting*, so as to cause the light to emerge *horizontally*. The apparatus has received many smaller changes by the introduction of a new mode of grouping the various parts of the frame work, by which the passage of the light is less obscured in every azimuth.

Mechanical lamps of four wicks, are used in these lighthouses; in these the oil is kept continually overflowing by means of pumps which raise it from the cistern below; thus the rapid carbonisation of the wicks, which would be caused by the great heat, is avoided. The flames of the lamp reach their best effect in three hours after lighting, i. e. after the whole of the oil in the cistern, by passing and re-passing over the wicks repeatedly, has reached its maximum temperature. After this the lamp often burns 14 hours without sensible diminution of the light, and then rapidly falls. The height varies from 16 to 20 times that of the argand flame of an inch in diameter; and the quantity of oil consumed by it is greater nearly in the same proportion.

In *Sternum's* ordinary *parabolic reflector*, rendered *holophotal* (where the entire light is parallelised) by a portion of a *catadioptric annular lens*, the back part of the parabolic conoid is cut off, and a portion of a spherical mirror substituted, so as to send the rays again through the flame; while his *holophotal catadioptric annular lens apparatus* is a combination of a hemispherical mirror and a lens having *totally-reflecting zones*; the peculiarity of this arrangement is, that the *catadioptric zones*, instead of transmitting the light in parallel horizontal plates, as in *Fresnel's* apparatus, produce, as it were, an extension of the lenticular or quaquaversal action of the central lens by assembling the light around its axis in the form of concentric hollow cylinders.

Mr. Chance, of Birmingham, constructed a lighthouse which may be regarded as *Fresnel's* revolving light rendered *holophotal*. This arrangement was divided into three compartments, the upper and lower of which were composed respectively of thirteen and six *catadioptric zones* which produce the vertical strip of light extending the whole length of the apparatus, and is similar to *Fresnel's* dioptric light. The central or *catoptric* compartment consisted of eight lenses of three feet focal length, each of which was the centre of a series of eleven concentric prismatic rings, designed to produce the same refractive effect as a solid lens of equal size. These compound lenses were mounted upon a revolving frame and transmitted horizontal flashes of light as they successively rotated. The motion was communicated to the frame by a clock movement, and performs one revolution in four minutes; consequently, as there are eight lenses, a flash of light is transmitted every thirty seconds to the horizon.

LIGNEOUS MATTER is vegetable fibre. See FINE VEGETABLE.

LIGNITE Under BROWN COAL, BROWN COAL, and COAL, the characteristics of lignite have already received attention, therefore little farther need be said. The term lignite should be confined to fossil wood, or, still more correctly to wood which has undergone one of the changes leading towards the production of coal. If wood is buried in moist earth there is the production of carbonic acid from the elements of the wood, and the wood is changed into either lignite or brown coal. Lignite and coal differ chemically from each other. Lignite yields by dry distillation acetic acid and acetate of ammonia, whereas coal produces only an ammoniacal liquor. (*Kiemers*) Woody fibre gives rise to acetic acid; therefore, lignite must still contain undecomposed woody fibre. The following table gives the composition of several well known lignites.

	Carbon	Hydrogen	Oxygen and Nitrogen	Earthy	Consist.
From Pittsburg - -	77.9	2.6	19.5	1	Karsten
" Hungary - -	67.3	4.3	-	0.3	Newborth
" the Rhine - -	73.4	4.2	20.1	1.8	Rognault
" Meisner - -	65.6	5.2	19.0	2.3	Gtäger
" Bovey Heathfield -	67.9	5.8	21.8	-	Vaux

In Prussia, Austria, and many other parts of the continent, lignite forms a very

important product, being largely employed for domestic and for manufacturing purposes. In this country, with the single exception of the Bovey Heathfield formation, which is used in the adjoining pottery, lignite is not employed.

LIGNUM-VITÆ, or *Guaiacum* (*Guaiacum officinale* and *G. sanctum*), a very hard and heavy wood. The fibrous structure of this wood is very remarkable; the fibres cross each other sometimes as obliquely as at an angle of 30 degrees with the axis, as if one group of the annual layers wound to the right the next to the left and so on, with any exactitude. The wood can hardly be split, it is therefore divided by the saw. *Lignum-vitæ* is much used in machinery for rollers, presses, mills, &c., and for pestles and mortars, sheers for ship's blocks, skittle balls, and a great variety of other works requiring hardness and strength.

The gum guaiacum of the apothecary is extracted from this wood.

ILLAC DYE. See CALICO-PRINTING, DYEING, AND ANILINE.

LIME. *Quicklime*, an *Oxide of Calcium*. This useful substance is prepared by expelling the native carbonate of lime to heat, by which the carbonic acid is expelled.

This operation is performed in a manner more or less perfect, by burning calcareous stones in kilns or furnaces.

Limestone used to be calcined in a very rude kiln, formed by inclosing a circular space of 10 or 15 feet diameter, by rude stone walls 4 or 5 feet high, and filling the cylindrical cavity with alternate layers of turf or coal and limestone broken into moderate pieces. A bed of brushwood was usually placed at the bottom, to facilitate the kindling of the kiln. Whenever the combustion was fairly commenced, the top, piled into a conical form, was covered in with soot, to render the calcination slow and regular. This method being found relatively inconvenient and ineffectual, was succeeded by a permanent kiln built of stones or brickwork, in the shape of a truncated cone with the narrow end undermost, and closed at bottom by an iron grate. Into this kiln, the fuel and limestone were introduced at the top in alternate layers, beginning of course with the former; and the charge was either allowed to burn out, when the layer was altogether removed at a door near the bottom, or the kiln was successively fed with fresh materials, in alternate hauls, as the former supply sunk down by the calcination, while the thoroughly burnt lime at the bottom was successively raked out by a side door immediately above the grate. The interior of the lime kiln has been changed of late years from the conical to the elliptical form, and probably the best is that of an egg placed with its narrow end undermost, and truncated both above and below; the ground plot or bottom of the kiln being compressed so as to give an elliptical section, with a eye or draft-hole towards each end of that ellipse. A kiln thus arched in above gives a reverberatory heat to the upper materials, and also favours their falling freely down in proportion as the finished lime is raked out below; advantages which the conical form does not afford. The size of the draft-holes for extracting the quicklime, should be proportionate to the size of the kiln, in order to admit a sufficient current of air to ascend with the smoke and flame, which is found to facilitate the extrication of the carbonic acid. The kilns are called *perpetual*, because the operation is carried on continuously as long as the building lasts; and *draw-kilns*, from the mode of discharging them by raking out the lime into carts placed against the draft-holes. Three bushels of calcined limestone, or lime-shells, are produced on an average for every bushel of coals consumed. Such kilns should be built up against the face of a cliff, so that easy access may be gained to the mouth for charging, by making a sloping cart road to the top of the bank.

Figs 1134, 1135, 1136, 1137 represent the *lime-kiln* of Rudersdorf near Berlin, upon the continuous plan, excellently constructed for economising fuel. It is triple, and yields a threefold product. Fig 1136 is a view of it as seen from above; fig 1137, the elevation and general appearance of one side; fig 1134, a vertical section, and fig 1135, the ground plan in the line A n c n of fig 1134. The inner shaft fig 1135, has the form of two truncated cones, with their larger circular ends applied to each other; it has the greatest width at the level of the fire-door *b*, where it is 8 feet in diameter; it is narrower below, at the discharge door, and at the top orifice, where *R* is about 6 feet in diameter. The interior wall *d*, of the upper shaft is built with hewn stones to the height of 38 feet, and below that for 25 feet, with fire-bricks *d'* laid stepwise. This inner wall is surrounded with a mantle *e*, of limestone, but between the two there is a small vacant space of a few inches filled with ashes, in order to allow of the expansion of the interior with heat taking place without shattering the mass of the building.

The fire-grate, *h*, consists of fire-tiles, which at the middle, where the single pieces press together, lie upon an arched support *f*. The fire-door is also arched, and is secured by fire-tiles. *g* is the iron door in front of that orifice. The tiles which form the grate have 3 or 4 slots of an inch wide for admitting the air, which enters through the canal *k*.

The under part of the shaft from the fire to the hearth is 7 feet, and the outer enclosing wall is constructed of limestone, the lining being of fire-bricks. Here are the ash-

1134

1136

1137

1135

pit *i*, the discharge outlet *a*, and the canal *k*, in front of the outlet. Each ash pit is shut with an iron door, which is opened only when the space becomes filled with ashes. These indeed are allowed to remain till they get cool enough to be removed without inconvenience.

The discharge outlets are also furnished with iron doors, which are opened only for taking out the lime, and are carefully luted with loam during the burning. The outer walls *l m n* of the kiln, are not essentially necessary, but convenient, because they afford room for the lime to lie in the lower floor, and the fuel in the second. The several stories are formed of groined arches *a*, and platforms *p*, covered over with limestone slabs. In the third and fourth stories the workmen lodge at night. See fig. 1137. Some enter their apartments by the upper door *q*; others by the lower door *r*. *r* is one of the chimneys for the several fireplaces of the workmen. *z*, *u*, *v* are stairs.

As the limestone is introduced at top, the mouth of the kiln is surrounded with a strong iron balustrade to prevent the danger of the people tumbling in. The platform is laid with rails *w*, for the waggons of limestone, drawn by horses, to run upon. *x* is another railway, leading to another kiln. Such kilns are named after the number of their fire-doors, single, twofold, threefold, fourfold, &c.; from three to five being the most usual. The outer form of the kiln also is determined by the number of the furnaces; being a truncated pyramid of equal sides, and in the middle of each alternate side, there is a fireplace, and a discharge outlet. A cubic foot of limestone requires for burning, one and five-twelfths of a cubic foot of wood, and one and a half of turf.

When the kiln is to be set in action, it is filled with rough limestones, to the height *c d*, or to the level of the firing; a wood fire is kindled in *a*, and kept up till the lime is calcined. Upon this mass of quicklime, a fresh quantity of limestone is introduced, not thrown in at the mouth, but let down in buckets, till the kiln is quite full; while over the top a cone of limestones is piled up, about 4 feet high. A turf-fire is now kindled in the furnaces *b*. Whenever the upper stones are well calcined, the lime

under the fire-level is taken out, the superior column falls in, a new cone is piled up, and the process goes on thus without interruption, and without the necessity of once putting a fire into it; for in the space *c n*, the lime must be always well calcined. The discharge of lime takes place every 12 hours, and it amounts at each time in a three-fold kiln, to from 20 to 24 Prussian *tonnen* of 6 imperial bushels each; or to 130 bushels imperial upon the average. It is found by experience that fresh-broken limestone, which contains a little moisture, calcines more readily than what has been tried by exposure for some time to the air; in consequence of the vapour of water promoting the escape of the carbonic acid gas; a fact well exemplified in distilling essential oils, as oil of turpentine and naphtha, which come over with the steam of water at upwards of 100° Fahr. below their natural term of ebullition. Six bushels of Rüdersdorf quicklime weigh from 250 to 306 pounds.

Anhydrous lime, or, as it is commonly called "*quicklime*," is an amorphous solid, varying much in coherence, according to the kind of rock from which it is obtained; its specific gravity varies from 2.3 to 3. Lime is one of the most infusible bodies which we possess; it resists the highest heats of our furnaces.

When exposed to air, quicklime rapidly absorbs water and crumbles into a powder, commonly known as *slaked lime*, which is a *hydrate of lime*.

Hydrate of lime when exposed to the air absorbs carbonic acid, and after long exposure it is converted into a mixture of carbonate of lime and hydrate of lime in single equivalents. Hydrate of lime is but slightly soluble in water, 729 to 733 parts of that fluid dissolving only 1 part of the lime at ordinary temperatures.

Hydrate of lime is applied to numerous purposes in the arts and manufactures. It is chiefly employed in the preparation of mortar for building purposes. See MORTAR.

The pure limes, prepared from the carbonates of lime, form an imperfect mortar suitable only for dry situations. In damp buildings or in wet situations they never set (as the process of hardening is technically termed), but always remain in a pulpy state. General Pasley says, "The unsuitableness of pure lime for the purposes of hydraulic architecture has been proved by several striking circumstances that have come under my personal observation, of which I shall only mention a few. First, a great portion of the boundary wall of Rochester Castle having been completely undermined, nearly throughout its whole thickness, which was considerable, whilst the upper part of the same wall was left standing, I had always ascribed this remarkable breach to violence, considering it as having been the act of gunners intending to destroy the wall for the sake of the stone; but on examining it more accurately after I had begun to study the subject of limes and cements, I observed that the whole of the breached part was washed by the Medway at high water, and that all the mortar of a small portion of the back part of the foot of the wall still left standing was quite soft, but that towards the ordinary high water level it became a little harder, and above that level it was perfectly sound. I observed the same process at the outer wall of Cockham Wood Fort, on the left bank of the Medway below Chatham, of which the upper part was standing, whilst the lower part of it had been gradually ruined by the action of the river at high water destroying the mortar."

Observations on limes, calcareous cements, &c. — The peculiar conditions necessary to insure a good and useful mortar for building purposes, and, the peculiarities of the hydraulic mortars or cements, will be treated of under MORTAR, which see.

LIMESTONE. (*Calcaire*, Fr; *Kalkstein*, Germ.) A great variety of rocks contain a sufficient quantity of lime in combination to be called limestones.

Chalk is an earthy massive opaque variety, usually soft and without lustre, and may be regarded as a tolerably pure carbonate of lime. Carbonate of lime dissolves in 1000 parts of water charged with carbonic acid. (*Shalk f.*) Fresenius states that it dissolves in 8334 parts of boiling water and in 10,601 parts of water at ordinary temperatures.

Carbonate of lime is found in nature more or less pure, both crystallised perfectly, as in calc spar and aragonite imperfectly; as in granular limestone; and in compact masses, as in common limestone, chalk, &c.

Stalactitic carbonate of lime, frequently called concretionary limestone, is formed by the infiltration of water through rocks containing lime, which is dissolved out, and as it slowly percolates the rocks into cavernous openings, the water parts with its carbonate of lime, which is deposited in zones more or less undulated, which have a fibrous structure from the crystalline character of the concretionary lime. The long fibrous pieces called stalactites show these fibres very beautifully. The straliform masses called stalagmites exhibit a similar structure, varied only by the conditions under which they are formed. A very remarkable stalagmitic limestone found in Egypt is known as oriental alabaster.

True *Alabaster* is a sulphate of lime (see ALABASTER), but the stalagmitic carbonate is not unfrequently called by this name.

Increasing concretionary limestones differ but little from the above. They are depos-

from calcareous springs which are common in some parts of Derbyshire, Yorkshire, and other places. It is a common practice to place vegetable substances in those springs; they then become incrustated with carbonate of lime, and are sold as petrifications, which they are not. In volcanic districts many very remarkable springs of this character exist. One of the most remarkable is at the baths of San Filippo in Tuscany, where the water flows in almost a boiling state; carbonate of lime here appears to be held in solution by sulphuretted hydrogen, which flies off when the water issues to day. Dr. Vegny has taken advantage of this property of the spring to obtain basso-relievo figures of great whiteness and solidity by occasioning the lime to deposit in sulphur moulds.

Agaric mineral, Spongy limestone, Rock milk, is found at the bottom of and about lakes whose waters are impregnated with lime. The calcareous tufa of Derbyshire is of this character; it may be studied in every stage of formation.

Travertine, which served to construct most of the monuments in ancient Rome, appears to have been formed by the deposits of the Anio and the Solfatara of Tivoli. The temples of Paestum, which are of extreme antiquity, have been built with a *travertine*, formed by the waters which still flow in this territory.

Compact limestone has a compact texture, usually an even surface of fracture, and dull shades of colour.

Granular limestone includes common statuary and architectural marble, and has a texture something like loaf-sugar. (See MARBLE.) Under those two heads are grouped a great number of varieties.

Oolite or rice stone consists of spherical grains of various sizes, from a millet seed to a pea or even an egg.

Coarse grained limestone. Coarse lias has been referred to this head.

Marly limestone. Lake and fresh-water limestone formation, texture fine grained, more or less dense; apt to crumble down in the air; colour white or pale yellow; fracture rough grained, somewhat conchoidal; somewhat tenacious. Texture occasionally cavernous, with cylindrical winding cavities. This true limestone must not be confounded with lime marl, which is composed of calcareous matter and clay.

Siliceous limestone. A combination of silica and carbonate of lime, varying very much in the proportions and sometimes passing from *cherty limestone* into *chert*. It scratches steel, and leaves a siliceous residuum after the action of muriatic acid.

Stinkstone or Swinestone. A carbonate of lime combined with sulphur and organic matter. It emits the smell of sulphuretted hydrogen by a blow or by friction. It occurs at Assynt, in Sutherlandshire, in Derbyshire, and some parts of Ireland.

Bituminous limestone. Limestone containing various hydrocarbon compounds, diffusing by the action of fire a bituminous odour, and becoming white when burnt.

Limestones of whatever kind may be referred to deposition effected by chemical change. The immense lapse of time required to form the great limestone ranges of this country can scarcely be estimated. Professor Phillips has the following remarks on this:—

"It is certain that while the sandstones, shales, coals, and thin oolitic limestones of the North York moors were deposited upon the lias, a deposit almost wholly calcareous was occasioned near Bath. The whole time consumed was the same in each locality. We may, therefore, perhaps infer the comparative rate of deposition of the oolite and the sandstones. The total thickness of the mass in Yorkshire is about 750 feet, of which about 20 may be called limestone; of that near Bath 480, of which nearly half is sand and clay with calcareous matter interspersed. Hence we have the proportion of three feet of sandstone deposited in the same time as one of limestone. Another instance is afforded, by comparing the sections of the lower carboniferous limestone in Derbyshire and in Tyndale. In the former tract we may take 750 feet as the thickness of limestone, with no admixture of sands or clays; in the latter; the contemporaneous strata are at least 1,750 feet thick, and contain 367 feet of limestone, and 1,283 feet of sands and clays, &c. consequently, 3.3 of limestone correspond in time to 1,283 of sand, clays, and coal, or 1 to 3.3."

The formation of limestone under different circumstances is an interesting study. Some of our great limestone formations indicate a marine, while others very clearly show a fresh water origin. Mr. Jukes, in his *Student's Manual of Geology*, says: "The marine depositions of carbonate of lime now taking place are best studied in coral reefs. In almost all tropical seas increasing patches or small banks of living coral are to be found along the shores, wherever they consist of hard rock and the water is quite clear. In the Indian and Pacific Oceans, however, far away from any land, huge masses of coral rock rise up from vast and unknown depths just to the level of low water. These masses are often unbroken for many miles in length and breadth, and groups of such masses, separated by small intervals, occur over spaces sometimes 400 or 500 miles long by 50 or 60 in width. The barrier reef along the

north-east coast of Australia is composed of a chain of such masses, and is more than 1000 miles long, from 10 to 90 miles in width, and rises at its seaward edge to depths which in some places certainly exceed 1800 feet. These reef masses consist of living corals only at their upper and outer surface, all the interior is composed of dead corals and shells, either whole or in fragments, and the calcareous portions of other marine animals. The interstices of the mass are filled up and compacted together by calcareous sand and mud, derived from the waste and debris, the great and tear of the corals and shells, and by countless myriads of minute organisms, mostly calcareous also. The surface of a reef when exposed at low water is composed of solid looking stone, which is often capable of being split up and lifted in slabs, bearing no small resemblance to some of our oldest limestones. . . . Guided by these facts and observations we may form tolerably accurate notions of the mode of origin of all our marine limestones, and attribute to them an organic-chemical origin, taking into account, at the same time, how easily they may have been subsequently altered in texture by the metamorphic action either of water or heat." Dr. Lyon Playfair suggests two additional modes by which a chemical precipitation of carbonate of lime might in some places be formed on the bottom of the sea. He says most rivers contain small quantities of silicate of potash; and when this is carried into the sea, some of the carbonic acid contained therein may unite with the potash, thus rendering possible a precipitation of carbonate of lime in a solid form, and also of silica. Marine vegetables also, like terrestrial vegetation, require carbonic acid, and, by extracting it from sea water, may reduce the amount in particular localities below that which is necessary to keep all the carbonate of lime in a fluid state, and thus render a solid precipitation of that substance possible. — *De la Roche*.

"Limestones," says Mr. Jukes, "may be hard or soft, compact, concretionary, or crystalline, consisting of pure carbonate of lime or containing silica, alumina, iron, &c., either as mechanical admixtures or as chemical deposits along with it. Different varieties of limestone occur in different localities, both geographical and geological, peculiar forms of it being often confined to particular geological formations over wide areas, so that it is much more frequently possible to say what geological formation a specimen was derived from, by the examination of its lithological characters, in the case of limestone than in that of any other rock. Compact limestone is a hard smooth fine-grained rock, generally bluish-grey, but sometimes yellow, black, red, white or mottled. It has either a dull earthy fracture or a sharp splintery and conchoidal one. It will frequently take a polish, and when the colour is a pleasing one is used as an ornamental marble. Crystalline limestone may be either coarse or fine-grained, varying from a rough granular rock of various colours to a pure white fine-grained one, resembling loaf-sugar in texture. This latter variety is sometimes called *saccharine*, sometimes *statuary marble*."

Oolite limestone includes Bath stone, Portland stone, and Caen stone.

Pisolite is a variety of oolite, in which the concretions become as large as peas.

Nummulitic limestone, *Cymenian*, *Crinoidal* limestones are so called from the fossils which the rock contains.

Shell limestone or *muschelkalk* has its name in the same way from its composition.

Cipolino is a granular limestone containing mica.

Majolica, a white and compact limestone.

Scaglia, a red limestone in the Alps. For the three last see MARBLE.

LIMESTONE, **MAGNESIAN**, see **DOLOMITE**. (*Dolomie*, Fr.; *Bitterkalk*, *Talkspath*, Germ.), is a mineral which crystallises in the rhombohedral system. Spec. grav. 2.85; scratches calc-spar; does not fall spontaneously into powder when calcined, as common limestone does. It consists of 1 prime equivalent of carbonate of lime = 50, associated with 1 of carbonate of magnesia = 42.

Massive magnesian limestone, is yellowish-brown, cream-yellow, and yellowish-grey; brittle. It dissolves slowly and with feeble effervescence in dilute muriatic acid; whence it is called *Calcaire lent dolomieu*, by the French mineralogists. Specific gravity 2.6 to 2.7.

Near Sunderland, it is found in flexible slabs. The principal range of hills composing this geological formation in England, extends from Sunderland to the north-east coast to Nottingham, and its beds are described as being about 300 feet thick on the east of the coal field in Derbyshire, which is near its northern extremity. — H.W. B.

LIME TREE (*Tilia Europæa*). The well-known linden tree, common to all Europe. The wood is very light-coloured, fine and close in the grain, and when properly seasoned, not liable to warp. It is much used in the manufacture of piano fortes and harps. It is made into cutting boards for carriers, shoemakers, &c., as it does not turn the knife in any direction of the grain, nor injure the edge.

Lime tree wood is especially useful for carving, from its even texture and freedom

from knots. The beautiful works of Gibbons at Hampton Court, at Windsor, and at Chatsworth, are executed in lime tree wood.

The no less beautiful works of our celebrated living wood carver, Rogers, are executed in this wood.

LIMOGE WARE. See **POTTERY.**

LIMONITE. A name for several varieties of iron ore, such as the brown hematite and bog iron ore. There is much difficulty in distinguishing the various kinds of iron ore, they shade so gradually one into the other; but it is clearly a very unscientific mode of proceeding to group things unlike each other under a common name.

LINSEYS, sometimes called *linsey-woolsey*; being a combination of flax and wool, which are woven into coarse cloth, usually employed to clothe those who are entirely dependent on public charity.

LINEN. See **FLAX**, and **TEXTILE FABRICS.**

LINEN distinguished from cotton. Cotton may be distinguished from linen or flax by immersing the former, well washed and dried, for about a minute in strong sulphuric acid. It is then to be withdrawn and washed with water containing a little alkali. The cotton will dissolve as a gummy mass, while the linen will retain its thready texture.

The manufacture of linens is carried on extensively in the north of Ireland, and on the continent in Bohemia, Moravia, Silesia, and Galicia. Of the entire production, independent of the Irish linen, about five-twelfths are brought into the market, and of this quantity the bulk must be of domestic manufacture, since few great linen manufactures exist in Austria. Within the Austrian dominions, among the linen fabrics, table-cloths and napkins, veils, cambrics, dimities, twills, and drills are important articles. In the next rank we must place the manufacture of thread, especially in Bohemia, Moravia, and Lombardy. The tape manufacture is of less consequence; and as to the business of dyeing and printing, that has been almost entirely absorbed by the cotton manufacture, and is now in requisition for thread and handkerchiefs only.

As the loss resulting from the processes of weaving, bleaching, &c. is estimated at about 10 per cent. the net aggregate of these manufactures of linen, thread, &c., may be assumed at, say, 1,037,000 cwt.; of which quantity about 450,000 cwt. come into the market, the rest being absorbed by domestic consumption. Since, upon an average of the five years from 1843 to 1847, there appear to have been imported from abroad only 242 cwt. whereas the average of exports for the same period shows 42,609 cwt., it follows that there remained for home consumption about 1,000,000 cwt. Thus, on a population of 38,000,000 of persons, about 2½ lbs. would fall to the share of each; but this estimate falls much below the truth, when we consider that the national costume in Hungary and Galicia requires more than double the quantity we have allowed for. In fact the crop of flax is estimated to be 10 per cent. higher than is given in the official reports; but the consumption of even 3 lbs. per head, which would thus result, is yet smaller than in reality it must be. In the imperial army of Austria the quantity used up annually by each man averages more than 7 lbs.

In the above statistics of the manufacture of linen goods no allowance has been made for the extensive production of rope work and the like.

From the article **FLAX**, reference has been made to this article for available information in the statistics of the production of the raw material and of the finished article in this country. The following simple tables will fully set forth the value of this important manufacture.

After the information already conveyed to the reader in the article **FLAX**, what has been said with regard to **COTTON MANUFACTURE**, and the additional matter in the article **TEXTILE FABRICS**, it does not appear necessary to say anything more on the subject of linen manufacture.

Imports of Flax in 1857.

LINSEED. (*Grains de lin*, Fr.; *Leinsame*, Germ.) The seed of the flax, *Linum Catharticum*, which is indigenous to our islands, and is cultivated extensively in this and other countries for its seed, and for flax. Linseed contains in its dry state, 11.265 of oil; 0.146 of wax; 2.4908 of a soft resin; 0.350 of a colouring resinous matter; 0.926 of a yellowish substance analogous to tannin; 0.134 of gum; 15.12 of vegetable mucilage; 1.45 of starch; 2.932 of gluten; 2.782 of albumine; 10.881 of saccharine extractive; 44.392 of envelopes, including some vegetable mucilage. It contains also free acetic acid; some acetate, sulphate, and muriate of potash, phosphate and sulphate of lime; phosphate of magnesia; and silica.

LINSEED OIL is obtained from linseed by first bruising the seeds, grinding them, and subjecting them to violent pressure, either by means of wedges, or of the hydraulic or screw press. Cold drawn linseed oil is obtained cold, and is paler coloured, less odorous, and has less taste than that which is obtained when heat is applied.

It is usual to employ a steam heat of about 200° Fahr. By cold expression the seeds yield about 20 per cent., while by the aid of heat nearly 27 per cent. of oil can be obtained. The ultimate composition of linseed oil is carbon 76.014, hydrogen 11.351, and oxygen 12.635; its proximate constituents being oleic and margaric acids, and glycerine. Linseed oil is much used as a vehicle for colours by the painter. If linseed oil is exposed in a thin coat to the air it absorbs oxygen and becomes tenacious, and in many respects like caoutchouc: upon this property mainly depends its use in the arts. To secure this more readily a drying process is adopted, which must be described.

When linseed oil is carefully agitated with acetate of lead (tribasic acetate of lead), and the mixture allowed to clear by settling, a copious white cloudy precipitate forms, containing oxide of lead, whilst the raw oil is converted into a drying oil of a pale straw colour, forming an excellent varnish, which, when applied in thin layers, dries perfectly in twenty four hours. It contains from four to five per cent. of oxide of lead in solution. The following proportions appear to be the most advantageous for its preparation.

In a bottle containing 4½ pints of rain water, 15 ounces of neutral acetate of lead are placed, and when the solution is complete, 15 ounces of litharge in a very fine powder are added; the whole is then allowed to stand in a moderately warm place, frequently agitating it to assist the solution of the litharge. This solution may be considered as complete when no more small scales are apparent. The deposit of a shining white colour (oxebasic acetate of lead) may be separated by filtration. This conversion of the neutral acetate of lead into vinegar of lead, by means of litharge and water, is effected in about a quarter of an hour, if the mixture be heated to ebullition. When heat is not applied, the process will usually take three or four days. The solution of vinegar of lead, or tribasic acetate of lead, thus formed, is sufficient for the preparation of 22 lbs. of drying oil. For this purpose, the solution is diluted with an equal volume of rain water, and to it is gradually added, with constant agitation, 22 lbs. of oil, with which 16 ounces of litharge have previously been mixed.

When the points of contact between the lead solution and the oil have been frequently renewed by agitation of the mixture three or four times a day, and the mixture allowed to settle in a warm place, the limpid straw-coloured oil rises to the surface, leaving a copious whitish deposit. The watery solution rendered clear by filtration, contains intact all the acetate of lead first employed, and may be used in the next operation, after the addition to it as before of 16 ounces of litharge.

By filtration through paper or cotton the oil may be obtained as limpid as water, and by exposure to the light of the sun it may also be bleached.

Should a drying oil be required absolutely free from lead, it may be obtained by the addition of dilute sulphuric acid to the above, when, on being allowed to stand, a deposit of sulphate of lead will take place, and the clear oil may be obtained free from all trace of lead.

Linseed oil was at one time much used in the preparation of a liniment, which, as it is one of the very best possible applications to a burnt surface, cannot be too generally known. If equal parts of lime-water and linseed oil are agitated together, they form a thick liniment, which may be applied to the burn with a brush or feather. It relieves at once from pain, and forming a pellicle, protects the abraded parts from the air. The *linimentum calcis* of the Pharmacopœia is equal parts of

linewater and olive oil; this is a more elegant but a less effective preparation.

See Oil.

LINT for Surgery, was formerly prepared by scraping up linen by the hand; the preparation of it, however, has been made the subject of a patent by Mr. Thomas Hoss, which consists in the employment of peculiarly constructed scrapers for abrading the surface of the linen cloth, and producing a pile or nap upon it. The scrapers are worked by a rotary motion.

Instead of rotary scrapers, a reciprocating pendulous movement is sometimes applied to a single scraper. Chisel-formed blades are claimed by the patentee as scrapers for raising the pile, by working with the bevel edges forwards, so as to scrape and not to cut the fabric. He also claims in the rotary form a ledge or bed concentric with the axis of the scraper, which he also claims; both of which seem to be serviceable. Several kinds of lint-making machines are now employed, but as they all partake more or less the above principles they do not require description.

LIQUATION (Eng. and Fr.; *Saigerung*, Germ.) is the process of sweating out, by a regulated heat, from an alloy, a more easily fusible metal, from the interstices of a metal, which is more difficult of fusion. Lead and antimony are the metals most commonly subjected to liquation: lead for the purpose of removing by its superior affinity the silver present in any complex alloy; antimony as an easy means of separating it from its combinations in the ores.

Figs. 1138, 1139, 1140, represent the celebrated antimonial liquation furnaces of Malosse, in the department of Ardèche, in France. Fig. 1138, is a ground plan taken at the level of the draught holes *g*, fig. 1139, and of the dotted line *u r*; fig. 1139, is a vertical section through the dotted line *a n*, of fig. 1138; and fig. 1140, is a vertical section through the dotted line *c d* of fig. 1138. In the three figures, the same letters denote like objects. *a, b, c* are three grates upon the same level above the floor of the works, $4\frac{1}{2}$ feet long, by $10\frac{1}{2}$ inches broad; between which are two rectangular galleries, *d e*, which pass transversely through the whole furnace, and lie at a level of 12 inches above the ground. They are separated by two walls from the three fire places. The walls have three openings *f, g, h*, alternately placed for the flames to play through. The ends of these

galleries are shut in with iron doors *i, i*, containing peep holes. In each gallery are two conical cast-iron crucibles *A A*, into which the *liquating* sulphuret of antimony drops. Their height is from 12 to 14 inches; the width of the mouth is 10 inches, that of the bottom is 6, and the thickness four-thirds of an inch. They are coated over with fire-clay, to prevent the sulphuret from acting upon them; and they stand upon cast-iron pedestals with projecting ears, to facilitate their removal from the gallery or platform. Both of these galleries are lined with tiles of fire-clay *l, l*, which also serve as supports to the vertical liquation tubes *m m*, made of the same clay. The tiles are

gents fire until two gallons are obtained. This is reduced to a proof spirit, and a few drops of the oil of aniseed added.

These forms exemplify the character of all kinds of liqueurs. They are coloured yellow by the colouring matter of *carthamus*. *Pura* is produced by caramel; red, by cochineal; violet, by limus, or archil; blue by the sulphate of indigo; green, by mixing the blue and the yellow together.

Ratafia is the generic name, in France, of liqueurs compounded with alcohol, sugar, and the odoriferous or flavouring principles of vegetables. Bruised cherries with their stones are infused in spirit of wine to make the *ratafia* of *Grenoble de Tignes*. The liquor being boiled and filtered, is flavoured, when cold, with spirit of *myrica*, made by distilling water off the bruised bitter kernels of apricots, and mixing it with alcohol. Syrup of bay laurel and galango are also added.

LIQUID AMBAR. See *AMBAR*. *LIQUIN*.

LIQUORICE (*Glycyrrhiza Officinalis*; from *glychs*, sweet, and *rhiza*, a root). The root only is employed; these roots are thick, long, and running deep in the ground.

Besides the use of liquorice roots in medicine, they are also employed to brewing, and are pretty extensively grown for these purposes in some parts of England. Liquorice requires a rich deep dry sandy soil, which, previous to forming a new plantation, should be trenched to the depth of about three feet, and a liberal allowance of manure regularly mixed with the earth in trenching. The plants which are procured by slipping them from those in old plantations are, either in February or March, dibbled in rows three feet apart, and from eighteen inches to two feet in the row. They require three summers' growth before being fit for use, when the roots are obtained by retrenching the whole, and they are then stored in sand for their preservation until required. — *Peter Lawson*.

LITHARGE (Eng. and Fr.; *Glätte*, Germ.) is the fused yellow protoxide of lead, which on cooling passes into a mass consisting of small six-sided plates, of a reddish yellow colour and semitransparent. It generally contains more or less red lead, whence the variations of its colour, and carbonic acid, especially when it has been exposed to the air for some time. See **LEAD** and **SULPHUR**, for its mode of preparation.

LITHIA is a simple earthy or alkaline substance, discovered in the minerals called petalite and triphane. It is white, very caustic, reddens litmus and red cabbage, and saturates acids with great facility. When exposed to the air it attracts humidity and carbonic acid. It is more soluble in water than baryta; and has such a strong affinity for it as to be obtained only in the state of a hydrate. It forms neutral salts with all the acids. It is most remarkable for its power of acting upon or corroding platinum.

LITHIUM is the metallic basis of lithia; the latter substance consists of 100 of metal, and 123 of oxygen. Neither lithium nor its oxide are of any use in the arts.

LITHOGRAPHIC PRESS. The lithographic press in common use has long been regarded as a very inadequate machine. The amount of manual power required to work it, and the slow speed at which, under the most favourable circumstances, copies can be produced, disables lithography in its competition with letter-press. A career of brilliant success has attended the efforts of scientific men towards speed and perfection in this latter branch of the art; and the present printing machines surpass the hand-press somewhat in the same ratio as does our express speed the jog-trot of our forefathers. The engravings annexed, *figs.* 1141, 1142, will serve to illustrate Messrs. Napier & Sons' improvements upon the lithographic press. The machine is arranged to be driven by steam power; has belts, "crossed" and "open," supposed to be in connection with the engine, and to run upon the pulleys A, B, C. The crank pulley, A, is fixed on the screw-spindle D, and the other two work loose, or "dead," on the same spindle; these bands with their striking forks, G, are arranged so as to be brought alternately upon the fixed pulley G, and thus a reversing motion is given to the screw. The nut in which the screw works is fixed to a crosspiece R, which braces the side frames T T, together at bottom, while the bar C, performs the same office at top; the scraper-box, H, is sustained between

these frames at bearings *t*, and is so fitted as to work freely. To support the frames and scraper-box independent of the screw and maintain them in

1142

position, allowing freedom of action, the rollers *z, z*, are provided, which run in the planed recesses, *x*, along the top of the main standards *L*.

The machine is shown with its tympan down, ready for starting: this is effected by pressing lightly upon the lever, *b*, which raises a catch, and allows the weight *M*, to descend in the direction of its present inclination, and act upon the connections with the striking forks, so as to bring one of the bands upon the fast pulley, *u*, and make the scraper and its frames move forward. The return is caused by the frame, *r*, coming in contact with a stop *c*, which, yielding, acts upon the striking forks by its bar *d*, upon which it may be adjusted to give the travel required. On the return being accomplished, the machine stops itself by a striking action against stop *e*, the catch *b* falling in to prevent the weight descending to its full throw, and thus retaining the two bands upon the two dead pulleys, *a* and *c*, while the machine is prepared for another impression.

The action of the scraper is peculiar and novel: it is balanced, so that its tendency is to remain slightly raised, but in its forward movement, and at the point desired, it is made to descend by a stop fixed upon the top of the main standard, *L*, into a position vertical, or nearly so, in which position it is retained by its own onward progress against strong abutments projecting from the frames, *r*; on the return it resumes its raised position and passes back without impediment. The scraper may be adjusted to give the pressure desired, or the table on which the stone is placed regulated by screws.

The advantages embodied in this machine will be at once recognised by those interested. The pulling down of the scraper, and the labour and inconvenience attendant upon that operation, are entirely superseded by the simple and effectual valve-like movement just explained, which forms the ground work of this combination, although it will alike apply to the press work by hand, and is the most striking novelty in the machine.

LITHOGRAPHY. Though this subject belongs rather to the arts of taste and design than to productive manufactures, its chemical principles fall within the province of this Dictionary.

The term *lithography* is derived from *λίθος*, a stone, and *γραφω*, writing, and designates the art of throwing off impressions upon paper of figures and writing previously traced upon stone. The processes of this art are founded:—

1. Upon the adhesion to a grained or smoothly-polished limestone, of an encaustic fat which forms the lines or traces.
2. Upon the power acquired by the parts penetrated by this encaustic, of attracting to themselves, and becoming covered with, a printer's ink, having linseed oil for its base.
3. Upon the interposition of a film of water, which prevents the adhesion of the ink in all the parts of the surface of the stone not impregnated with the encaustic.
4. Lastly upon a pressure applied to the stone, such as to transfer to paper the greater part of the ink which covers the greasy tracings or drawings of the encaustic.

The lithographic stones of the best quality are still procured from the quarry of Solenhofen, a village at no great distance from Munich, where this mode of printing had its birth. They resemble in their aspect the yellowish-white lias of Bath, but their geological place is much higher than the lias. Abundant quarries of these fine-grained limestones occur in the county of Huppenheim, along the banks of the Danube, presenting slabs of every required degree of thickness, parted by regular seams, and ready

for removal with very little violence. The good quality of a lithographic stone is generally denoted by the following characters: its hue is of a yellowish grey, and uniform throughout; it is free from veins, fibres, and spots; a steel point makes an impression on it with difficulty; and the splinters broken off from it by the hammer display a conchoidal fracture.

The Munich stones are retailed on the spot in slabs or layers of equal thickness; they are quarried with the aid of a saw, so as to sacrifice as little as possible of the irregular edges of the rectangular tables or plates. One of the broad faces is then dressed, and coarsely smoothed. The thickness of these stones is nearly proportional to their other dimensions; and varies from 1½ inches to 3 inches.

In each lithographic establishment, the stones receive their finishing, dressing, and polishing; which are performed like the grinding and polishing of mirror plate. The work is done by hand, by rubbing circularly a movable slab over another in a horizontal position, with fine sifted sand and water interposed between the two. The style of work that the stone is intended to produce determines the kind of polish that it should get. For crayon drawing the stone should be merely grained more or less fine according to the fancy of the draughtsman. The higher the finish of the surface the softer are the drawings; but the printing process becomes sooner pappy, and a smaller number of impressions can be taken. Works in ink require the stone to be more softened down, and finally polished with pumice and a little water. The stones thus prepared are packed for use with white paper interposed between their faces.

Zinc plates are sometimes used in lieu of stones; they are prepared by graining the surface with fine sand, rubbed over by means of a small piece of the metal. Zinc takes a finer surface than stone, and yields more delicate impressions; but great care is necessary in keeping it dry, so that it does not corrode; this is almost the only objection to its more general use, for it is far more convenient to handle and move about than heavy stones.

Lithographic crayons.—Fine lithographic prints cannot be obtained unless the crayons possess every requisite quality. The ingredients composing them ought to be of such a nature as to adhere strongly to the stone, both after the drawing has undergone the preparation of the acid, and during the press-work. They should be hard enough to admit of a fine point, and trace delicate lines without risk of breaking. The following composition has been successfully employed for crayons by MM. Bernard and Delarue, at Paris:—

Pure wax (first quality)	-	-	-	-	4 parts.
Dry white tallow soap	-	-	-	-	2 "
White tallow	-	-	-	-	2 "
Gum lac	-	-	-	-	2 "
Lamp black, enough to give a dark tint	-	-	-	-	1 "
Occasionally copal varnish	-	-	-	-	1 "

The wax should be melted over a gentle fire, and the lac, broken to bits, is then added by degrees, stirring all the while with a spatula; the soap is next introduced in fine shavings; and when the mixture of these substances is very intimately accomplished, the copal-varnish, incorporated with the lamp black, is poured in. The heat and agitation are continued till the paste has acquired a suitable consistence; which may be recognised by taking out a little of it, letting it cool on a plate, and trying its quality with a penknife. This composition, on being cut, should afford brittle slices. The boiling may be quickened by setting the rising vapours on fire, which increases the temperature, and renders the exhalations less offensive. When ready, it is to be poured into a brass mould, made of two small cylinders joined together by clamps or rings, forming between them a cylindric tube of the crayon size. The mould should be previously rubbed with a greasy cloth.

The soap and tallow are to be put into a small goblet and covered up. When the while is thoroughly fused by heat, and no clots remain, the black is gradually sprinkled in with careful stirring.

Lithographic ink is prepared nearly on the same principle:—

Wax	-	-	-	-	-	16 parts
Tallow	-	-	-	-	-	6 "
Hard tallow soap	-	-	-	-	-	6 "
Shell-lac	-	-	-	-	-	12 "
Mastic in tears	-	-	-	-	-	8 "
Venice turpentine	-	-	-	-	-	10 "
Lamp black	-	-	-	-	-	4 "

The mastic and lac, previously ground together, are to be carefully heated in the turpentine; the wax and tallow must be added after they are taken off the fire and when their solution is effected, the soap shavings are to be thrown in. Lastly, the lamp

black is to be well intermixed. Whenever the union is accomplished by heat the operation is finished; the liquor is left to cool a little, then poured out on tables, and, when cold, cut into square rods.

Lithographic ink of good quality ought to be susceptible of forming an emulsion so attenuated, that it may appear to be dissolved when rubbed upon a hard body in distilled or river water. It should flow in the pen, but not spread on the stone; capable of forming delicate traces, and very black, to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to reproduce the most delicate outlines of the drawing, and to afford numerous impressions. It must therefore be able to resist the acid with which the stone is moistened in the preparation, without letting any of its greasy matter escape.

M. de Lasterrie states that after having tried a great many combinations, he gives the preference to the following:—

Tallow soap dried	-	-	-	30 parts.
Mastic in tears	-	-	-	30 ..
White soda of commerce	-	-	-	30 ..
Shell-lac	-	-	-	150 ..
Lamp-black	-	-	-	12 ..

The soap is first put into the goblet and melted over the fire; the lac being added it fuses immediately; the soda is then introduced, and next the mastic, stirring all the while with a spatula. A brisk fire is applied till all these materials are melted completely, when the whole is poured out into the mould.

The inks now prescribed may be employed either with the pen and the hair pencil, for writings, black-lead drawings, *aqua tinta*, mixed drawings, those which represent engravings on wood (woodcuts), &c. When the ink is to be used it is to be rubbed down with water, in the manner of China ink, till the shade be of the requisite depth. The temperature of the place ought to be from 84° to 90° Fahr., or the saucer in which the ink stick is rubbed should be set in a heated plate. No more ink should be dissolved than is to be used at the time, for it rarely keeps in the liquid state for 24 hours; and it should be covered or corked up.

Autographic paper.—Autography, or the operation by which a writing or a drawing is transferred from paper to stone, presents not merely a means of abridging labour, but also that of reversing the writings or drawings into the direction in which they were traced, whilst, if executed directly upon the stone, the impression given by it is inverted. Hence, a writing upon stones must be inverted from right to left to obtain direct impressions. But the art of writing thus is tedious and difficult to acquire, while, by means of the autographic paper and the transfer, proofs are obtained in the same direction with the writing and drawing.

Autographic ink.—It must be fatter and softer than that applied directly to the stone, so that though dry upon the paper, it may still preserve sufficient viscosity to adhere to the stone by mere pressure.

To compose this ink, we take—

White soap	-	-	-	100 parts.
White wax of the best quality	-	-	-	100 ..
Mutton suet	-	-	-	30 ..
Shell-lac	-	-	-	50 ..
Mastic	-	-	-	50 ..
Lamp black,	-	-	-	30 or 35 ..

These materials are to be melted as above described for the lithographic ink.

Lithographic ink and paper.—The following recipes have been much commended:—

Virgin or white wax	-	-	-	8 parts.
White soap	-	-	-	2 ..
Shell-lac	-	-	-	2 ..
Lamp black	-	-	-	3 table-spoonfuls.

Preparation.—The wax and soap are to be melted together, and before they become so hot as to take fire, the lamp black is to be well stirred in with a spatula, and then the mixture should be allowed to burn for 30 seconds; the flame being extinguished, the lac is added by degrees, carefully stirring all the time; the vessel is to be put upon the fire once more in order to complete the combination, and till the materials are either kindled or nearly so. After the flame is extinguished, the ink must be suffered to cool a little, and then put into the moulds.

With the ink crayons thus made, lines may be drawn as fine as with the point of the graver, and as full as can be desired, without risk of its spreading in the carriage. Its traces will remain unchanged on paper for years before being transferred.

Some may think it strange that there is no suet in the above composition, but it has

been found that ink containing it is only good when used soon after it is made, and when immediately transferred to the stone, while traces drawn on paper with the same ink become defective after 4 or 5 days.

Lithographic paper.—Lay on the paper 3 successive coats of sheep-foot jelly, 1 layer of white starch, 1 layer of gamboge.

The first layer is applied with a sponge dipped in the solution of the hot jelly, very equally over the whole surface, but thin; and if the leaf be stretched upon a cord, the gelatine will be more uniform. The next two coats are to be laid on, until each is dry. The layer of starch is then to be applied with a sponge, and it will also be very thin and equal. The coat of gamboge is lastly to be applied in the same way. When the paper is dry, it must be smoothed by passing it through the lithographic press; and the more polished it is, the better does it take on the ink in fine lines.

Transfer—When the paper is moistened, the transfer of the ink from the gamboge is perfect and infallible. The starch separates from the gelatine, and if, after taking the paper off the stone, we place it on a white slab of stone, and pour hot water over it, it will resume its primitive state.

The coat of gamboge ought to be laid on the same day it is dissolved, as by keeping it becomes of an oily nature; in this state it does not obstruct the transfer, but it gives a gloss to the paper which renders the drawing or tracing more difficult, especially to persons little accustomed to lithography.

The starch paste can be employed only when cold, the day after it is made, and after having the skin removed from its surface.

A leaf of such lithographic paper may be made in two minutes.

In transferring a writing, an ink drawing, or a lithographic crayon, even the impression of a copper-plate, to the stone, it is necessary, 1, that the impressions be made upon a thin and slender body like common paper; 2, that they may be detached and fixed totally on the stone by means of pressure; but as the ink of a drawing sinks to a certain depth in paper, and adheres rather strongly, it would be difficult to detach all its parts, were there not previously put between the paper and the traces a body capable of being separated from the paper, and of losing its adhesion to it by means of the water with which it is dampened. In order to produce this effect, the paper gets a certain preparation, which consists in coating it over with a kind of paste ready to receive every delineation without suffering it to penetrate into the paper. There are different modes of communicating this property to paper.

Besides the above, the following may be tried. Take an unsized paper, rather strong, and cover it with a varnish composed of:—Starch, 120 parts; gum arabic, 40 parts; alum, 20 parts.

A paste of moderate consistence must be made with the starch and some water, with the aid of heat, into which the gum and alum are to be thrown, each previously dissolved in separate vessels. When the whole is well mixed, it is to be applied, still hot, on the leaves of paper, with a flat smooth brush. A tint of yellow colour may be given to the varnish with a decoction of the berries of Avignon, commonly called French berries by our dyers. The paper is to be dried, and smoothed by passing under the scraper of the lithographic press.

Steel pens are employed for writing and drawing with ink on the lithographic stones; in many establishments a sable brush is more frequently used.

Engraving on stone, for maps, geometrical drawings of every kind, patent inventions, machinery, &c., is performed with a diamond point as clearly and distinctly as if executed on copper or steel plates; to print these engraved stones, the ink should be laid on with a dabber, not a roller. Another method is by preparing the surface of the stone with a thin covering, or etching ground, of gum and black, upon which the design is traced or engraved with an etching point; it then appears in white lines upon a black surface. In this state the stone is taken to the printer, who applies ink to the engraved part, and washing off the gum, the drawing appears in black lines upon the white surface of the stone, and after being submitted to the process of fixing, described below, is ready for printing.

Litholat, a process of drawing upon stone was adopted, first, by Mr J. D. Harding, a few years back; and since by one or two other artists; several works were at the time executed by this method, which consists in painting the subject with a camel hair pencil, dipped in a preparation of liquid lithographic chalk, using the latter as if it were an ordinary colour, or Indian ink, sepia, &c. The results of this process were, however, so uncertain in printing, that it has been almost, if not entirely, abandoned.

The process of printing a subject executed in lithography is as follows.—The drawing is first executed by the artist on the stone in as perfect and finished a manner as if done on paper or card-board; the stone is then washed over with nitric acid, diluted with gum, which neutralises the alkali, or soap, contained in the chalk,

fixes the drawing, and cleanses the stone at the same time: this is technically called *etching*. The acid is then washed off with cold water, and any particles of the crayon or other substances which may have adhered to the surface, are removed by the application of a sponge dipped in spirits of turpentine: the stone is now ready for printing. It is slightly wetted, charged with printing-ink by means of a roller, the sheet of paper, which is to receive the impression, is laid on it in a damp state, and the whole is passed through the press.

Chromolithography, or printing in colours from stones (*χρῶμα*, colour) is a comparatively recent introduction, but has been brought to such perfection, that works of art of the highest pictorial excellence are sometimes so closely imitated, as to deceive very competent judges. A portrait of Shakspeare, for example, executed in chromolithography by Mr. Vincent Brooks, of London, from an old oil painting, is so marvellous a copy of the original as almost to defy detection. Chromolithography, as a beautiful medium of illustration, is now in very general use: the process may be thus described. A drawing of the subject, in outline, on transfer tracing-paper, is made in the ordinary way when transferred to a stone, this drawing is called the *égoutte*, and it serves as a guide to all the others, for it must be transferred to as many different stones as there are colours in the subject; as many as thirty stones have been used in the production of one coloured print. The first stone required, generally for flat, local tints, is covered with lithographic ink where the parts should be of solid colour: the different gradations are produced by rubbing the stone with *rubbing-stuff*, or tint-ink, made of soap, shell lac, &c. &c., and with a painted lithographic chalk where necessary; the stone is then washed over with nitrous acid, and goes through the entire process described above. A roller charged with lithographic printing-ink is then passed over it to ascertain if the drawing comes as desired; and the ink is immediately afterwards washed off with turpentine: if satisfactory, this stone is ready for printing, and is worked off in the requisite colour; the next stone undergoes the same process for another colour, and so with the rest till the work is complete: it will of course, be understood, that before any simple impression is finished, it will have to pass through as many separate printings as there are drawings on stones. The colours used in printing are ground up with burnt linseed oil, termed *varnish*. — J. D.

LITHOMARGE. A silicate of alumina, in many respects resembling China clay or kaolin, *whence see*.

LITMUS (*Tournefort, Fr.; La Lina, Germ.*) is prepared in Holland from the species of lichen called *Lecanora tartarea*, *H. in tartarea*. The ground lichens are first treated with urine containing a little potash, and allowed to ferment for several weeks, whereby they produce a purple-red; the coloured liquor, treated with quicklime and some more urine, is set again to ferment during two or three weeks, then it is mixed with chalk or gypsum into a paste, which is formed into small cubical pieces by being pressed into brass moulds, and dried in the shade. Litmus has a violet-blue colour, is easy to pulverise, is partially soluble in water and dilute alcohol, leaving a residuum consisting of carbonate of lime, of clay, silica, gypsum, and oxide of iron combined with the dye. The colour of litmus is not altered by alkalis, but is reddened by acids; and is therefore used in chemistry as a delicate test of acidity, either in the state of solution or of unsized paper stained with it. See **LICHEN**.

The preparation of litmus has been described by Ferber, Morriox, and others.

Dr. Percival writes, "Litmus is imported from Holland, in the form of small, rectangular, light, and friable cakes of an indigo blue colour. Examined by the microscope, we find sporules and portions of the epidermis and mesothallus of some species of lichen, mixed with sand, &c. The colour of the cakes is that of indigo and violet. The violet odour is acquired while the mixture is undergoing fermentation, and is common to all the tinctorial lichens. It has led some writers into the error of supposing that the litmus makers use Florentine orris in the manufacture of litmus. The indigo colour depends on the presence of indigo in the litmus cakes."

LITMUS PAPER. Paper coloured with an infusion of litmus, used as a test for the presence of acids.

Faraday, in his *Chemical Manipulation*, recommends an infusion of one ounce of litmus, and half a pint of hot water. Rhetorical paper is saturated with this. Professor Graham prefers good letter paper to the unsized paper. In order to obtain very delicate test-paper, the alkali in the litmus must be almost neutralised by a minute portion of acid.

LITTORAL (a geological term). Belonging to the sea-shore.

LIVI-DIVI. Another name for Divi-divi. See **LEATHER**.

LIXIVIATION (*Lixivage, Fr.; Auslügen, Germ.*) signifies the abstraction by water of the soluble alkaline or saline matters present in any earthy admixture; as from that of quicklime and potashes to make potash lye, from that of effloresced alum schist to make aluminous liquors, &c.

LLAMA. A genus of animals belonging to the class *Mammalia*, order *Ungulata*, family *Bovidae*, and tribe *Camelina*. They are the camels of South America, to which country they are confined. In the wild state the llamas keep together in herds of from one to two hundred. There are two distinct species found wild in South America, inhabiting the Peruvian Alps, the Panipaa, and the mountains of Chili. These animals are used as beasts of burden; cords and sacks, as well as stuffs for ponchos, &c., are fabricated from their wool; and their bones are converted into instruments for weaving the same. The Alpaca, which is a variety of the llama, has given its name to a cloth manufactured from its hair; and this has become so valuable, that attempts have been made to naturalise the animal in Europe. The success, however, which has attended these attempts has not been great. The following note from the *Penny Cyclopædia*, article *Llama*, is important.

"In reference to the wool, we may here state that a herd of thirty-six, including the kinds called llamas, alpacas, and vicuñas or viconias, were sent from Lima (Peru) and Concepcion (Chili) to Buenos Ayres by journeys of two or three leagues. In those who may be inclined to import these animals, it may be necessary to state that they were fed during the journey with potatoes, malae, and hay. As soon, however, as the potatoes were exhausted, constipation came on so obstinately, that medical relief was required. They were shipped as a present from Godoy, the Prince of Peace, to the Empress Josephine, but only eleven arrived at Cadiz in 1808, just as Godoy fell into disgrace. More two died, and the rest were near being thrown into the sea by the infuriated rabble, in their detestation of the late minister and minion. The poor llamas were however saved from the tender mercies of the populace by the governor of Cadiz, and were consigned to Don Francisco de Tberan of Andalusia, who had a fine menagerie at San Lúcar de Barrameda. When the French occupied the province, Marshal Soult protected them; and M. Dury St. Vincent, who was with the army, studied their habits, and executed drawings of them, which were lost at the battle of Vittoria. M. Dury paid great attention to their wool, and some from each kind was sent to the Academy of Sciences at Paris. From the report of the French naturalist and the philosophical Spaniard, it would appear that the fleece of the alpa-viconia (produced by a cross between a viconia and an alpaca) has much greater length than any other variety, and is six times heavier."

The following is from *James's History of the Woollen Manufacture in England*, p. 662:—

To commence with the earliest mention of the alpaca, we must recur to so early a period as the year 1525, when Pizarro and his ferocious companions invaded Peru. It is related by the Spanish historians, that they found there four varieties of sheep; two, the guanaco and the vienna, in a wild state, ranging the mountainous tracts of South America; and the others, the llama and the paco, or alpaca, domesticated. The former of these domestic animals, partaking somewhat of the nature and size of the Arabian camel, was in like manner employed as a beast of burden. Though in many features similar to the llama, the alpaca had several clear marks of distinction, and among others was less, and the fleece much longer and softer in fibre. In the sixteenth century, and even from the remotest times, the Peruvians being comparatively (to the other tribes of the great continent of America) a civilised people, and well acquainted with the arts of spinning and weaving, fabricated from alpaca wool textures of much delicacy and beauty, which were highly prized as articles of dress. And that the use of them had prevailed for centuries is demonstrated by the opening of several very ancient tombs of the Peruvians, in which the dead had been enwrapped in stuffs made from the fleece of the alpaca.

In general, the alpaca ranges about four feet in height, the size of a full grown deer, and, like it, is of graceful appearance. Its fleece is superior to the sheep in length and softness, averaging six inches (the length of the staple of the alpaca fleece is on an average much less than formerly, probably from being shorn oftener), and sometimes it has been procured even of an extraordinary length; a specimen shown at the Great Exhibition, by Messrs. Walter Milligan and Son, reaching to forty-two inches in length. The fleeces, when annually shorn, range from five to six pounds. Contrary to experience in other descriptions of wool, the fibre of the Alpaca fleece acquires strength without coarseness; besides, each filament appears straight, well formed, and free from crispness, and the quality is more uniform throughout the fleece. There is also a transparency, a glittering brightness upon the surface, giving it the glossiness of silk, which is enhanced on its passing through the dye-vat. It is also distinguished by softness and elasticity, essential properties in the manufacture of fine goods, being exempt from spiral, curly, and shaggy defects; and it spins, when treated properly according to the present improved method, easily, and yields an even, strong, and true thread. With all these remarkable qualities, it was long before the value of alpaca wool was known or appreciated in this country.

Recurring to the application of the alpaca fleece to manufacturing purposes in England, it was long delayed. Though so early as the year 1807, the British troops returning from the attack of Buenos Ayres brought with them a few bags of this wool, which were submitted for inspection in London; but, observes Walton in his work on alpaca, "owing to the difficulty of spinning it, or the prejudice of our manufacturers, it did not then come into notice," and for more than twenty years the attempt does not seem to have been renewed; thus depriving, for that period, the country of the advantage derived from this notable manufacture.

According to the best authorities, the first person in England who introduced a marketable fabric made from this material was Mr. Benjamin Cutram, a scientific manufacturer of Greetland, near Halifax, who, about the year 1830, surmounted, with much difficulty, the obstacles encountered in spinning the wool, and eventually produced an article which sold at high prices for ladies carriage shawls and cloakings; but their value arose more from being rare and curious articles than from intrinsic worth.

These were, it is well established, quite destitute of the peculiar gloss and beauty which distinguish the alpaca lustrous and fabrics of later times, and after a short period the manufacture was abandoned.

About the same time as Mr. Cutram was weaving goods from alpaca, the wool attracted the notice of the Bradford spinners. Messrs. Wood and Walker spun it to some extent for camelot warps used in the Norwich trade. Owing to the cheapness of alpaca wool during the first years of its consumption in England, it was occasionally employed instead of English long wool for preparing lasting and camelot warps, being spun to about No 48.

The earliest manufacture of the alpaca wool into goods at Bradford appears to have occurred under these circumstances. In the commencement of 1832 some gentlemen, connected with the trade to the west coast of South America, were on a visit at the house of J. Garnett, Esq., of Clithero, and, on their alluding to the difficulty of meeting with suitable returns for goods forwarded to that part of the world, he suggested to them the transmission of alpaca wool, and offered, if they would send him a few pounds weight, to ascertain its value for manufacturing purposes. In a few months he received some samples of alpaca wool, which, on the 2nd of October, 1832, he forwarded to Messrs. Horsfall, of Bradford, with a request that they would test its value. Accordingly they fabricated from this wool a piece resembling heavy camelot, which they showed to the Leeds merchants; but the piece, not developing any peculiar qualities of alpaca, did not please, so that Messrs. Horsfall were not encouraged to proceed further with experiments. However, in the same year Messrs. Hyam, Hall, and Co., spirited merchants of Liverpool, perceiving the value of the alpaca wool, directed their agents in Peru to purchase and ship over all the parcels of alpaca wool they could meet with; some of which, being sent to the Bradford district, was spun and manufactured by several parties there. The pieces chiefly fabricated from alpaca in the neighbourhood of Bradford were figures made with worsted warp and alpaca weft, the figure being raised and lustrous like union damasks. These goods were in vogue for a limited time, for neither the figured nor plain ones seem to have suited the public taste.

Until the introduction of cotton warps into the worsted trade, it may safely be asserted that the alpaca manufacture had not been developed, and would never have made much progress without being combined with cotton or silk warp. To Titus Salt, Esq., of Bradford, most undoubtedly be awarded the high praise of finally overcoming the difficulties of preparing and spinning the alpaca wool so as to produce an even and true thread, and, by combining it with cotton warps, which had then (1836) been imported into the trade of Bradford, improved the manufacture so as to make it one of the staple industries of the kingdom. He has, by an admirable adaptation of machinery, been enabled to work up the material with the ease of ordinary wool, and thus present beautiful alpaca stuffs at a reasonable rate. Every previous attempt had been made, so far as can be ascertained, with worsted warps, with which the alpaca did not easily assort.

About the year 1836 the alpaca trade had become established, and has since risen to much importance. After this period the manufacture rapidly extended. The great mercantile house of A. and S. Henry took very large quantities of alpaca stuffs, which began to be made in an endless variety of goods suited both for male and female dress, including scarfs, handkerchiefs, and cravats, plain and figured goods, both with silk and cotton warp, for ladies' dresses, dyed alpaca checks of beautiful texture, and a variety of gingham, cordingtons, silk-striped, checked, and figured alpacas and alpaca linings. The demand for these various alpaca fabrics during the period between 1831 and 1846 remained uniform and steady.

At the commencement of the manufacture of alpaca goods with cotton warps (silk

was not used), the web was spun from fine qualities of the wool into low numbers, and the pieces were made much richer and heavier than has been the case more recently, the demand having altered in favour of lighter and less costly cloth.

Most of the alpaca wool brought into the United Kingdom is unshipped at Liverpool, but a small portion is also carried to London. At these two ports, it may be asserted, the whole imported into this country is landed. It arrives in small bales, called ballots, weighing about seventy pounds, and is generally in an impure state, with different qualities mixed. Like the fleece of the sheep, that of the alpaca is composed of different qualities, so that the portion growing on the hind quarters is of an inferior description. The wool is sorted into about eight different qualities, each fitted for a particular class of goods. Owing to the dirty state of the fleeces, and the peculiar nature of the dusty particles arising during the progress of sorting, the operation is an unhealthy one, unless great care be taken by ventilation to counteract this baneful effect. After being sorted, it is at Saltaire washed and combed by machinery. Until of late years it was combed wholly by hand, and the combs used for the purpose were of a deeper pitch than those usually adopted for preparing sheep's wool, that is, those combs had a larger number of teeth than ordinary. The next process is to draw the sliver, which is perfected by an improved gill machine, especially adapted for this material. And here, in combing and preparing the alpaca wool, so as to make a clean, even, and glossy thread, lay the grand difficulty in the way of applying the alpaca fibre to the worsted manufacture, and which was so successfully surmounted by Mr. Salt.

The main articles now manufactured from alpaca wool consist of alpaca lustras, which are dyed, and alpaca mixtures, which are undyed, and both are made of cotton or silk warp. These plain goods may from their extensive and steady use be termed stock articles. Large quantities of fancy alpacas are made, but they are rapidly varying and are distinguished by innumerable names. The material is at present much shorter in staple than formerly, owing to the alpaca being shorn oftener, so that it is now commonly from five to eight inches in length. Nearly all the alpaca wool consumed in England is worked up in the Bradford district.

Dating from the year 1834, when the importation of alpaca wool sprung up as a permanent branch of commerce, the demand in this country has, with the exception of the last two years, on the whole been a growing one. Mr. Walton, in his work on the alpaca, exhibits the quantities exported chiefly to England until the year 1843, when the tariff law having come into operation, the returns began to be more correctly framed, and the alpaca wool was then classed by itself.

Years.	Lbs.	Years.	Lbs.
1834	5,700	1839	1,215,000
1835	194,400	1840	1,650,000
1836	199,000	1841	1,541,000
1837	385,400	1842	1,443,200
1838	459,300		

In the interval of these twelve years, the price had, with the demand, progressively increased: the price in 1834 only amounted to about eightpence halfpenny per pound; next year it reached nearly tenpence; the year after one shilling; in 1838, to upwards of one shilling and threepence halfpenny; and in 1839, to one shilling and fourpence per pound.

Since the year 1842, the returns of alpaca wool imported into this country are of a more reliable character. The following table has been drawn up from data furnished by the Board of Trade.

Years.	Lbs.	Years.	Lbs.
1843	1,458,002	1850	1,659,793
1844	635,357	1851	2,013,303
1845	1,261,905	1852	2,064,894
1846	1,554,257	1853	2,148,267
1848	1,521,370	1854	1,967,513
1849	1,655,300	1855	1,446,707

Astonishing as it may appear, the bulk of these importations have been consumed in England, and the quantity re-shipped to the Continent has been comparatively trifling in amount.

During the last ten years, the prices have fluctuated considerably. In 1844, one shilling and eightpence per pound was quoted as the price of the white fleece, and two shillings for the black one. In the year 1855, according to the price currents, the average rates were thus quoted :

	s.	d.	s.	d.
Alpaca, best white	-	-	3	6 to 2 8
Idem, brown and black	-	-	2	6 " 2 8
Vicuna, best dark coloured	-	-	3	0 " 3 6
Llama	-	-	0	10½ " 1 3

But these quotations are undoubtedly higher for alpaca wool than the prices realised, which of late years have ranged from two shillings and twopence to two shillings and sixpence per pound.

LOAD. A burthen or freight. As the various quantities of material contained in a load cannot but be useful, the following table is borrowed from *Mr. P. L. Simmonds' "Trade Products,"* &c.

Corn	-	3 qrs. or 40 bushels.	Coffee, in bags	-	12 cwt.
Straw	-	36 trusses or 11 cwt. 6½ lbs.	Hice	-	10 cwt.
Old hay	-	16 cwt.	Timber—		
New hay	-	12 cwt. 32 lbs.	1 inch plank	-	600 square feet.
Bricks	-	500.	1½ inch "	-	400 " "
Tiles	-	1000.	2 inch "	-	300 " "
Lead ore (in Derbyshire) 2 dishes or nearly 3 cwt.			2½ inch "	-	240 " "
Batrabes	-	63 bundles.	3 inch "	-	200 " "
Mortar	-	27 feet.	3½ inch "	-	170 " "
			4 inch "	-	150 " "

LOADSTONE, MAGNETIC IRON-STONE. (*Fer aspidul.* Fr.; *Magnetstein*, Germ.) An iron ore consisting of the protoxide and peroxide of iron in a state of combination.

It was first discovered in Magnesia, and from that province has been derived the name *Magnet* applied to this ore of iron. The term loadstone, however, is given to those specimens which are powerfully magnetic only. A considerable number of the igneous rocks containing iron are magnetic, and many magnetic oxides of iron are found in England, especially near Penryn in Cornwall, near Brent in Devonshire, at Rosedale in Yorkshire, and some other places. See *Iron*.

LOAM. (*Terre luneraire*, Fr.; *Lehm*, Germ.) A native clay mixed with quartz sand and iron ochre, and occasionally with some carbonate of lime.

" More commonly we find sand and clay or clay and marl intermixed in the same mass. When the sand and clay are each in considerable quantities, the mixture is called 'loam.'—*Lyell*.

LOCKS. Although locks are distinctly a manufacture, yet they were not embraced in former editions of this work, the chief cause of this being the desire on the part of Dr. Ure to limit the articles of the dictionary to such manufactures as were not comprehended within his meaning of the term handicraft.

The lock manufacture is essentially one of handicraft, and seeing that these volumes could not possibly enter into any detailed description of this and numerous other trades, as watchmaking and the like, it has been determined that a brief notice of the several kinds of locks alone shall find a place in its pages.

The lock manufacture of this country is confined almost exclusively to Wolverhampton and the neighbouring village of Willenhall. There are very few large manufactories, almost all kinds of locks being made by small masters, employing from nearly a dozen to a dozen men.

In half a every kind of lock, a bolt shoots out from the box or lock, usually of an oblong shape, and catches in some kind of staple or box fixed to receive it. In some a staple enters the lock, and the bolt passes through the staple within the lock. The lock of a room door is of the first character. The lock of a writing desk or ordinary box, is of the second kind. The key is merely a bent piece of iron which, on entering the lock, can move freely and push forward the bolt. To the bolts of superior locks springs are attached, and the force required to turn the key in a lock is the force necessary to overcome the resistance of the springs. The following two figures, 1143, 1144, represent the character of a lock with wards or wheels which are introduced to give safety. Fig. 1143 is an ordinary back spring lock, representing the bolt half shot; a' a' are notches on the under side of the bolt connected by a curved

portion; *b* is the back spring, which is of course compressed as the curved portion of the bolt passes through the aperture prepared for it in the rim of the lock; when

1144

1143

the bolt is withdrawn, the notch *a'* rests in the rim; when the bolt is shot, the notch *a'* rests in the same manner. The action of the key and wards is shown in fig. 1144. The curved pieces of metal are the wards; and there are two clefts in the bit of the key to enable it to move without interruption.

The tumbler lock is shown in its most simple form in fig. 1145. Here the bolt has two slots *a* in the upper part; and behind the bolt is a kind of latch *b* which carries a projecting piece of metal; *c*, this is the tumbler which moves freely on a pivot at the other end. When the bolt is fully shot the projecting piece of metal falls into one notch; and when withdrawn, it falls into the other. It will be evident here that the action of the key is to raise the tumbler, so that the bolt has free motion; this action will be intelligible by tracing the action of the key on the dotted lines. These tumbler locks are greatly varied in character; but in principle they are as above described. Numerous well known locks have been patented, the most remarkable being Chubb's lock, which has been fully described by the inventors in a paper read before the Institution of Civil Engineers; and also in an excellent treatise on locks to be found in Mr. Weale's series of useful manuals. This lock is essentially a tumbler lock, it being fitted up with no less than six tumblers; and the key has to raise by a series of steps these, before the bolt is free to move. It will be obvious, that unless the key is exactly fitted to move these, there is no chance of moving the bolt. In his paper already alluded to, Mr. Chubb says—

1145

"The number of changes which may be effected on the keys of a three inch drawer lock is $1 \times 2 \times 3 \times 4 \times 5 \times 6 = 720$, the number of different combinations which may be made on the six steps of unequal lengths, without altering the length of either step. The height of the shortest step is however capable of being reduced 20 times; and each time of being reduced, the 720 combinations may be repeated; therefore $720 \times 20 = 14,400$ changes." By effecting changes of this character therefore, almost any number of combinations can be produced. The Bramah lock has been long celebrated, and most deservedly so. Notwithstanding the fact that this lock was picked by Mr. Hobbs after having the lock in his possession for sixteen days, it appears to us that it most fully justifies the boast made by Mr. Bramah in his "*Dissertation on the Construction of Locks*." "Being confident," he says, "that I have contrived a security which no instrument but its proper key can reach, and which may be so applied as not only to defy the art and ingenuity of the most skilful workman, but to render the utmost force ineffectual, and thereby to secure what is most valuable as well from dishonest servants as from the midnight ruffian, I think myself at liberty to declare (what nothing but the discovery of an infallible remedy would justify my disclosing) that all dependence on the inviolable security of locks, even of those which are constructed on the best principle of any in general use, is fallacious." He then proceeds to demonstrate the imperfections of ordinary locks and to describe his own.

"The body of a Bramah lock may be considered as formed of two concentric brass barrels, the outer one fixed, and the inner rotating within it. The inner barrel has a projecting stud, which, while the barrel is rotating, comes in contact with the bolt in such a way as to shoot or lock it; and thus the stud serves the same purpose as

the bit of an ordinary key, rendering the construction of a bit to the Bramah key unnecessary. If the barrel can be made to rotate to the right or left, the bolt can be locked or unlocked, and the problem is, therefore, how to insure the rotation of the barrel. The key, which has a pipe or hollow shaft, is inserted in the keyhole upon the pin, and is then turned round; but there must be a nice adjustment of the mechanism of the barrel before this turning round of the key and the barrel can be insured. The barrel has an external groove at right angles to the axis, penetrating to a certain depth; and it has also several internal longitudinal grooves from end to end. In these internal grooves thin pieces of steel are able to slide, in a direction parallel with the axis of the barrel. A thin plate of steel called the locking plate, is screwed in two portions to the outer barrel, concentric with the inner barrel; and at the same time occupying the external circular groove of the inner barrel; this plate has notches, fitted in number and size to receive the edges of the slides which work in the internal longitudinal grooves of the barrel. If this were all, the barrel could not revolve, because the slides are catching in the grooves of the locking plate; but each slide has also a groove, corresponding in depth to the extent of this entanglement; and if this groove be brought to the plane of the locking plate, the barrel can be turned, so far as respects the individual slide. All the slides must, however, be so adjusted, that their grooves shall come to the same plane; but, as the notch is cut at different points in the lengths of the several slides, the slides have to be pushed in to different distances in the barrel, in order that this juxtaposition of notches may be insured. This is effected by the key, which has notches or elevations at the end of the pipe equal in number to the slides, and made to fit the ends of the slides when the key is inserted; the key presses each slide, and pushes it so far as the depth of its elevations will permit; and all these depths are such that all the slides are pushed to the exact position where their notches all lie in the same plane; this is the plane of the locking plate, and the barrel can be then turned." (*Tomlinson on the Construction of Locks*.) In this work the details on construction are given with great clearness.

The American bank locks, especially that of Messrs. Day and Newall, have excited much attention. Their English patent describes it thus:—

"The object of the present improvements is the constructing of locks in such manner that the interior arrangements, or the combination of the internal movable parts, may be changed at pleasure according to the form given to, or change made in, the key, without the necessity of arranging the movable parts of the lock by hand, or removing the lock or any part thereof from the door. In locks constructed on this plan the key may be altered at pleasure; and the act of locking, or throwing out the bolt of the lock, produces the particular arrangements of the internal parts, which correspond to that of the key for the time being. While the same is locked, this form is retained until the lock is unlocked or the bolt withdrawn, upon which the internal movable parts return to their original position, with reference to each other; but these parts cannot be made to assume or be brought back to their original position, except by a key of the precise form and dimensions as the key by which they were made to assume such arrangement in the act of locking. The key is changeable at pleasure, and the lock receives a special form in the act of locking according to the key employed, and retains that form until in the act of unlocking by the same key it resumes its original or unlocked state. The lock is again changeable at pleasure, simply by altering the arrangement of the movable bits of the key; and the key may be changed to any one of the forms within the number of permutations of which the parts are susceptible."—April 15, 1851.

Mr. Hobbs who has been carrying out the manufacture of American locks in this country has introduced an inexpensive lock, which he calls a *protektor lock*. The following description is borrowed from Mr. Charles Tomlinson's *Treatise on the Construction of Locks*:—

"When the American locks became known in England, Mr. Hobbs undertook the superintendence of their manufacture, and their introduction into the commercial world. Such a lock as that just described must necessarily be a complex piece of mechanism; it is intended for use in the doors of receptacles containing property of great value; and the aim has been to baffle all the methods at present known of picking locks, by a combination of mechanism necessarily elaborate. Such a lock must of necessity be costly; but in order to supply the demand for a small lock at moderate price, Mr. Hobbs has introduced what he calls a *protektor lock*. This is a modification of the ordinary six-tumbler lock. It bears an affinity to the lock of Messrs. Day and Newall, inasmuch as it is an attempt to introduce the same principle of security against picking, while avoiding the complexity of the changeable lock. The distinction which Mr. Hobbs has made between secure and insecure locks will be understood from the following proposition, viz. 'that whenever the parts of a lock which come in contact with the key are so affected by any pressure applied to

the bolt, or to that portion of the lock by which the bolt is withdrawn, as to indicate the points of resistance to the withdrawal of the bolt, such a lock can be picked. Fig. 1147 exhibits the internal mechanism of this new patent lock. It contains the usual contrivances of tumblers and springs, with a key cut into steps to suit the different heights to which the tumblers must be raised. The key is shown separately in fig. 1148. But there is a small additional piece of mechanism, in which the tumbler stump shown at *s* in figs. 1146 and 1147 is attached; which piece is intended to work under or behind the bolt of the lock. In fig. 1147, *b* is the bolt; *tt* is the front

or foremost of the range of six tumblers, each of which has the usual slot and notches. In other tumbler-locks the stump or stud which moves along these slots is riveted to the bolt, in such manner that, if any pressure be applied in an attempt to withdraw the bolt, the stump becomes pressed against the edges of the tumblers, and bites or binds against them. How far their biting facilitates the picking of a lock will be shown further on; but it will suffice here to say, that the movable action given to the stump in the Hobbs lock transfers the pressure to another quarter. The stump *s* is riveted to a peculiarly-shaped piece of metal *h p* (fig. 1146), the hole in the centre of which fits upon a centre or pin in a recess formed at the back of the bolt; the piece moves easily on its centre, but is prevented from so doing spontaneously by a small binding spring. The mode in which this small movable piece takes part in the action of the lock is as follows: when the proper key is applied in the usual way, the tumblers are all raised to the proper heights for allowing the stump to pass horizontally through the gating; but should there be an attempt made, either by a false key or by any other instrument, to withdraw the bolt before the tumblers are properly raised, the stump becomes an obstacle. Meeting with an obstruction to its passage, the stump turns the piece to which it is attached on its centre, and moves the arm of the piece *p* so that it shall come into contact with a stud riveted into the case of the lock; and in this position there is a firm resistance against the withdrawal of the bolt. The tumblers are at the same moment released from the pressure of the stump. There is a dog or lever *d*, which catches into the top of the bolt, and thereby serves as an additional security against its being forced back. At *k* is the drill-pin on which the pipe of the key works; and *e* is a metal piece on which the tumblers rest when the key is not operating upon them.

Another lock, patented by Mr. Hobbs in 1852, has for its object the absolute closing of the key-hole during the process of locking. The key does not work or turn on its own centre, but occupies a small cell or chamber in a revolving cylinder, which is turned by a fixed handle. The bit of the movable key is entirely separable from the shaft or stem, into which it is screwed, and may be detached by turning round a small milled headed thumb-screw. The key is placed in the key-hole in the usual way, but it cannot turn; its circular movement round the stem as an axis is prevented by the internal mechanism of the lock; it is left in the key-hole, and the stem is detached from it by unscrewing. By turning the handle, the key-bit, which is left in the chamber of the cylinder, is brought into contact with the works of the lock, so as to shoot and withdraw the bolt. This revolution may take place whether the bit of the movable key occupies its little cell in the plate or not; only with this difference—that if the bit be not in the lock, the plate revolves without acting upon any of the tumblers; but if the bit be in its place, it raises the tumblers

in the proper way for inserting or withdrawing the bolt. It will be understood that there is only one key-hole, namely, that through which the movable key is inserted; the other handle or fixed key working through a hole in the cover of the key only just large enough to receive it, and not being removable from the lock. As soon as the plate turns round so far as to enable the key to act upon the tumblers, the key-handle becomes entirely closed by the plate itself, so that the usual locking is effected at the very time when all locked in the interior through the key-hole is cut off. When the bolt has been shot, the plate comes round to its original position, it uncovers the key-hole, and enables the key to occupy the latter and into which it had been dropped; the stem is then to be screwed into the bolt, and the latter withdrawn. It is one consequence of this arrangement, that the key has to be screwed and unscrewed when used; but through this arrangement the key will become a sealed book to one who has not the right key. Nothing can be moved, provided the bit and stem of the key be both left in; but by pulling in the bolt the former without the latter, the plate can rotate, the tumblers can be lifted, and the bolt can be shot.

LOCOMOTIVE ENGINES. The character of this work excludes any special notice of anything so entirely belonging to a work on Mechanical Engineering, as that of locomotive engines. Nevertheless, since so much has lately been said and written on the question of employing coal on our railways instead of coke, we are induced to introduce the following arrangement, which seems to combine without smoke. It is known as Druery's plan. The annexed drawing, fig. 1147, is a section of a locomotive engine, used on the (Chann) Railway. The coal is thrown into the pipes A B, which open below the platform on which the engine stands. These pipes conduct the coal by their own gravity to the lower level of the bars, where they are thrust in the direction of the arrows C D, by a kind of comb, or rotating pin, which in its rotation around the axis E, forces the coal to ascend the bars forward by the bars.

without smoke. It is known as Druery's plan. The annexed drawing,

fig. 1147, is a section of a locomotive engine, used on the (Chann) Railway. The coal is thrown into the pipes A B, which open below the platform on which the engine stands. These pipes conduct the coal by their own gravity to the lower level of the bars, where they are thrust in the direction of the arrows C D, by a kind of comb, or rotating pin, which in its rotation around the axis E, forces the coal to ascend the bars forward by the bars.

This then takes place the coal in its rude state (i. e. as it comes from the pit) coming from below, falls itself immediately in contact with the fire, which induces an escape of the gases, and with the pure air which permits their combustion to take place in the only condition in which it is possible, i. e. in small jets, which facilitate the complete oxygenation of all the parts.

The gases once produced and burnt, the rest of the operation scarcely needs explanation. The coal is converted into coke, and finishes its passage while burning under this form: and as the remainder of the solids, cinders and slag (or

clinkers), are not abandoned by the fire until after all that it contains of a combustible nature has disappeared, all the detritus (refuse) and dust, cinders, ashes, &c. are deposited on the surface (sommet) of the bars in the centre of the fire, where they would offer an obstruction similar to that found in ordinary fire-places, if the inventor had not taken care to make the bars oscillate from the centre by a small movement. Thus, when a drop of slag approaches the bars, it is displaced and thrown out (by the opening of the bars) in small particles. This necessary arrangement apparently possesses great advantages for a locomotive in saving the trouble of scraping and cleaning the bars.

So if, as in an ordinary fire, coke or anthracite, &c., be burnt, the combustion would be very complete. Air fresh from the ash-pit, in passing over the combustible, would be converted into carbonic acid, i. e. into a gas which is unfit for further combustion. But if in the place of coke or anthracite, &c. we use smoke-producing coal, i. e. com-

1147

posed of two elements, one solid, the other gaseous, the result follows. The combustible gas disengaging themselves (in this case from the *bastille*) in a state of ignition, the air which will become vitiated in trying to effect the combustion of the solid combustible, will be found unable to effect the combustion of the gases which escape above the fire, and smoke will make its appearance *i. e.* the combustion will be incomplete and imperfect. This is what takes place with combustion of coal in ordinary fire-places.

There are also other causes which contribute to the imperfection of this result. These gases in disengaging themselves do not always acquire a temperature sufficiently high to produce flame, and the volume of combustible gas is almost always too considerable to allow of its being sufficiently penetrated with oxygen. These are some of the radical vices which M. Duméry has removed in thus placing the gases at once in the combustion heat suited for their combustion. This process is admirable, since, without any preparation, it allows of coal being burnt with as much facility as coke, and saves the great expense of converting coal into coke.

LOCUST TREE. A North American tree, the *Rubus parodiarum*. "It grows most abundantly in the southern States, but it is pretty generally diffused throughout the whole country. It sometimes exceeds four feet in diameter and seventy feet in height. The locust is one of the very few trees planted by the Americans."—*Stevenson's Civil Engineering of North America*. "This wood is much used for ships' tree-nails, and is employed for stakes and poles.

LODE (a mining term). A mineral lode, or a mineral vein, is the name given to a fissure in the crust of the earth which has been filled in with metalliferous matter. The miner gives the same name *lode* to a fissure filled with quartz, carbonate of lime, &c., but then he says the lode is not "mineralised," confining the word mineral to metalliferous matter.

The term vein has frequently led to the idea that it expresses the condition of something analogous to the blood vessels of the animal body, to which a lode has not in the remotest degree, any resemblance. During some primary convulsions, the crust of the earth has been cracked, these fissures having, of course, some special relation to the direction of the force which produced them. These cracks have during ages of submergence been filled in, according to some law of polarity with mineral matter, the character of the lode having generally some special relation to its direction. See *Mining*, &c.

LOGWOOD (*Bons de Campêche*, *Bois bleu*, Fr.; *Blauholtz*, Germ.) is the wood of the *Hematurylon Campachianum*, a native tree of Central America, grown in Jamaica since 1715. It was first introduced into England in the reign of Elizabeth, but as it afforded to the unskilful dyers of her time a fugitive colour, it was not only prohibited from being used, under severe penalties, but was ordered to be burned whenever found, by a law passed in the 23rd year of her reign. The same prejudices existed, and the same law was enacted against indigo. At length, after a century of absurd prohibition, these two most valuable dyestuff matters, by which all our luns, and the greater part of our woollen cloths, are dyed, were allowed to be used. The logwood trees grow from 40 to 50 feet high, the stems are cut into logs of about 3 feet long, the bark and white sap (albumen) of which are clipped off, the heart or red part only being sent to England. Chevreul gave the constituents of logwood as *volatile oil*, *hematin*, *resinous matter*, *tannin*, *glutinous matter*, *acetic acid*, *sundry salts of lime*, with *alumina*, *silica*, *manganese*, and *iron*. The decoction of logwood is of a deep dull red, which is rendered paler and of a brighter colour by acids. Alkalies give it a purplish or violet colour. Acetate of lead causes a blue, alum a violet precipitate; the salts of iron make it a dark violet blue, gelatine forming a reddish precipitate with it.

Old wood, with black bark and with the tile of the white albumen, is preferred. Logwood is denser than water, specific gravity, 1.057, very hard, of a fine compact grain, and almost indestructible by the atmospheric elements; it has a sweet and stringent taste, and a peculiar but inoffensive smell, and will take a fine polish.

When clipped logwood for some time exposed to the air, it loses a portion of its dyeing power. Its decoction absorbs the oxygen of the atmosphere, and then acquires the property of precipitating with gelatine, which it had not before. The dry extract of logwood, made from an old decoction, affords only a fugitive colour.

For its applications in dyeing, see **BLACK DYE**; **CALICO PRINTING**; **DYEING**; **HAT DYEING**, &c.

The imports of logwood were in

LOOKING GLASS. See **MIRROR**.

LOOM (*Metier a tisser*, Fr.; *Weberstuhl*, Germ.) is the ancient and well-known machine for weaving cloth by the decussation of a series of parallel threads, which run lengthwise, called the warp or chain, with other threads thrown transversely with the shuttle, called the woof or weft. See **JACQUARD LOOM** and **WEAVING**.

LUBRICANTS. Oleaginous or fatty bodies employed for the purpose of reducing the friction between two parts of a machine or carriage.

LUBRICATION. The lubrication of the wheel and axle of railway carriages is effected by a kind of soap, a combination of cocoa-nut oil or palm-oil, or ordinary tallow, with soda being the "grease" with which the boxes are filled. The heat produced by the friction melts the grease, and it flows out upon the parts in motion through an opening in the bottom of the box. Heavy machinery, such as pumping engines, require tenacious bodies as their lubricants, while the finer parts must be carefully oiled with oils as free as possible from any of the fatty acids. Spinning machinery for example, must be lubricated with the finest oils, or, as is found to be still better, with those peculiar hydro-carbon compounds, as paraffine, glycerine, and the like. The following is a simple and efficacious plan of lubricating the joints and bearings of machinery by capillary attraction, the invention of Edward Woolsey, Esq. :—

Fig. 1150 represents a tin cup, which has a small tin tube *A*, which passes through the bottom, as shown by the dotted lines. It may have a tin cover to keep out the dust.

Fig. 1151 is a plan of the same.

Fig. 1152 is a section of the same. Oil is poured into the cup, the one end of a worsted or cotton thread is dipped into the oil, and the other end passed through the tube.

The capillary attraction causes the oil to ascend and pass over the orifice of the tube, whence it gradually descends, and drops slower or quicker according to the length of the thread or its thickness, until every particle of oil is drawn over by this capillary siphon. The tube is intended to be put into the bearings of shafts, &c., and is made of any size that may be wished. If oil, or other liquids, is desired to be dropped upon a grindstone or other surface,

this cup can have a handle to it, or be hung from the ceiling.

Fig. 1153. It is frequently required to stop the capillary action when the machinery is not going; and this has been effected by means of a tightening screw, which passes through a screw hole in the cover of the cup, and presses against the internal orifice of the tube, preventing the oil from passing.

Fig. 1154. As when these screw cups are used upon beams of engines and moving bearings, the screw is apt to be tightened by the motion; and also, as the action of the screw is uncertain, from the workman neglecting to screw it down sufficiently, it answers best to take out the capillary thread when the lubrication is not required; and to effect this easily, a tin top is fixed to the cup, with a round pipe soldered to it; this pipe has a slit in it, like a pencil case, and allows a bolt *B* to slide easily. In fig. 1155 the bolt is down; in fig. 1156 the bolt, which is a piece of brass wire, is drawn up, and thus the flowing of the oil is checked. In fig. 1156 it will be observed, that the bolt is kept in its place by its head *C*, resting in a lateral slit in the pipe, and it cannot be drawn out on account of the pin *D*. One end of the thread is fastened to the eye hole at the bottom of the bolt, and the other end is tied to a small wire which crosses the lower orifice of the tube at *E*, and which is shown in plan fig. 1157.

The saving by this plan, instead of pouring oil into the bearings, is 2 gallons out of 3, while the bearings are better oiled.

The saving in labour is considerable where there are many joints to keep oiled three or four times a day; and the workman does not, with this apparatus, run the risk of being caught by the machinery. To tie on the cotton or worsted thread, pass a long thread through the eye-hole of the bolt, and then draw the two ends through the tube by a fine wire with a hook to it, one end on one side of the cross wire in, and the other end on the other side. Then put the cover on, and the bolt in the position shown in fig. 1156; when by drawing the two ends of the thread, and tying them across the wire D, you have the exact length required. When you wish to see the quantity of oil remaining in the lubricator, the bolt must be dropped as in fig. 1155, and you can then lift the cover a little way off, without breaking the thread, and replenish with oil. The figures in the woodcuts are one third of the full size.

LUCIFER MATCHES. The importance of this manufacture has been shown by Mr. Tomlinson in a communication made by that gentleman to the Journal of the Society of Arts.

"It has been estimated," he says, "that the English and French manufacturers of phosphorus are now producing at the rate of 300,000 lbs. of common phosphorus per annum, nearly the whole of which is consumed in making lucifer matches. In compounding the emulsion for tipping the matches, the German manufacturers make three pounds of phosphorus suffice for five or six millions of matches. If we suppose only one half of the French and English annual product of phosphorus to be employed in making matches, this will give us 250,000,000,000 of matches as the annual product consequent on the consumption of one half of the French and English phosphorus. We need not suppose this to be an exaggerated statement, when we consider the daily product of some of our match manufactories. I lately had occasion to describe the processes of a London factory, which produces 2,500,000 matches daily. For this purpose, 14 3-inch planks are cut up; each plank produces 30 blocks; each block, of the dimensions of 11 inches long, 4½ inches wide, and 3 inches thick, produces 100 slices, each slice 31 splints, each splint 2 matches. thus we have— $14 \times 30 \times 100 \times 31 \times 2 = 2,604,000$ matches as the day's work of a single factory in London. At Messrs. Dixon's factory near Manchester, from 6,000,000 to 9,000,000 of matches are produced daily."—Tomlinson.

For the rapid manufacture of the wooden splints for lucifer matches, a patent was obtained by Mr. Reuben Partridge, in March, 1842. He employs a perforated metallic plate, having a steel face, strengthened by a bell metal back; see figs. 1158, 1159. The size of the perforations must depend on that of the desired splints, but they

must be as close together as possible, that there may be a very small blank space between them, otherwise the plate would afford too great resistance to the passage of the wood. By this construction, the whole area of the block of wood may be compressed laterally into the countersunk openings, and forced through the holes, which are slightly countersunk to favour the entrance and separation of the wooden fibres.

Fig. 1128 represents the face of one of these plates; and fig. 1129 is a rectangular section through the plate. A convenient size of plate is three inches broad, six inches long, and one thick. The mode of pressing is by fixing the back of the plate against a firm resisting block or bearing, having an aperture equal to the area of the perforations in the plate, and then placing the end of the piece or pieces of wood in the direction of the grain against the face of the plate within the area of the perforated portion. A plunger or lever or other suitable mechanical agent being then applied to the back or reverse end of the piece of wood, it may be forced through the perforations in the plate, being first split as it advances by the cutting edges of the holes, and afterwards compressed and driven through the perforations in the plate, coming out on the opposite side or back of the plate in the form of a multitude of distinct splints, agreeably to the shapes and dimensions of the perforations.—*Newton's Journal*, O. S. vol. xxii. 263.

Manufacture of Lucifers.—The first stage in the manufacture of lucifers is the cutting the wood, which is done, according to the extent of the manufactory, either by hand or by machinery. This, as well as the subsequent process of counting and placing the matches in frames, is in itself necessarily free from any inconvenience or evil consequences; nor does it appear that the third stage, which consists of melting the sulphur and dipping the heads of the matches in it, produces any inconvenience. The fourth, fifth, sixth, and seventh stages comprise the grinding, mulling, and mixing of the explosive compound; the process of dipping the matches in it, the counting and boxing. The dipping, counting, and packing, appear to be, according to Mr. Geist, the only departments in which the workpeople are in any way affected with peculiar complaints; we would even limit the appearance of the jaw disease to those engaged in dipping; at least all that we have examined on the subject were unanimous as to the fact that dippers only were attacked. There is a certain degree of secrecy observed relative to the proportions of the composition; and the mixture of the materials is generally formed by the proprietor of the manufactory, or by a confidential workman. Chloride of potash is considered an essential ingredient in England; but in the manufactory at Nürnberg it has not been employed for a number of years, as its explosive properties much endangered the safety of the buildings and the limbs of the workmen.

The composition used in Nürnberg consists of one-third of phosphorus, of gum arabic (which is eschewed by English manufacturers on account of its hygroscopic property), of water, and of a colouring matter, for which either minium or Prussian blue is employed. If ignition be required without a flame, the quantity of phosphorus is diminished, or nitrate of lead is added. The mixing is conducted in a water-bath; and during this process, and as long as the phosphorus is being ground or "mulled," the composition is spread upon a board covered with cloth or paper, and the workman dips the two ends of the matches alternately that are fixed in the frame; and as this is done with great rapidity, the disengagement of fumes is very considerable, and is more liable to be injurious, as they are evolved in a very concentrated form close to the face of the workman. This department is generally left to a single workman; and the average number that he can dip in an hour, supposing each frame to hold 3,000 matches, would be 1,000,000.

As the matches have been dipped, they require to be dried. This is generally done in the room in which the former process is carried on; and as a temperature of from 50° to 90° Fahr. is necessary, the greatest quantity of fumes is evolved at this stage. When the matches are dried, the frames are removed from the drying room, and the lucifers are now ready to be counted out into boxes. As this is done with great rapidity, they frequently take fire, and, although instantly extinguished in the sawdust or the water which is at hand, the occurrence gives rise to an additional and frequent evolution of fumes.

According to Dr. R. Boettger, in *Annalen der Chemie und Pharmacie*, vol. xlvii. p. 334, the best composition for lucifer matches is

Phosphorus - - -	4 parts	Red ochre, or red lead - -	5 parts
Nitre - - -	10 "	Smalt - - -	2 "
Fine glass - - -	6 "		

Convert the glass with a little water by a gentle heat into a smooth jelly; put it into a slightly warm porcelain mortar to liquefy; rub the phosphorus down through this gelatine at a temperature of about 140° or 150° Fahr.; add the nitre, then the red powder, and lastly the smalt, till the whole forms a uniform paste. To make writing-paper matches, which burn with a bright flame and diffuse an agreeable odour, moisten each side of the paper with tincture of benzoin, dry it, cut it into slips, and smear one of their ends with a little of the above paste by means of a hair pencil. On rubbing the end after it is dry against a rough surface the paper will take fire, without the intervention of sulphur.

To form lucifer wood matches, that act without sulphur, melt in a flat-bottomed

tin pan as much white wax as will stand one-tenth of an inch deep; take a bundle of wooden matches free from resin, rub their ends against a red hot iron plate till the wood be slightly charred; dip them now in the melted wax for a moment, shake them well on taking them out, and finally dip them separately in the above viscous paste. When dry, they will kindle readily by friction.

A "Safety Lucifer Match," as it is called, has been manufactured in Sweden. Its patent was obtained in that country by Messrs. Bryant and May, for this match. Its peculiarity consists in the division of the combustible ingredients of the lucifer between the match and the friction paper. In the ordinary lucifer, the phosphorus, sulphur, and chlorate of potash or nitre, are all together on the match, which ignites when rubbed against any rough substance. In the Swedish matches these materials are so divided that the phosphorus is placed on the sand-paper, whilst the sulphur and a minimum amount of chlorate or nitrate of potash is placed on the match. In virtue of this arrangement it is only when the phosphorised sand-paper and the sulphurised match come in contact with each other that the ignition occurs. Neither match nor sand-paper, singly, takes fire by moderate friction against a rough surface.

The composition of lucifer matches varies greatly, as it regards the proportions of the materials employed. In principle they are, however, as we have described them above; everything depending on the ignition of the phosphorus, and the perfection of a lucifer match is in tipping the match with a composition which will ignite quietly upon attrition against any rough surface, but which is not liable to ignite by such pressure as it may be subjected to under the ordinary condition of keeping in closed boxes.

The preparation of lucifer matches has been attended with much human suffering. Every person engaged in a factory of this kind is more or less exposed to the fumes of phosphorus, and this exposure produces a disease which has been thus described by Mr. Harrison, in the *Quarterly Journal of Medical Science*.—"This disease," he says, "is of so insidious a nature that it is at first supposed to be common toothache, and a most serious disease of the jaw is produced before the patient is fully aware of his condition. The disease gradually creeps on, until the sufferer becomes a miserable and loathsome object, spending the best period of his life in the wards of a public hospital. Many patients have died of the disease; many, unable to open their jaws, have lingered with carious and necrosed bones; others have suffered dreadful mutilations from surgical operations, considering themselves happy to escape with the loss of the greater portion of the lower jaw."

By the introduction of an amorphous phosphorus discovered by M. Schrotter, which is in nearly all respects unlike the ordinary phosphorus, but which answers exceedingly well for the manufacture of lucifer matches, this disease is prevented, the manufacture is rendered more healthy, and the boxes of matches themselves less dangerous. See PHOSPHORUS. In 1857 our imports and exports were—

LEMACHELLE, or Fire Marble. This is a dark brown shelly marble, having brilliant fire or chatoyant reflections from within.—See MARBLE.

LUNAR CALSTIC. A name for nitrate of silver, when fused and run into cylindrical moulds.

LUPININE, is a substance of a gummy appearance, so named by M. Cuscola, because it was obtained from Lupines.—C. G. W.

LUPULINE, from *Humulus Lupulus*; is the peculiar bitter aromatic principle of the hop. See BEER.

LUSTRING, sometimes spelled also *lustre*, used *Lustrestring*; a peculiar shining silk.

LUTE (from *lutum*, clay; *Lut*, Fr.; *Kutte*, *Bewlut*, Germ.) is a paste or loamy matter employed to close the joints of chemical apparatus, or to coat their surfaces, and protect them from the direct action of flame. Lutes differ according to the nature of the vapours which they are destined to confine, and the degree of heat which they are to be exposed to.

1. *Lute of accidental*, made into a soft plastic dough with water, and immediately applied pretty thick to junctions of glass, or stone-ware, makes them perfectly tight, hardens speedily, resists acid and ammoniacal vapours, as also a moderate degree of heat. It becomes stronger when the meal is kneaded with milk, lime-water, or solution of glue, and is the best lute for fluo-silicic acid.

2. *Lute of thick gum-water*, kneaded with clay, and iron filings, serves well for permanent junctions, as it becomes extremely solid.

3. By softening in water a piece of thick brown paper, kneading it, first with yeflower paste, and then with some paper's clay, till it acquire the proper consistence, a lute is formed which does not readily crack or scale off.

4. Lute, consisting of a strong solution of glue kneaded into a dough with new slaked lime, is a powerful cement, and with the addition of white of egg forms the *lut d'ane*;—a composition adapted to mend broken vessels of porcelain and stone-ware.

5. Skim-milk cheese, boiled for some time in water, and then triturated into paste with fresh-slaked lime, forms also a good lute.

6. Calcined gypsum, diffused through milk, solution of glue, or starch, is a valuable lute in many cases.

7. A lute made with linseed, melted caoutchouc, and pipe-clay, incorporated into a smooth dough, may be kept long soft when covered in a cellar, and serves admirably to confine acid vapours. As it does not harden, it may therefore be applied and taken off as often as we please.

8. Caoutchouc itself, after being melted in a spoon, may be advantageously used for securing joints against chlorine and acid vapours, in emergencies when nothing else would be effectual, or we may use 1 part of caoutchouc dissolved in two parts of hot linseed-oil, and worked up with pipe-clay (3 parts) into a plastic mass. It bears the heat at which sulphuric acid boils.

9. The best lute for joining crucibles inverted into each other, is a dough made with a mixture of fresh fire-clay, and ground fire-bricks, worked with water. That cement, if made with solution of borax, answers still better, upon some occasions, as it becomes a compact vitreous mass in the fire.

LUTEOLINE, is the colouring principle of the weld (*Rhamnus luteola*), a slender plant growing to the height of about three feet, and cultivated for the use of dyers. When ripe it is cut and dried.

Chevreul was the first to separate the luteoline; it is extracted from the weld by boiling water, and when this solution is concentrated and allowed to cool, the luteoline separates; it is then collected, dried, and submitted to sublimation, when it is condensed in yellow needles.

It is valued for its durability, and is used as a yellow dye, on cottons principally, and also on silks, but is little used at present. It was formerly used by paper-hanging manufacturers, to form a yellow pigment, but has been entirely superseded for that purpose, by *guercitron bark* and *Persian berries*. It unites with acids and alkalis, the former making the colour paler, and the latter heightening the colour. The compound which it forms with potash is of a golden colour, becoming greenish when exposed to the air, by absorption of oxygen, and at length becomes red.

It forms yellow compounds with alum, protochloride of tin, and acetate of lead; with the salts of iron it produces a blackish grey precipitate, and with sulphate of copper a greenish brown precipitate.

It is readily soluble in alcohol and ether, but sparingly so in water.—H. K. B.

LUTIDINE, $C^{14}H^8N$. A volatile nityle base, discovered by Anderson in bone oil. It has also been found in shale naphtha, coal naphtha, and in crude chinoline.—C. G. W.

LYCOPodium CLAVATUM. The seeds of the lycopodium ripen in September. They are employed, on account of their great combustibility, in theatres, to imitate the sudden flash of lightning, by throwing a quantity of them from a powder puff, or bellows, across the flame of a candle.

LYDIAN STONE, *Touchstone*, or *Basinite*. A flinty variety of jasper, used on account of its hardness, fine texture, and velvet black colour, for trying the purity of the precious metals. The amount of alloy is indicated by the colour left on the stone after the metal has been rubbed across it.

LYNX.—An animal producing a favourite fur of a greyish white, with dark spots.
